## About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

## Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

## Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

## What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: [frontiersin.org/about/contact](http://frontiersin.org/about/contact)

## TRANSLATIONAL ADVANCES IN ALZHEIMER'S, PARKINSON'S, AND OTHER NEURODEGENERATIVE DEMENTIAS

Topic Editors:

**Jiehui Jiang**, Shanghai University, China

**Kuangyu Shi**, University of Bern, Switzerland

**Fangyu Peng**, University of Texas Southwestern Medical Center, United States

**Chih-Yu Hsu**, Fujian University of Technology, China

**Woon-Man Kung**, Chinese Culture University, Taiwan

**Citation:** Jiang, J., Shi, K., Peng, F., Hsu, C.-Y., Kung, W.-M., eds. (2022).

Translational Advances in Alzheimer's, Parkinson's, and Other Neurodegenerative Dementias. Lausanne: Frontiers Media SA. doi: 10.3389/978-2-88976-371-9

# Table of Contents

- 10 Editorial: Translational Advances in Alzheimer's, Parkinson's, and Other Neurodegenerative Dementias**  
Jiehui Jiang, Kuangyu Shi, Fangyu Peng, Chih-Yu Hsu and Woon-Man Kung
- 15 Depression Affects Intrinsic Brain Activity in Patients With Mild Cognitive Impairment**  
Yang Yu, Ziqi Li, Yajie Lin, Jie Yu, Guoping Peng, Kan Zhang, Xize Jia and Benyan Luo
- 24 TDP-43 and Limbic-Predominant Age-Related TDP-43 Encephalopathy**  
Lumi Zhang, Yi Chen, Min Liu, Yunyun Wang and Guoping Peng
- 30 An Informant-Based Simple Questionnaire for Visuospatial Dysfunction Assessment in Dementia**  
Ching-Tsu Wang, Guang-Uei Hung, Cheng-Yu Wei, Ray-Chang Tzeng and Pai-Yi Chiu
- 39 Electroacupuncture Ameliorates Cognitive Impairment by Inhibiting the JNK Signaling Pathway in a Mouse Model of Alzheimer's Disease**  
Yinshan Tang, Anping Xu, Shujun Shao, You Zhou, Bing Xiong and Zhigang Li
- 51 A Systematic Bioinformatics Workflow With Meta-Analytics Identified Potential Pathogenic Factors of Alzheimer's Disease**  
Sze Chung Yuen, Hongmei Zhu and Siu-wai Leung
- 74 The Apolipoprotein E  $\epsilon$ 4 Allele-Dependent Relationship Between Serum Lipid Levels and Cognitive Function: A Population-Based Cross-sectional Study**  
Shan Wei, Ling Gao, Yu Jiang, Suhang Shang, Chen Chen, Liangjun Dang, Jin Wang, Kang Huo, Jingyi Wang and Qiumin Qu
- 84 Brain-Region Specific Metabolic Abnormalities in Parkinson's Disease and Levodopa-Induced Dyskinesia**  
Changwei Yang, Tingting Zhang, Wuqiong Wang, Yilan Xiang, Qun Huang, Chenglong Xie, Liangcai Zhao, Hong Zheng, Yunjun Yang and Hongchang Gao
- 95 Relationship Between Exercise and Alzheimer's Disease: A Narrative Literature Review**  
Qing Meng, Muh-Shi Lin and I-Shiang Tzeng
- 101 Predicting Alzheimer's Disease Conversion From Mild Cognitive Impairment Using an Extreme Learning Machine-Based Grading Method With Multimodal Data**  
Weiming Lin, Qinquan Gao, Jiangnan Yuan, Zhiying Chen, Chenwei Feng, Weisheng Chen, Min Du and Tong Tong  
for the Alzheimer's Disease Neuroimaging Initiative
- 110 Functional and Structural Brain Alterations in Encephalitis With LGI1 Antibodies**  
Jianping Qiao, Xiuhe Zhao, Shengjun Wang, Anning Li, Zhishun Wang, Chongfeng Cao and Qing Wang

- 121 ***Freezing of Speech Single Questionnaire as a Screening Tool for Cognitive Dysfunction in Patients With Dementia With Lewy Bodies***  
Pai-Yi Chiu, Guang-Uei Hung, Cheng-Yu Wei, Ray-Chang Tzeng and Ming-Chyi Pai
- 128 ***Nanotheranostic Applications for Detection and Targeting Neurodegenerative Diseases***  
Ajay Kumar, Ravi Kumar Chaudhary, Rachita Singh, Satya P. Singh, Shao-Yu Wang, Zheng-Yu Hoe, Cheng-Tang Pan, Yow-Ling Shiue, Dong-Qing Wei, Aman Chandra Kaushik and Xiaofeng Dai
- 139 ***Clustering Analysis of Aging Diseases and Chronic Habits With Multivariate Time Series Electrocardiogram and Medical Records***  
Kuo-Kun Tseng, Jiaqian Li, Yih-Jing Tang, Ching-Wen Yang, Fang-Ying Lin and Zhaowen Zhao
- 149 ***Safety and Efficacy of 630-nm Red Light on Cognitive Function in Older Adults With Mild to Moderate Alzheimer's Disease: Protocol for a Randomized Controlled Study***  
Nayan Huang, Dandan Yao, Wenjing Jiang, Cuibai Wei, Mo Li, Wenjie Li, Haiyan Mu, Maolong Gao, Zongjuan Ma, Jihui Lyu, and Zhiqian Tong
- 158 ***Detection of Mild Cognitive Impairment Using Convolutional Neural Network: Temporal-Feature Maps of Functional Near-Infrared Spectroscopy***  
Dalin Yang, Ruisen Huang, So-Hyeon Yoo, Myung-Jun Shin, Jin A. Yoon, Yong-Il Shin and Keum-Shik Hong
- 175 ***Brain Functional and Structural Signatures in Parkinson's Disease***  
Chunhua Liu, Jiehui Jiang, Hucheng Zhou, Huiwei Zhang, Min Wang, Juanjuan Jiang, Ping Wu, Jingjie Ge, Jian Wang, Yilong Ma and Chuantao Zuo
- 189 ***Prevention of Early Alzheimer's Disease by Erinacine A-Enriched Hericium erinaceus Mycelia Pilot Double-Blind Placebo-Controlled Study***  
I-Chen Li, Han-Hsin Chang, Chuan-Han Lin, Wan-Ping Chen, Tsung-Han Lu, Li-Ya Lee, Yu-Wen Chen, Yen-Po Chen, Chin-Chu Chen and David Pei-Cheng Lin
- 202 ***The Comparative Efficacy of Multiple Interventions for Mild Cognitive Impairment in Alzheimer's Disease: A Bayesian Network Meta-Analysis***  
Xin Lai, Hao Wen, Yu Li, Liming Lu and Chunzhi Tang
- 214 ***Telmisartan and Rosuvastatin Synergistically Ameliorate Dementia and Cognitive Impairment in Older Hypertensive Patients With Apolipoprotein E Genotype***  
Wenjing Hu, Ying Li, Yingxin Zhao, Yuanli Dong, Yi Cui, Shangwen Sun, Gary Gong, Hua Zhang, Qiang Chai, Juan Wang and Zhendong Liu
- 227 ***Parkinson's Disease and the Gut: Future Perspectives for Early Diagnosis***  
Jana Harsanyiova, Tomas Buday and Alzbeta Kralova Trancikova
- 244 ***SRC-1 Knockout Exerts No Effect on Amyloid  $\beta$  Deposition in APP/PS1 Mice***  
Qiong Wu, Bin Wang, Qi-Fa Li, Xuan Zhang, Michael Ntim, Xue-Fei Wu, Na Li, Dan-Dan Zhu, Rong Jiang, Jin-Yi Yang, Yu-Hui Yuan and Shao Li

- 252 ***Calcium-Sensing Receptor Mediates  $\beta$ -Amyloid-Induced Synaptic Formation Impairment and Cognitive Deficits via Regulation of Cytosolic Phospholipase A2/Prostaglandin E2 Metabolic Pathway***  
Chenxi Feng, Xiaoming Bao, Ling Shan, Yunxiang Ling, Yanfei Ding, Jia Wang, Yanzi Cao, Qinwen Wang, Wei Cui and Shujun Xu
- 267 ***Default Mode Network Analysis of APOE Genotype in Cognitively Unimpaired Subjects Based on Persistent Homology***  
Liqun Kuang, Jiaying Jia, Deyu Zhao, Fengguang Xiong, Xie Han, Yalin Wang and for the Alzheimer's Disease Neuroimaging Initiative
- 278 ***Associations of [ $^{18}$ F]-APN-1607 Tau PET Binding in the Brain of Alzheimer's Disease Patients With Cognition and Glucose Metabolism***  
Jiaying Lu, Weiqi Bao, Ming Li, Ling Li, Zhengwei Zhang, Ian Alberts, Matthias Brendel, Paul Cumming, Huimeng Lu, Zhenxu Xiao, Chuantao Zuo, Yihui Guan, Qianhua Zhao and Axel Rominger
- 291 ***Periodontitis Induced by P. gingivalis-LPS Is Associated With Neuroinflammation and Learning and Memory Impairment in Sprague-Dawley Rats***  
Yi Hu, Huxiao Li, Jing Zhang, Xu Zhang, Xinyi Xia, Che Qiu, Yue Liao, Huiwen Chen, Zhongchen Song and Wei Zhou
- 306 ***Brain Metabolisms Involved in Self-Reported Quality of Mobility in Parkinson's Disease***  
Lu Fei, Feng-Tao Liu, Yi-Qi Liu, Jing-Jie Ge, Jia-Ying Lu, Shu-Jin He, Yi-Min Sun, Jian-Jun Wu, Chuan-Tao Zuo and Jian Wang
- 313 ***Integrated Pathways of COX-2 and mTOR: Roles in Cell Sensing and Alzheimer's Disease***  
Arti Tyagi, Mohammad A. Kamal and Nitesh Kumar Poddar
- 327 ***The Validation of Multifactor Model of Plasma  $A\beta_{42}$  and Total-Tau in Combination With MoCA for Diagnosing Probable Alzheimer Disease***  
Fubin Jiao, Fang Yi, Yuanyuan Wang, Shouzi Zhang, Yanjun Guo, Wenjin Du, Ya Gao, Jingjing Ren, Haifeng Zhang, Lixin Liu, Haifeng Song and Luning Wang
- 336 ***Pathological Mechanisms Linking Diabetes Mellitus and Alzheimer's Disease: the Receptor for Advanced Glycation End Products (RAGE)***  
Yanyan Kong, Fushuai Wang, Jiao Wang, Cuiping Liu, Yinping Zhou, Zhengqin Xu, Chencheng Zhang, Bomin Sun and Yihui Guan
- 346 ***Volumetric and Diffusion Abnormalities in Subcortical Nuclei of Older Adults With Cognitive Frailty***  
Mingyue Wan, Rui Xia, Huiying Lin, Pingting Qiu, Jianquan He, Yu Ye, Jing Tao, Lidian Chen and Guohua Zheng
- 355 ***Tremor in Vascular Cognitive Impairment Raises the Possibility of Mixed Pathology With Lewy Body Disease***  
Pai-Yi Chiu, Ray-Chang Tzeng, Cheng-Yu Wei, Guang-Uei Hung and Chaur-Jong Hu
- 362 ***Early Diagnosis of Mild Cognitive Impairment Based on Eye Movement Parameters in an Aging Chinese Population***  
Jing Nie, Qi Qiu, Michael Phillips, Lin Sun, Feng Yan, Xiang Lin, Shifu Xiao and Xia Li

## Editorial on the Research Topic

### Editorial: Translational Advances in Alzheimer's, Parkinson's, and Other Neurodegenerative Dementias

The increase in number of people suffering from neurodegenerative dementia (ND), such as Alzheimer's disease (AD) and Parkinson's disease (PD), has placed a huge burden on society. Precise detection of ND in an early phase is still challenging in daily clinical practice (Tisher and Salardini, 2019). There is a continuous escalation in effort from more researchers to investigate molecular mechanism of ND pathophysiology and develop new biomarkers for diagnosis and treatment of ND, as reflected by significant numbers of articles contained in this Research Topic.

In addition to metabolic changes such as altered glucose metabolism, alterations of amyloid-beta and tau protein are biomarkers associated with pathology of AD, whereas alpha-synuclein is proven to be related to PD and other NDs (Congdon and Sigurdsson, 2018; Rocha et al., 2018; Butterfield and Halliwell, 2019; Pinheiro and Faustino, 2019). Molecular imaging techniques using radiotracers like 2-deoxy-2-[<sup>18</sup>F]fluoroglucose (<sup>18</sup>F-FDG), 4-[(E)-2-(6-[2-(2-(<sup>18</sup>F)fluoroethoxy)ethoxy]ethoxy)pyridin-3-yl)ethen-1-yl]-N-methylaniline (<sup>18</sup>F-AV45), and 7-(6-(<sup>18</sup>F)fluoropyridin-3-yl)-5H-pyrido[4,3-b]indole (<sup>18</sup>F-AV1451) have been widely used in research and diagnostic imaging of ND. Development of bioinformatics analysis and artificial intelligence methods has significantly facilitated advances in research of ND. Nowadays, researchers are facing difficulties in choosing the best method in order to conduct research in a comprehensible fashion with estimates of accuracy and reproducibility.

Taking this into consideration, the present Research Topic on "Translational Advances in Alzheimer's, Parkinson's, and Other Neurodegenerative Dementias" by Frontiers in Aging Neuroscience made a contribution with updates and different perspectives on this important theme to contain over 69 papers. These updates focus on exploring reliable biomarkers and prediction indexes for the progression of ND from multidisciplinary perspectives. In addition, researches in development of novel therapies were also included.

Based on univariate and multivariate analyses, Wei et al. found that the apolipoprotein E (APOE) e4 allele might affect the relationship between serum lipid levels and cognitive impairment. In addition, Hu, Li, Zhao, et al. provided evidence that the combination of telmisartan and rosuvastatin might be an effective prevention and/or treatment strategy for cognitive impairment

and dementia, especially in hypertensive patients with the APOE  $\epsilon 4$  allele. Kuang et al. demonstrated that the  $\epsilon 4$  genotype leads to distinct default mode network (DMN) functional alterations in early phases of AD using persistent homology approach. Lin investigated whether CDGSH iron-sulfur domain 2 (CISD<sub>2</sub>) gene attenuation had an influence on anti-inflammatory effects and M1-M2 polarization in microglia. This study promised a potential therapeutic target for ND.

For clinical diagnosis of AD, Jiao et al. focused on plasma biomarkers which are less expensive and invasive than those necessitating a spinal fluid sample. The results of their study showed that the multifactor model of plasma amyloid-beta 42 and total-tau in combination with Montreal Cognitive Assessment (MoCA) could be a viable model separate health and AD subjects in clinical practice. Gao et al. characterized the relationship between plasma amyloid-beta levels and cognitive decline in 1,240 cognitively normal participants. The relationship between plasma amyloid-beta 40 and cognitive decline was an inverted-U shape in a cognitively normal population. None of relationship between plasma amyloid-beta 42, amyloid-beta 42/40, and cognitive decline was found during a 2-year follow-up. Lin et al. enrolled cognitively normal amyloid-beta-positive participants from 2 cohort studies, all types of resilience to cerebrospinal fluid (CSF) amyloid-beta could predict longitudinal cognitive decline.

Identification of novel molecular biomarkers for diagnosis and treatment of AD is urgently demanded. Based on bioinformatics analysis, Yu et al. identified 16 hub genes correlated to the neuropathological stage and 35 potential biomarkers for the diagnosis of AD. Yuen et al. demonstrated a systematic workflow for evidence synthesis of transcriptomic studies using both meta-analysis and bioinformatics methods to identify potential pathogenic factors. The results showed that reduced amyloid-beta clearance in AD pathogenesis was associated with genes encoding Fyn and EGFR, which were key receptors in amyloid-beta downstream signaling. Robin et al. comprehensively profiled phenotypic features over time in one commercially-available induced Pluripotent Stem Cell (iPSC)-derived human neuron cell line. This study provided a tool to investigate neurodegenerative and other central nervous system (CNS) diseases. Deng et al. applied multivariate model to estimate the association between leukocyte telomere length (LTL) and cognitive performance. Their results suggested that LTL might be a biomarker of cognitive aging.

Kong et al. explored the links between diabetes and AD by studying the advanced glycation end products (AGEs) and the receptors for AGEs (RAGE). The results of their study suggested that patients with diabetes were at a higher risk of developing AD. They further reviewed the interaction between RAGE and amyloid-beta as well as tau, which highlighted the potential of RAGE to be used as an effective target for AD diagnosis and treatment. Ho et al. explored type 2 diabetes mellitus (T2DM) pathogenesis in the amyloidogenic evolvability. A better understanding of the role of T2DM in amyloidogenic evolvability might reveal new targets for therapeutic intervention in AD patients who are comorbid with T2DM.

Using magnetic resonance (MR) imaging, Li et al. found that T2DM could give rise to the white matter atrophy of several brain regions, including left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus. In addition, they investigated the white matter structural network disruption in T2DM patients with MCI. Chen et al. developed MR glucose chemical exchange saturation transfer (glucoCEST) imaging in a rat model of AD. The findings from their study showed that this method could explore the occurrence and progress of diabetes-related AD or dementia.

Based on live-cell imaging combined with behavioral tests, Feng et al. explored the role and underlying mechanism of calcium-sensing receptor (CaSR) in cognitive deficits in AD mice. Their study might provide novel insights on the potential of CaSR as a therapeutic target for AD. Wu et al. examined whether steroid receptor coactivator 1 (SRC-1) is involved in pathogenesis of AD. Tyagi et al. reviewed the role of cyclooxygenases (COX) and mammalian/mechanistic target of rapamycin (mTOR) and potential therapeutic approaches targeting COX-2 and mTOR in AD and cancer.

Bjorkli et al. reviewed the preclinical and clinical investigations of commonly used biomarkers in animal models of AD and AD patients respectively. They also provided recommendations for standardization of procedures in sample collection to enhance the translational validity of preclinical study using AD animal models.

TDP-43 is a protein related to amyotrophic lateral sclerosis (ALS) and many cases of tau-negative frontotemporal lobar degeneration. Zhang, Chen, et al. reviewed the researches about TDP-43 and its relationship with limbic-predominant age-related TDP-43 encephalopathy (LATE).

In an effort to develop neurodegenerative disease model at cellular level, Zhang, Xie, et al. reported prospects of 2 kinds of reprogramming technologies for neurodegenerative diseases: (1) convert adult somatic cells to iPSCs and (2) directly reprogramming adult somatic cells to induced Neurons (iN).

Jang et al. provided updates on current progress in stem cell-derived dopaminergic neuron transplantation as a therapeutic alternative for PD. Yang, Zhang, et al. aimed to uncover the metabolic pathways across anatomical regions in the brain of PD and levodopa-induced dyskinesia (LID). Based on principal component analysis (PCA) and multivariate general linear model, the midbrain and right cortex were identified as the primary regions of metabolic abnormalities in PD and LID rats. In addition, PD and LID rats exhibited lower levels of synaptophysin (SYP). All results provided key insights for developing targeted therapies in PD. Harsanyiova et al. discussed the relationship between gastrointestinal tract and the pathology or treatment of PD symptoms.

Bao et al. surveyed the various positron emission tomography (PET) radiotracers available for AD imaging and discussed their clinical applications especially in terms of early detection and cognitive relevance. Based on [<sup>18</sup>F]-APN-1607 PET tracer, Lu et al. detected tau deposition in AD and reported that individual tauopathy is correlated with impaired cerebral glucose metabolism and cognitive function. Using combined PET and MR imaging, Kim et al. investigated the effect of conductive

hearing loss in an AD mouse model. The findings from their study indicated that even partial hearing loss could aggravate memory impairment in AD.

$^{11}\text{C}$ -PE2I is a PET radiotracer targeting neuronal dopamine transporters (DaT). Ivanidze et al. investigated neurovascular unit (NVU) integrity by using arterial spin labeling (ASL) MR imaging and correlated the findings of NVU integrity with striatal DaT density from  $^{11}\text{C}$ -PE2I PET imaging. This exploratory research could serve as a foundation for further development of combined NVU and striatal DaT density as early disease biomarkers and potential new therapeutic targets. Based on  $^{11}\text{C}$ -CFT and  $^{18}\text{F}$ -FDG PET imaging data, Fei et al. studied the relevancy between UPDRS motor scores and PDQ39 mobility sub-scores.

Based on partial volume-coil  $^{31}\text{P}$  MR spectroscopy of parieto-occipital lobes with 7-Tesla MR imaging, Das et al. accurately quantified high-energy phosphate and membrane phospholipid metabolites in amnesic MCI (aMCI). Furthermore, they have also found that brain energy metabolism and membrane phospholipid indexes were related to cognitive performance in domains of executive function (EF), memory, attention, and visuospatial skills using aMCI.

Liu, Jiang, et al. explored functional and structural properties of abnormal brain networks associated with PD. The authors showed that both the expressions of metabolic and structural patterns in PD patients were significantly higher than healthy controls, and verified their results in connectome analysis, which provided new information for elucidating the neuropathological mechanisms of PD. Shu et al. developed an integrative nomogram based on white matter radiomics biomarkers and nonmotor symptoms for the identification of early-stage PD.

Tsai et al. explored the skull score (SS) distribution of tremor patients, and correlated the SS with image feature from customized skull density ratio (cSDR). This study provided useful information for clinical study of MR-guided focused ultrasound thalamotomy. Chiu, Tzeng, et al. found that the patients with tremor and vascular cognitive impairment (VCI) had high possibility of mixed pathology of PD and Lewy body disease (LBD).

Ye et al. investigated the volumetric changes in thalamus and hypothalamus in ALS. The results from their study revealed no significant difference of the volume in thalamus and hypothalamus between ALS patients of normal frontotemporal function and healthy controls.

Yu et al. identified the brain function activity differences between MCI patients with depression and MCI patients without depression using resting state MR imaging measurements. This study provided useful information for a better understanding of the relationship between depressive symptoms and memory deficits. Xing et al. explored the alterations in intra- and inter-network functional connectivity of multiple networks in presbycusis patients, suggesting that functional network connectivity can be used to predict potential cognitive impairment in their early stage.

Wan et al. compared the changes in subcortical nuclei in older adults with cognitive frailty (CF) and studied their relationship with cognitive decline and physical frailty. Their results showed

significant volume reductions in five subcortical nuclei, including the bilateral thalami, left caudate, right pallidum, and accumbens area in older adults with CF. Lee et al. used surface-based analysis to evaluate subcortical structural characteristics and its relationship with early onset Alzheimer's disease (EOAD) and late-onset Alzheimer's disease (LOAD). The results from their study demonstrated that EOAD and LOAD might have different courses of pathomechanism.

Qiao et al. examined the neural substrates and mechanisms that generate memory deficits, seizures, and neuropsychiatric abnormalities in encephalitis with leucine-rich, glioma-inactivated 1 (LGI1) antibodies. The results showed that neural disorder and behavioral deficits of anti-LGI1 encephalitis might be associated with extensive changes in brain connectivity and microstructure.

Bruchhage et al. performed machine learning to assess the contribution of volume fraction myelin and gray matter volume. They proposed a refined model of cerebellar contribution to early AD development. The results from their study showed higher anterior cerebellar contribution to MCI and higher posterior cerebellar contribution to mild/moderate stages of AD for each tissue property. Ma et al. proposed a generative adversarial network (GAN) framework to distinguish brain images of human subjects of normal brain aging from those of human subjects with AD and frontotemporal dementia (FTD). The results from their study showed an accuracy of 88.28% in distinguishing human subjects of normal brain aging from those of human subjects with AD and FTD based on GAN framework derived from brain image.

Hu, Li, Zhang, et al. found that periodontitis was associated with learning and memory impairment, probably induced by neuroinflammation via activating the toll-like receptor 4/Nuclear factor kappa B signaling pathway. Ding et al. aimed to evaluate the value of odors in olfactory identification (OI) test and other known risk factors for predicting incident dementia. The results from their study suggested that peppermint smell capability might be one of the useful indicators for predicting dementia. Nie et al. assessed the differences of eye movement parameters between healthy elderly individuals and patients with MCI. They found that cognitive deficits and eye movement indexes were correlated, which could be further explored as early markers for MCI.

The paper by Yang, Huang, et al. proposed a neuroimaging approach to identify MCI using a deep learning method and functional near-infrared spectroscopy (fNIRS). Their results indicated that fNIRS imaging approach based on temporal feature maps as a promising diagnostic method for early detection of MCI and clinicians might use it as a tool for evaluation of MCI.

Tseng et al. used multivariate time-series electrocardiogram (ECG) analysis to diagnose cardiovascular diseases. They investigated various ECG features and found some associations between features of ECG and medical records (e.g. smokers, obesity, and hypertension).

Chiu, Hung, et al. studied the relationship between freezing of speech (FOS) and dementia with Lewy bodies (DLB). They

designed a freezing of speech single questionnaire (FOSSQ) and compared the association factors of FOS in non-demented participants, patients with AD, vascular dementia (VaD), and DLB. The results of their study supported validity of the FOSSQ for discriminating DLB from individuals with non-demented or other forms of dementia. Similarly, Wang, Hung, et al. designed a novel questionnaire for visuospatial dysfunction (VSD) in DLB.

To distinguish stable MCI (MCIs) from converting MCI (MCIc), Gupta et al. proposed different neuroimaging modalities combined with APOE genotype to form a multimodal system for discrimination of AD to increase the classification accuracy.

In order to determine whether a MCI patient is at high risk of progressing to AD, Lin et al. developed an extreme learning machine (ELM)-based grading method to predict MCI-to-AD conversion. The method was validated by Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort, with an accuracy of 84.7% in prediction of MCI progression to AD within 3 years.

Wang, Wei, et al. conducted a systematic review and meta-analysis to assess the available preclinical evidence and possible mechanisms of baicalin for animal models of PD. Li et al. investigated the efficacy and safety of 3 Erinacine A-enriched *Hericium erinaceus* mycelia (EAHE) capsules for the treatment of patients with mild AD. The study lasted for 49 weeks and the results showed that EAHE was well-tolerated without significant side effects. Flavonoid containing natural products, Myricetin (MYR) and Dihydromyricetin (DMY) are abundant in fruits and vegetables. Liu, Guo, et al. reviewed the benefits of MYR and DMY in AD patients at molecular level, including effects on amyloid-beta protein imbalance, neuroinflammation, dyshomeostasis of metal ions, autophagy disorder, and oxidative stress.

The early intervention for MCI could decrease the rate of conversion from MCI to AD. Lai et al. compared and ranked 9 treatment methods for MCI in AD based on meta-analysis. They pointed out that music therapy might be the best treatment for MCI followed by acupuncture, among the nine treatment methods included for their meta-analysis. Similar to those non-pharmacological interventions, Pei et al. proposed a neurofeedback training based on mismatch negativity to regulate sensory ability and memory.

Stuckenschneider et al. investigated the effects of a 12-month structured exercise program on the progression of 183 amnesic MCI patients. No significant improvement of cognitive performance was found based on the results from their study. In another study based on event-related measurement of auditory memory, Laptinskaya et al. found no improvements of cognitive performance in a 10-week unimodal cognitive or physical training and an active lifestyle for older adults at risk for dementia. In the narrative review by Meng et al., patients with AD who presented with long-term exercise interventions appeared

to have improved blood flow, increased hippocampal volume, and improved neurogenesis. These results indicated that exercise intervention might be an important moderator to prevent long term disease progression.

Kumar et al. reviewed and discussed nano-enabled drug delivery systems and their current and potential applications for the treatment of various NDs, including AD and PD, in studies to overcome the limits of blood-brain barrier (BBB). Huang et al. developed a medical red light treatment (RLT) device to treat older adults with mild to moderate AD. They planned a study protocol to verify the safety and efficacy for a 24 weeks period. On the other hand, Zhu et al. found that there was more efficacy via tele-health interventions in lowering depression for careers of dementia patients based on meta-analysis.

Deep brain stimulation (DBS) is widely used in the field of mental and neurological diseases. Luo et al. reviewed the therapeutic effect of DBS in AD, and analyzed its stimulation parameters and potential mechanism of action. Tan et al. used a convolutional neural network (CNN) to classify handwritten digits and letters and applied dropout at different stages to simulate DBS effects on engrams. The results of their study showed that dropout of engram nodes might be a possible mechanism by which neuromodulation techniques could disrupt or enhance memory. Hwang et al. pointed out the applications of phase amplitude coupling-based phase-dependent DBS technique in PD, which aimed to deliver timed stimulation pulses to a specific phase precisely to modulate pathological network activities and behavior in real time.

Tang et al. investigated the effect of electroacupuncture (EA) on cognitive impairment and the role of c-Jun N-terminal kinase (JNK) signaling pathway in AD model mice. The results of their study showed that EA could reverse cognitive deficits and substantially lower the burden of amyloid precursor protein. In another study, Hongna et al. demonstrated the improvements of locomotor function by promoting autophagy flux and inhibiting necroptosis in rats with spinal cord injury treated with Jia-Ji electro-acupuncture.

In summary, large number of articles collected in this Research Topic reflected recent advances in mechanistic study of pathophysiology of AD and PD, development of biomarkers and molecular imaging techniques for diagnosis and treatment of AD and PD. We hope that publications of this Research Topic will not only report recent advances in ND research, but also facilitate translation of new discovery to development of new diagnostic tests and therapeutic agents for early diagnosis and treatment of ND, including AD and PD.

## AUTHOR CONTRIBUTIONS

JJ and KS wrote the draft. FP copyedited for the language. C-YH and W-MK reviewed and revised the manuscript. All authors listed have made a substantial, direct, and intellectual contribution to the work and approved it for publication.

doi: 10.3389/fnins.2019.01333

Numerous observational studies have shown that depressive symptoms are common in individuals with mild cognitive impairment (MCI) who have a higher rate of progress to dementia. However, it is still uncertain whether there are any differences between MCI patients with and without depression symptom in their brain function activities. Here we have identified the brain function activity differences in two groups of MCI patients (with depression or without depression) using the resting state MRI (rsfMRI) measurements. 76 right-handed MCI subjects have been recruited in this study, including 27 MCI patients with depression symptom (MCID), 49 MCI patients without depression symptom (MCIND). Analyses based on 7 rsfMRI measurements, including four static measurements (ALFF, fALFF, PerAF, and ReHo) and three dynamic measurements (dALFF, dfALFF, and dReHo) have been used to explore the temporal variability of intrinsic brain activity. No significant differences in ALFF and dALFF between the two group were found. In the MCID group, fALFF decreased in temporal gyrus, frontal gyrus, inferior occipital gyrus, middle frontal gyrus and cerebellum, but increased in cuneus, calcarine, lingual; while PerAF increased in left parahippocampus. The differences of ReHo in the two groups was only found in cerebellum. Compared to MCIND group, dfALFF in MCID decreased in cuneus, occipital gyrus and calcarine, while dReHo in MCID increased in bilateral temporal gyrus, frontal gyrus, superior parietal gyrus, inferior parietal gyrus and precuneus. Our results may provide a better understanding in the relationship between the depressive symptoms and memory deficits.

**Keywords:** Alzheimer's disease, aging, cognition, depression, brain function

## INTRODUCTION

Mild cognitive impairment (MCI) is the clinical status of an individual with memory impairment who had memory defect but is otherwise functioning properly and does not meet clinical diagnosis criteria for dementia (Petersen et al., 1999, 2001). Cognitive deficits can be a single symptom, they also coexist with other non-cognitive features, of all the non-cognitive features, the prevalence of depression is the highest (Chi et al., 2015). Further, evidence suggests that MCI patients combined with depression symptoms (MCID) progress more rapidly from MCI to Alzheimer's disease (AD)

along the neurodegenerative spectrum, with a reported prevalence of 32% (Gao et al., 2013; Chi et al., 2015; Ismail et al., 2017). Thus, for early diagnosis and treatment purposes, an appropriate screening strategy to define the probable risk factors in those cognitive impaired individuals is meaningful (Ismail et al., 2017).

In recent years, based on the development of neuroimaging technology, magnetic resonance imaging, as a tool for detecting brain structure and function has been provided. Blood oxygenation level-dependent (BOLD) resting-state functional MRI (rsfMRI), has attracted enormous research interest in studying the neural mechanisms of cognitive dysfunction in individuals with psychiatric disorders (Biswal, 2012). Various rsfMRI measures such as functional connectivity (FC) (Biswal et al., 1995), amplitude of low-frequency fluctuation (ALFF) (Zang et al., 2007) fractional ALFF (fALFF) (Zou et al., 2008), percent amplitude of fluctuation (PerAF) (Jia et al., 2017, 2019) regional homogeneity (ReHo) (Zang et al., 2004) and degree centrality (DC) (Zuo et al., 2012) have been used to describe the intrinsic brain activity (IBA). IBA involves dynamic neural and metabolic activities, it is activity and plays a pivotal role in brain function (Dai and He, 2014; Raichle, 2015). These methods have been widely used to evaluate the IBA of neurological disorders or neuropsychiatric disorders, such as AD, depression, and MCI (Yao et al., 2009; Zhang et al., 2012; Guo et al., 2016; Wee et al., 2016; Li et al., 2017; Stoyanov et al., 2017; Zhang et al., 2017; Kandilarova et al., 2018; Yang et al., 2018; Liu et al., 2019). Furthermore, evidence indicated that once brain got an internal or external stimuli, it could respond by dynamic integration or adjustment over multiple time scales (Hutchison et al., 2013; Bassett and Sporns, 2017; Yan et al., 2017). However, the aforementioned measures are static, which ignoring the characteristics of dynamic changes of IBA over time, they assumed that during the entire rsfMRI scan, the BOLD signal is stationary (Liao et al., 2014, 2015). Compared with the static rsfMRI measures, the dynamic sliding window approaches are effective for capturing the dynamic characteristics of regional brain activity over different times which could be used to examine abnormal brain function (Yan et al., 2017; Tang et al., 2018). These evidence all indicated that rsfMRI is a proper approach to compare the differences between MCID and MCIND.

Studies have identified regions in MCI compared with the NC, with a decreased or increased ALFF/fALFF/ReHo (Han et al., 2011; Zhang et al., 2012; Dai and He, 2014; Li et al., 2017; Liu et al., 2018, 2019; Yang et al., 2018). Previous study found that changes from ALFF/fALFF measurements of IBA may be worthwhile to characterize the early and gradual changes in physiological alterations throughout AD progression (Yang et al., 2018). Moreover, in MCID group the FC density values were higher in the left MTG than those in the MCI without depression patients (MCIND) (Liu et al., 2018). Another study found that abnormal ALFF values in MCID group could serve as markers to effectively differentiate MCID from MCI patients (Li et al., 2017). As for ReHo, it can be used to classify the depression subtypes and MCI, also changes in ReHo could be a biomarker for the pathophysiology and therapeutic response of depression (Guo et al., 2013; Liu et al., 2019). Previously, by combining dynamic FC with static FC, some studies found

that the diagnostic accuracy for MCI could be significantly improved (Wee et al., 2016; Zhang et al., 2017). So far, no study explored the dynamic characteristics of local brain activity indexes in MCID patients.

We employed 7 resting state measurements, including four static measurements (ALFF, fALFF, PerAF, and ReHo) and three dynamic measurements (dALFF, dfALFF, and dReHo) to investigate the temporal variability of voxel-wise brain activity. These combinations were designed to explore the variability of IBA and to enhance our understanding of brain function by recognizing specific pathophysiological features and further deepen our understanding of cognitive behavior. We assumed that MCID patients would exhibit abnormal spontaneous brain activity compared with those MCIND. These would enhance understanding of the relationship between depressive symptoms and memory deficits.

## MATERIALS AND METHODS

### Participants

The study was endorsed by the Research Ethics Review Board of the First Affiliated Hospital of Medical School of Zhejiang University (FAHZU). A total of 76 right-handed MCI subjects were recruited in the study, including 27 patients combined with depression symptoms (MCID), 49 MCI without depression patients (MCIND). All MCI patients were recruited at the clinic of the Department of Neurology, FAHZU. Diagnoses of MCI were made by experienced neurologists according to Petersen's criteria (Petersen, 2004). Depressive symptoms were identified by qualified psychiatrists according to the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-V) and the Geriatric Depression Scale (GDS) (Yesavage et al., 1982; Chau et al., 2006) [we also recruited 50 right-handed normal controls, who were matched for age and gender from the local communities (**Supplementary Methods in Supplementary Material**)].

The diagnosis of MCID and MCIND both fulfilled the published MCI diagnostic criteria (Petersen, 2004). The inclusion criteria for the MCID group included an acute episode of mild depression with DSM-V for the diagnosis of depression symptom who were first suffered from MCI and the 30-item GDS was > 10 scores (Yesavage et al., 1982; Chau et al., 2006). The MCIND subjects were excluded if they had been diagnosed with major depression, recurrent depression, or other psychiatric disorders as described in DSM-V.

### Imaging Data Acquisition

MRI data were obtained using a 3.0 Tesla GE Discovery MR750 scanner (HD, General Electric Healthcare, Waukesha, WI, United States). 3D T1-weighted structural images were acquired using the following parameters: 128 slices, TR of 8,100 ms, TE of 3.1 ms, slice thickness of 1 mm, FA of 8°, matrix size of 256 × 256, FOV of 256 × 256 mm<sup>2</sup>. Functional images were acquired using the following parameters: 43 contiguous axial slices, repetition time (TR) of 2,000 ms, echo time (TE) of 30 ms, slice thickness of 3.2 mm, flip angle (FA) of 90°, matrix size of 64 × 64, field of view (FOV) of 200 × 200 mm<sup>2</sup>, total scan time of 8'00". During the

rsfMRI scan, the patients were given no task but were instructed to simply rest with eyes closed.

## rsfMRI Preprocessing

The rsfMRI data were processed using SPM12<sup>1</sup> and RESTplus (Jia et al., 2019)<sup>2</sup>. The first 10 time points were discarded as adaptation of the participant to the scanner noise. The data preprocessing steps included slice timing, realignment, and spatial normalization. First, an individual T1-weighted image was co-registered to the mean functional image and then the T1-weighted image was segmented into gray matter (GM), white matter (WM) signal, and cerebrospinal fluid (CSF) signal. The EPI images were spatially normalized to the Montreal Neurological Institute (MNI) space and voxel size was resampled to 3 mm × 3 mm × 3 mm using the normalization parameters estimated during segmentation. Smoothing was performed with a 6 mm full width - half maximum (FWHM) Gaussian kernel. After removing the linear trend, we regressed out of covariates, which consisted of Friston-24 head motion parameters (Friston et al., 1996; Yan et al., 2013), WM signal, and CSF signal. The time courses were filtered by a (0.01–0.08 Hz) band to reduce high-frequency noise and low-frequency drifts.

## Static ALFF, Fractional ALFF (fALFF), Percent Amplitude of Fluctuation (PerAF) and Regional Homogeneity (ReHo) Calculation

We performed ALFF, fALFF, PerAF and ReHo analysis for each scan. The calculation of ALFF was based on fast Fourier transform (FFT). Using FFT, each time course was converted to the frequency domain. Then, the square root of the power spectrum at each frequency was averaged across the filtered band (0.01–0.08 Hz). The ALFF of each voxel was then normalized by the global mean of the ALFF values (mALFF) for standardization. For each given voxel, mALFF reflected the degree of its raw ALFF value relative to the average ALFF value of the whole brain (Zang et al., 2007). Then we calculated fALFF by obtaining the ratio of the power spectrum of low frequency (0.01–0.08 Hz) to that of the entire frequency range. Then, the resulting spatial fALFF maps were then divided with each voxel divided by the whole-brain fALFF mean (mfALFF), providing mfALFF spatial maps (Zou et al., 2008). PerAF designated the percentage amplitude of BOLD fluctuation relative to the mean BOLD signal intensity of a given time series (Jia et al., 2017) with RESTplus (Jia et al., 2019). PerAF is standardized at the single voxel level, the resulting spatial PerAF maps were then normalized with each voxel divided by the global mean PerAF (mPerAF). Both PerAF and mPerAF can be used for group-level statistical analysis, here we used mPerAF for further statistical analyses (Jia et al., 2019; Yu et al., 2019). For ReHo, the Kendall's coefficient of concordance (KCC) of the time course of every 27 nearest neighboring voxels was calculated (Zang et al., 2004). To reduce the influence of individual variations in the KCC value, ReHo

map normalizations were performed by dividing the KCC among each voxel by the averaged KCC of the whole brain.

## Dynamic ALFF, fALFF and ReHo Calculation

Dynamic parameters were performed using Temporal Dynamic Analysis (TDA) toolkits based on DPABI (Yan et al., 2016) Sliding window-based analysis, which is sensitive in detecting time-dependent variations, was applied to examine three dynamic measurements (dALFF, dfALFF or dReHo) variability over the whole brain (Hindriks et al., 2016; Liu et al., 2017; Yan et al., 2017; Yip et al., 2017; Tang et al., 2018; Vergara et al., 2019).

In the sliding window analysis, a temporal window of certain size and shape is chosen, and ALFF, fALFF and ReHo within that window are calculated. Theoretically, the window size should be designed feasibly. It should be small enough to monitor potentially transient signals, and yet large enough to describe the lowest frequencies of interest in the signals (Sakoglu et al., 2010). Previous studies of sliding window connectivity have applied a sliding window length from 10 to 180 s (Thompson et al., 2013; Gonzalez-Castillo et al., 2015; Chen et al., 2018). Here we applied a sliding window length of 32 TR (64 s) and a shifting step size of two TR (4 s) (Chen et al., 2018). The remaining 230 time points after removing the first 10 time points for each individual were segmented into 100 windows in total. In each sliding window, ALFF, fALFF and ReHo were calculated. After calculating ALFF of all voxel in time windows, each participant will get several window-based ALFF maps (similar as fALFF and ReHo). Then, we computed the mean and standard deviation of each voxel in all window-based ALFF maps for each subject and further got the corresponding coefficient of variation (CV) which was acquired by dividing the standard deviation by the mean. To better measure the dynamic variation of regional brain activity between different individuals, we used CV as dALFF (similar as dfALFF), which represented the temporal variability of absolute energy consumption in low-frequency regional brain activity (Tang et al., 2018).

## Statistical Analyses

### Scales Analysis

To examine the between-group differences in the seven measurements, two-sample *t*-test was held between the MCID and MCIND groups using DPABI (Yan et al., 2016). The figure was drawn by both DPABI and BrainNet Viewer (Xia et al., 2013; Yan et al., 2016). To reduce the effect of confounding variables in the statistical analysis, we performed two-sample *t*-tests with the mean relative displacements of age, sex, and education as covariance. Multiple comparison correction was performed based on Gaussian random field theory (GRF, voxel-wise *p* < 0.05, cluster-wise *p* < 0.05, two-tailed).

### Correlation Analysis

With the peak voxels of abnormal regions as spherical centers, spherical ROIs were constructed around these abnormal regions (with a 6 mm radius). To assess the relationship between the behavioral scores (include MMSE, MoCA and GDS scores) and

<sup>1</sup><http://www.fil.ion.ucl.ac.uk/spm>

<sup>2</sup><http://www.restfmri.net/forum/>

metrics in these abnormal regions, we used Partial correlation analysis that controlled for age, sex and education by SPSS software (version 20.0; IBM, Chicago, IL, United States). Statistical significance was defined as  $p < 0.05$ . To control for false positives from multiple comparisons, we used the false discovery rate (FDR) correction in which the  $p$ -values were multiplied by the number of comparisons.

## RESULTS

### Neuropsychological Results

Demographic and clinical characteristics of 76 patients with MCI, 49 MCIND (19 men; mean age,  $65.88 \pm 9.762$  years) and 27 MCID (11 men; mean age,  $63.44 \pm 10.58$  years) are listed in **Table 1**. No significant differences were found ( $p > 0.05$ ) in gender, age, education level, and MMSE, MoCA scores between the MCID group and MCIND group. Detailed demographics and the psychological characteristics of the two groups are shown in **Table 1**.

### Alterations of Region IBA Changes Between MCID and MCIND

#### The Comparison of ALFF

There were no significant differences in ALFF between the MCID group and MCIND group.

#### The Comparison of fALFF

As shown in the **Figure 1**, for fALFF, MCID decreased in inferior temporal gyrus (ITG), middle temporal gyrus (MTG), middle frontal gyrus, inferior occipital gyrus, and cerebellum, but increased in cuneus, calcarine, lingual. The significant differences in fALFF between the two groups are shown in **Table 2** and **Figure 1A**.

#### The Comparison of PerAF

We found that in MCID group, PerAF increased in left parahippocampus gyrus and temporal gyrus. The significant differences in PerAF between the MCID and MCIND group are shown in **Table 2** and **Figure 1B**.

**TABLE 1 |** Demographic and neuropsychological data.

	MCIND ( $n = 49$ )	MCID ( $n = 27$ )	$p$
Age (y, mean $\pm$ SD)	$65.88 \pm 9.762$	$63.44 \pm 10.58$	0.2766 <sup>t</sup>
Gender (M/F)	19/30	11/16	0.053 <sup>x</sup>
Education (y, mean $\pm$ SD)	$9.8 \pm 3.563$	$9.444 \pm 3.105$	0.5412 <sup>t</sup>
MMSE (mean of all points $\pm$ SD)	$25.43 \pm 3.506$	$25.04 \pm 4.052$	0.6492 <sup>t</sup>
MoCA (mean of all points $\pm$ SD)	$19.92 \pm 3.416$	$19.78 \pm 4.917$	0.8166 <sup>t</sup>
GDS (mean of all points $\pm$ SD)	$5.66 \pm 2.847$	$15.44 \pm 4.635$	<0.0001 <sup>t</sup>

MCID, mild cognitive impairment with the symptom of depression; MCIND, non-depressed mild cognitive impairment; MMSE, Mini Mental State Examination; MoCA, Montreal Cognitive Assessment; GDS, Geriatric Depression Scale; SD, standard deviation. <sup>x</sup>, the  $p$ -value was obtained by the chi-square test; <sup>t</sup>, The  $p$ -value was obtained by the two-sample  $t$ -test.

### The Comparison of ReHo

Using ReHo, there were only a small amount of group differences between MCID and MCIND group in cerebellum. More details were shown in the **Table 2** and **Figure 1C**.

### The Comparison of dALFF

There were no significant differences in dALFF between the MCID group and MCIND group.

### The Comparison of dfALFF

As shown in the **Figure 1**, for dALFF, compared to MCIND group, MCID group showed decreased dALFF in the bilateral cuneus, middle occipital gyrus, right superior occipital gyrus and calcarine. The significant differences in dfALFF between the MCID group and MCIND group are shown in **Table 2** and **Figure 1D**.

### The Comparison of dReHo

Using dReHo, compared to MCIND group, MCID group exhibited obvious increase in bilateral MTG, ITG, superior temporal gyrus (STG), superior parietal lobule, inferior parietal gyrus (IPG), precuneus, superior frontal gyrus (SFG), middle frontal gyrus (MFG), opercular part of inferior frontal gyrus (IFG) and right cerebellum. More details were shown in the **Table 2** and **Figure 1E**.

### Correlational Analysis

There was no significant correlation between clinical behavioral scores and any rsfMRI metrics.

## DISCUSSION

Most previous studies have focused on the depression-related or MCI-related brain functional changes. However, the brain function in MCI patients combined with depression is still uncertain. In the current study, we observed alterations in IBA during the resting state in 7 resting state parameters, including four static measurements and three dynamic characteristics in MCID and MCIND patients. We found several brain regions especially in frontal gyrus, temporal gyrus and parahippocampus gyrus, showed significant differences in fALFF, PerAF, ReHo, dfALFF and dReHo between the MCID and MCIND groups. These findings may develop a better understanding of the relationship between depressive symptoms and memory deficits.

As we supposed, the differences of abnormal spontaneous brain activity between MCID and MCIND patients could be distinguished by rsfMRI. We found significant differences between MCID and MCIND group in frontal gyrus [included superior frontal gyrus (SFG), middle frontal gyrus (MFG) and inferior frontal gyrus (IFG)], temporal gyrus (included MTG, ITG and STG), hippocampus, parahippocampus gyrus, IPG and cuneus. The robustness of the results was tested to prove the regions we found was stability and repeatability (**Supplementary Figures S2, S3**). In the studies pretend to explore the neural mechanism about MCI, AD or depression, these regions also have been mentioned (Langenecker et al., 2007;

**TABLE 2 |** Brain regions with significantly differences rsfMRI values in the MCID group compared with the MCIND group.

Measurements	Brain regions	MNI coordinates			Voxles	T-value
		x	y	z		
fALFF	Cerebellum Posterior Lobe	-15	-54	-57	339	-3.9226
	Middle Temporal Gyrus_L	-57	-57	0	241	-3.8508

Alexopoulos et al., 2008; Yao et al., 2009; Lee et al., 2012; Xie et al., 2012; Zhang et al., 2012; Rizio and Dennis, 2014; Guo et al., 2016; Stoyanov et al., 2017; Kandilarova et al., 2018; Yang et al., 2018; Kandilarova et al., 2019). These brain regions may be the proof of a possible shared pathophysiology in both depression and MCI (Yao et al., 2009; Zhang et al., 2012). Other studies found that depressive symptoms in AD had biochemical manifestations similar to depression, suggesting that they might share a common pathway at the biochemical level, this phenomenon may be same in those MCI (Langenecker et al., 2007; Alexopoulos et al., 2008; Lee et al., 2012; Xie et al., 2012; Taylor et al., 2013; Rizio and Dennis, 2014). In studies focused on brain structure found that depression may cause structural changes in frontal and temporal regions (Koolschijn et al., 2009; Kandilarova et al., 2019). These findings suggested that a circuit may be involved in the frontal cortex is associated with the functional neuroanatomy of depression (Langenecker et al., 2007; Yang et al., 2016).

Meanwhile, regions we found the IBA changes mostly related to default mode network (DMN) and executive control network (ECN). Executive functions are control mechanisms that adjust aspects of emotion and cognition, and disruption to these processes is related to worse clinical prognosis of depression (Morimoto et al., 2015). According to previous neuroimaging studies, the DMN is linked to self-referential thought, and the episodic memory retrieval and scene construction (Lei et al., 2013). It is supported by results from previous studies about late-life depression (LLD). LLD usually has a hyperactive DMN (increased rumination, defected cognition) and a hypoactive ECN (low cognitive control associated with emotional response), which may reflect

clinical features of depressive symptoms (Aizenstein et al., 2014; Karim et al., 2017).

Above all the parameters we estimated, we didn't find significant differences in ALFF or dALFF. It has been pointed out that the ALFF could be influenced by the physiological noise irrelevant to brain activity, and dALFF has a temporal variability related to specific topographic (Zou et al., 2008; Liao et al., 2019). As for fALFF, it could effectively suppress the physiological noise, but is not as stable as ALFF in gray matter regions (Zou et al., 2008; Zuo et al., 2010). We firstly used PerAF to estimate IBA of MCID patients, in parahippocampus, MCID had an increased PerAF. Previous study by using both ALFF and PerAF found that the ALFF was similar to PerAF, but PerAF was better than ALFF in inter-scanner reliability (Zhao et al., 2018). Although it is still unclear what causes the difference between those parameters and the potential physiological significance might be, with the limitation of each parameters, it is still necessary to take into consideration all these metrics (Zuo et al., 2010). We found ReHo only decreased in cerebellum, while another study found that MCID patients showed significantly higher coherence ReHo (cReHo) than MCIND patients in the left Heschl's gyrus and thalamus, lower cReHo in the left postcentral gyrus (Liu et al., 2019). These differences may be influenced by different calculation of ReHo. Also, the recruit criteria of MCID group could be another factor. Depression is a highly heterogeneous disease, and there are no clear gold biomarkers for diagnosis (Ismail et al., 2017). In addition, the diagnose of depression syndrome is based on clinical symptoms and a rating scale, which is inevitably subjective. Further, evidence suggests that evaluating depressive symptoms comprehensively

and accurately in those with neurocognitive disorders is difficult because of atypical symptoms in elders, and the interaction between depression and cognitive impairment in older adults

makes it further complicated (Ting et al., 2010; Ismail et al., 2017). In our study, we selected the GDS to evaluate depressive symptoms in MCI, while other studies have used different scales, such as HAMD and the NPI (Liu et al., 2019).

Interestingly, we found that the results of dynamic measures differ from the static measures, this had also been found in other studies of diseases (Sourty et al., 2016; Cordova-Palomera et al., 2017). We found that fALFF in MCID decreased in temporal gyrus (ITG, MTG), MFG and inferior occipital gyrus, but increased in cuneus, calcarine, lingual, while in dALFF, we found an increase in the cuneus, middle occipital gyrus. Also, the ReHo doesn't change in line with dReHo. As for dReHo, compared to MCIND group, MCID group exhibited an obvious increase in temporal gyrus (MTG, ITG, STG), frontal gyrus (MFG, SFG, IFG) and right cerebellum. However, using ReHo, we only found differences in cerebellum. Sourty et al. (2016) implied that some brain function alterations in Lewy body dementia can be detected utilizing dynamic FC but not static FC by sliding-window analysis (Sourty et al., 2016). The concept of dynamic neuroimage characteristics may provide a proper way to summarize changes in spatial patterns over time and to track differences in disease (Calhoun et al., 2014).

This study had several potential limitations. Firstly, this is a cross-sectional study, we did not investigate the conversion of MCID/MCIND to AD. These two sub-types of MCI patients may have different disease progress into AD. We will focus on not only the different clinical symptoms and their different brain areas, but also the potential different follow up consequences for MCID and MCIND patients. Secondly, it remains unclear that the mechanism of the differences and abnormalities in the patients of MCID and MCIND. In further studies, we would like to combine the rsfMRI, structural MRI and other biophysical data simultaneously with a larger sample and would reveal structural and biological substrates underlying these functional deficits in MCI and MCID patients.

## CONCLUSION

In summary, we have investigated the IBA of MCID and MCIND using rsfMRI technique. We have found some obvious difference in the IBA between MCID and MCIND in the regions such as frontal gyrus (included SFG, MFG and IFG), temporal gyrus (included MTG, ITG and STG), parietal gyrus (superior parietal gyrus, IPG), occipital gyrus, parahippocampus gyrus and cuneus. The rsfMRI study suggests that the abnormal IBA pattern of the whole-brain functional activity may serve as an early biomarker for the detection of cognitive deficits and emotional problems in MCI patients.

## AUTHOR CONTRIBUTIONS

YY analyzed the data and wrote the manuscript. ZL analyzed the data. YL, JY, GP, and KZ evaluated

the subjects and collected the data. XJ and BL designed the experiment and monitored the quality of the experiment.

## FUNDING

This study was funded by grants from the Science and Technology Program of Zhejiang Province (2017C03011), the

National Key Research and Development Program of China (2016YFC1306402).

Through a number of an extensive autopsy, biomarker, and genomics studies, researchers have recently defined a novel type of dementia known as limbic-predominant age-related TDP-43 encephalopathy (LATE). LATE is perhaps best characterized by the presence of hyperphosphorylated TDP-43, which plays multi-functional roles through interactions with DNA and RNA, leading to significant alterations in the transcription and translation of particular genes. As individuals of advanced age represent a rapidly growing demographic group globally, there is a steadily increasing rate of LATE incidence that has to date received insufficient recognition despite its serious implications for public health. TDP-43 is the common pathology of various age-related dementia, therefore, it may be a potential and promising therapeutic target for such diseases. In the present review, we discuss the pathways regulating TDP-43 expression, metabolism, and disease activity in order to better understand the link between TDP-43 proteinopathy and LATE at the genetic, pathological, and clinical levels.

## INTRODUCTION

TDP-43 is a protein first discovered in 2006 to be present within the ubiquitinated inclusions that are a hallmark of amyotrophic lateral sclerosis (ALS) and in many cases of Tau-negative frontotemporal lobar degeneration (FTLD-TDP; Neumann et al., 2006; Cairns et al., 2007). More recent studies have shown that phosphorylated TDP-43 is similarly present in the brain of individuals over 80 years-old that have not been diagnosed with FTLD or ALS, but who often exhibit signs of Alzheimer's disease (AD) or hippocampal sclerosis (Amador-Ortiz et al., 2007a,b). These rates of TDP-43 proteinopathy as well as associated hippocampal sclerosis and amnesic dementia have been found to increase at more advanced ages, whereas severe AD cases become less common as individuals attain such advanced age (Nelson et al., 2019).

**Abbreviations:** LATE, limbic-predominant age-related TDP-43 encephalopathy; LATE-NC, LATE- neuropathological change; ALS, amyotrophic lateral sclerosis; FTLD-TDP, frontotemporal lobar degeneration with TDP-43 proteinopathy; FTLD, frontotemporal lobar degeneration; FTD, frontotemporal dementia; AD, Alzheimer's disease; ADNC, AD neuropathologic changes; HpScl, Hippocampal sclerosis; Aβ, amyloid-β; NFTs, Nerve Fiber Tangles; TARDBP, TAR DNA binding protein; GRN, granulin; APOE, apolipoprotein E; TMEM106B, transmembrane protein 106B; ABCC9, ATP-binding cassette sub-family member 9; VCP, valosin-containing protein; RRM, RNA recognition motifs; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; CSF, cerebrospinal fluid; UTR, untranslated region.

At present, therapeutic efforts have failed to achieve satisfactory outcomes for treating AD, and given its apparent differences from AD, limbic-predominant age-related TDP-43 encephalopathy (LATE) has recently been defined as a unique clinical entity. This new disease classification highlights the importance of thoroughly exploring the role of TDP-43 in the context of age-related dementia development in general, and in the context of LATE specifically. However, as LATE remains a relatively new concept, much of the surrounding literature pertaining to AD or hippocampal sclerosis may inadvertently refer in whole or in part to cases of LATE, thereby complicating interpretations.

## THE TDP-43 PROTEIN

TDP-43 is a protein that is 414 amino acids long and 43 kDa in size encoded by the *TARDBP* gene which includes nuclear localization and nuclear export signals, RNA recognition motifs (RRMs) and C-terminal domain (Diaper et al., 2013). The TDP-43 N-terminal domain is important as a regulator of monomer folding and homodimerizing (Zhang et al., 2013). In contrast, the C-terminal domain functions to control gene expression and nucleic acid binding, allowing it to modulate RNA turnover and alternative splicing (Buratti and Baralle, 2010; Lee et al., 2011). Normally, TDP-43 is found primarily in the nucleus of cells, with only 5–20% of TDP-43 being cytoplasmic (Woo et al., 2017), and this imbalance is thought to be autoregulated by negative feedback signaling mediated by nuclear TDP-43 (Polymenidou et al., 2011).

In the context of diseases such as ALS or FTL, TDP-43 can become cleaved, hyperphosphorylated, and ubiquitinated such that it aggregates and forms large inclusions within the cytoplasm of cells such as neurons and glia (Neumann et al., 2006). Normally, cellular stress-mediated TDP-43 aggregates are degraded following ubiquitination by the caspase-3-mediated proteasome, or through autophagic processes into fragments of 25 or 35 kDa (Chang et al., 2016). However, in pathological contexts this TDP-43 degradation is impaired thereby leading to increased aggregation of 25 and 35-kDa fragments that cannot be eliminated from cells (Huang et al., 2014).

As 25 kDa TDP-43 fragments accumulate, this drives the formation of cytoplasmic aggregates at the expense of normal nuclear localization (Chang et al., 2016). These 25 kDa TDP aggregates have been linked with cognitive deficits (Caccamo et al., 2012), whereas the 35 kDa fragments have been linked to behavioral deficits (Medina et al., 2014). Mutations in *TARDBP* have been shown to result in inflammation-mediated deregulation of TDP-43 homeostasis which through increased interleukin (IL)-6 levels that in turn drive the formation of aggregates and the progressive deterioration of motor neurons (Swarup et al., 2011; Diaper et al., 2013). TDP-43 expression levels have also been linked to the expression and activity of particular synaptic proteins including synapsin-I and alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptor subunits (Gulino et al., 2015). As such, when TDP-43 becomes dysregulated, this can result in a cascade of altered signaling events that

mediate impaired synaptic transmission, progressive neuronal deterioration, and motor defects (Diaper et al., 2013).

## TDP-43 RELATED PROTEINOPATHY

Pathological conditions associated with TDP-43 aggregates include: aggregate inclusions within the cytoplasm of neurons and glial cells, pathological swelling or dystrophy of axonal, rounded neuropil grains, diffuse cytoplasmic TDP-43 staining with a lack of normal nuclear TDP-43 staining indicative of pre-inclusions, and in rare cases the presence of TDP-43 inclusions within the nuclei of neurons (Geser et al., 2010). TDP-43-linked neurodegeneration are divided into four categories according to the lesion patterns: perivascular, focal, sub-pial/sub-ependymal, and diffuse in the deep brain parenchyma (Geser et al., 2010).

Various neurodegenerative diseases have been shown to exhibit signs of TDP-43 aggregates, including, dementia with Lewy bodies (Higashi et al., 2007), argyrophilic grain disease (Fujishiro et al., 2009) and corticobasal degeneration (Uryu et al., 2008). Individuals with perivascular TDP-43 pathology also frequently exhibit significant cardiovascular symptoms such as hypertension and cerebral microinfarcts (Geser et al., 2010), with certain chronic vascular disease having the potential to drive the phosphorylation and misfolding of TDP-43. The most prominent and well-understood forms of TDP-43 proteinopathy are FTL, ALS, and AD.

FTL is a form of pre-senile dementia that impacts between 0.01 and 0.03% of individuals between 45 and 65 years of age (Bennion Callister and Pickering-Brown, 2014), leading to progressive deterioration of the frontal and anterior temporal brain lobes, finally causing frontotemporal dementia (FTD). The two primary hallmarks of FTL at the pathological level include hyperphosphorylated tau protein and TDP-43 aggregate inclusions (Neumann et al., 2006).

ALS is a progressive disease best characterized by the gradual and progressive degeneration of motor neuron function, with males and females having respective lifetime ALS rates of 1/350 and 1/500 (Salameh et al., 2015). The presence of altered TDP-43 has been recognized as a hallmark of ALS. As with FTL, many studies have explored the mechanisms whereby TDP-43 influences ALS pathogenesis, but at present these studies have been inconclusive and have yielded inconsistent results, suggesting more work is needed to establish the therapeutic value of targeting TDP-43 in this disease.

AD is the best-known and most prevalent form of dementia affecting individuals of advanced age. Extracellular amyloid- $\beta$  ( $A\beta$ ) plaque deposition, hyperphosphorylated tau aggregates that form within neurons to generate nerve fiber tangles (NFTs) are hallmarks of AD. Recent work has shown that phosphorylated TDP-43 is also evident within the brains of those with AD (Amador-Ortiz et al., 2007a,b).

In certain cases, TDP-43 aggregation and associated pathology may be a secondary consequence of some upstream neurodegenerative, developmental, or stress-induced influence (Nelson et al., 2016). Much as is the case for tau aggregates, however, once these TDP-43 aggregates form, that can significantly and adversely impact normal protein homeostasis

and gene expression to increase the risk of a wide range of diseases, thereby facilitating their development and progression (Nelson et al., 2016).

Therefore, TDP-43 proteinopathy is a promiscuous misfoldingopathy and can overlap with each other in many aspects, so it's necessary to differentiate them for better clinical diagnosis (Nelson et al., 2010). The main differences are risk genes, pathological proteins and types, clinical syndromes, as well as biomarkers. As granulin (GRN), apolipoprotein E (APOE), TMEM106B and many other risk genes present in more than one TDP-43 proteinopathy, it would be a prosperous finding if there are risk genes that specific to a particular subtype. Previous reports found that ALS and FTLN patients had higher TDP-43 levels in cerebrospinal fluid (CSF; Steinacker et al., 2008), despite not so convinced currently, increased TDP-43 in CSF may be related to the involvement of lesions near the ventricle or a sign of disease severity. Other methods like magnetic resonance imaging (MRI) and FDG-PET has been used to aid diagnosis in TDP-43 proteinopathy. As studies indicate that neurodegenerative diseases are related with specific intrinsic functional connectivity networks that varied among individuals, functional MRI studies may help to explain which groups are susceptible to certain diseases based on brain connectivity (Franzmeier et al., 2018).

## THE ASSOCIATION BETWEEN LATE AND TDP-43

LATE has been classified as a form of TDP-43 proteinopathy that impacts adults of advanced age regardless of whether or not they exhibit hippocampal sclerosis; LATE neuropathological change (LATE-NC) is characterized by mislocalized and phosphorylated TDP-43 that mainly affects limbic structures (Nelson et al., 2019). According to the anatomical distribution of TDP-43, the simplified staging includes the amygdala (stage 1); hippocampus (stage 2); middle frontal gyrus (stage 3; Nag et al., 2018). An updated staging scheme suggests amygdala (stage 1); entorhinal cortex and subiculum (stage 2); dentate gyrus of the hippocampus and occipitotemporal cortex (stage 3); insular cortex, ventral striatum, basal forebrain and inferior temporal cortex (stage 4); substantia nigra, inferior olive and midbrain tectum (stage 5); basal ganglia and middle frontal cortex (stage 6; Josephs et al., 2016). From a clinical perspective, LATE is very similar to AD with patients exhibiting progressive memory loss (Nelson et al., 2019). One study described AD with different neuropathologic subtypes (typical, limbic-predominant, and hippocampal sparing; Murray et al., 2011), and another study suggested the association between pTau and pTDP-43 is important in the limbic-predominant subtype (Latimer et al., 2019). However, compared with AD, LATE most commonly affects individuals of very advanced age and many cases with "end-stage" AD neuropathologic changes (ADNC) disease actually lack TDP-43 proteinopathy (Nelson et al., 2019). The current definition of LATE-NC includes cases without ADNC and the subtypes of AD brought by Murray et al. (2011) may refer in part to cases of LATE. Despite this, TDP-43

can comorbid amyloid- $\beta$  and various tau pathologies in the context of LATE-NC. Studies have shown that A $\beta$  deposition can increase TDP-43 phosphorylation and cytoplasmic localization, whereas A $\beta$  clearance prevents TDP-43 propagation (Herman et al., 2011). TDP-43 and A $\beta$  can oligomerize to seed the amyloid oligomerization (Fang et al., 2014). TDP-43 inclusions have also been detected within neurons exhibiting NFTs that are distinct from tau-based NFTs, suggesting that TDP-43 can mediate NFT formation either alone or through tau interactions (Amador-Ortiz et al., 2007b). Further studies are needed to explore the relationships and interactions between TDP-43, A $\beta$ , and tau in order to determine whether these interactions can be targeted to mediate therapeutic treatment of AD and LATE.

LATE-NC shows feature reminiscent of FTLN-TDP Type A often related to HS, TMEM and GRN genetic risk factors, and it's necessary to discuss the overlap and differences between these two pathologies. As for differences, LATE-NC was more common in the elderly, associated with more marked neuronal and synaptic loss and with greater reactive gliosis, as well as more corpora amylacea and less cortical atrophy (Amador-Ortiz et al., 2007a). Previous studies found the fragments in LATE and FTLN-TDP TypeA were of no difference (Hasegawa et al., 2008). However, a recent study found that different band patterns of the C-terminal fragments can varied among diseases (Hasegawa et al., 2011).

## THE GENETIC RELATIONSHIP BETWEEN LATE AND TDP-43

Five risk alleles have been identified to be associated with LATE (Nelson et al., 2019). Both GRN and TMEM106B have been found to be linked to the risk of hippocampal sclerosis and TDP-43 proteinopathy in the context of FTLN (Baker et al., 2006; Boeve et al., 2006; Van Deerlin et al., 2010). Therefore FTLN and LATE may show one common pathologic pathway. The key to this pathway is reduced progranulin levels. Progranulin expression plays a modulatory role in tissue damage within the central nervous system (CNS) to suppress excessive immunity-based microglial activation and protecting neurons from reactive oxygen species and proinflammatory cytokines (Sun and Eriksen, 2011). Both GRN and TMEM106B variations can result in reduced progranulin levels, the former through creating null alleles while the latter function in the presence of GRN mutations (Finch et al., 2011; Murray et al., 2014; Nelson et al., 2015). In addition, there are pieces of evidence that TDP-43 can regulate the stability of the GRN mRNA through interacting with its 3'-untranslated region (UTR), thereby regulating progranulin levels (Fontana et al., 2015). The reduced progranulin level has direct neurotrophic and inflammatory response-modulating functions and higher susceptibility for stress, which is found to play a role in TDP-43 processing and increase the vulnerability of specific CA1 neuron populations (Zhang et al., 2007; Hokkanen et al., 2019). When GRN is depleted, this leads to enhanced caspase-3 activation, which may serve as an initiating event mediating TDP-43 cleavage and associated TDP-43 pathology (Guo et al., 2010).

Beyond these key risk genes, other genes such as TARDBP, valosin-containing protein (VCP), and C9ORF72 have been found to be associated with TDP-43 proteinopathy (Pesiridis et al., 2009; Mackenzie et al., 2011; Wilson et al., 2013). However, what if any relationship these genes may have with LATE remains to be determined.

## THE PATHOLOGICAL RELATIONSHIP BETWEEN LATE AND TDP-43

Previous study has described two types of TDP-43 distribution: limbic and diffuse (Amador-Ortiz et al., 2007b). One research found that a 10-year increase in age was associated with a 1.8-fold increase in the odds of limbic-type relative to being TDP-43 negative (Josephs et al., 2014b). Therefore, limbic group corresponds most closely to the stage I–III (Josephs et al., 2016), i.e., typical LATE. From stages I to III, besides the severity of amygdala TDP-43 immunoreactivity increased across the stages, only the hippocampus and entorhinal cortex volumes progressively declined with increasing stage (Josephs et al., 2014a). Hippocampal sclerosis (HpScl) in LATE cases, is frequently asymmetric, progressing along a rostral-caudal gradient compared with HpScl in AD (Nelson et al., 2019). Perhaps, the interaction of TDP-43 and tau could change and aggravate the HpScl in AD. In stage B2 and B3 of NFTs, hippocampal TDP-43 is associated with more rapid atrophy of this region, while a link between higher NFT stage and more rapid hippocampal atrophy was detected for TDP-43 stages of 0 and 1 (Josephs et al., 2017). However, as many other factors can cause HpScl and above half LATE cases without HpScl, it is hard to definitely tell that TDP-43 accelerate HpScl in LATE, more studies are needed to make clear relationships among TDP-43, HpScl and LATE.

TDP-43 pathological findings can also include the presence of abnormal TDP-43 fibrillary inclusions in astrocytes, potentially suggesting that the blood-brain barrier may be compromised in affected individuals (Lin et al., 2009). Meanwhile, TDP-43 inclusion-sensitive neurons have also been found in the limbic lobe (Amador-Ortiz et al., 2007b).

## THE CLINICAL ASSOCIATION BETWEEN LATE AND TDP-43

Both hippocampal sclerosis and TDP-43-associated pathology are increasingly recognized to adversely impact cognition (Dutra et al., 2015), with these two conditions acting in an additive manner to impair cognitive function (Josephs et al., 2014b). As mentioned before, LATE is associated with progressive memory deficits (Nelson et al., 2019), and recent work suggests that TDP-43 pathology must progress to stage 2 prior to these AD-like dementia symptoms being evident (James et al., 2016).

Increased TDP-43 inclusion levels have been linked to decreased global cognition and faster cognitive decline in a linear manner (Wilson et al., 2013). Combined hippocampal sclerosis and TDP-43 pathology have been linked to impairment of global cognition and episodic and semantic memory, while TDP-43 pathology in the absence of hippocampal sclerosis has been

linked only to poorer episodic memory (Lin et al., 2009; Wilson et al., 2013; Nag et al., 2015). Hippocampal sclerosis on its own has been linked to semantic memory deficits (Wilson et al., 2013). One study suggested that subjects with both AD and TDP-43 proteinopathy were more likely to exhibit symptoms of agitation and aggression (Sennik et al., 2017). These results clearly demonstrate that TDP-43 pathology plays a major role in the loss of cognitive function in those of a more advanced age. Moreover, the specific locations of TDP-43 aggregate formation likely impact the associated clinical symptoms. TDP-43 pathology is most frequently evident in the medial temporal lobe, potentially accounting for its clear link with the loss of episodic memory (Wilson et al., 2013). Other studies have also found TDP-43 deposition in the ventral striatum and basal forebrain is linked to poorer performance on memory, language, and executive tests (Josephs et al., 2016).

In all, the symptoms associated with TDP-43-linked pathology depend on the nature of the pathology and the brain regions wherein these aggregates manifest. As such, further studies of the stages and mechanistic basis for TDP-43 progression in the context of pathological and clinical progression are warranted.

## CONCLUDING REMARKS AND FUTURE PROSPECTS

There is increasing recognition of the prevalence and importance of TDP-43-associated neurodegenerative disease in individuals of advanced age. While many of the studies on this topic to date have demonstrated TDP-43 are associated with various diseases, it is unclear for the most part whether this pathology is causative, promote and/or enhance disease, or instead is a consequence of otherwise related pathophysiology. Although the mechanism is not that clear, Methylene blue and dimebon have been found to inhibit aggregation of TDP-43 in cellular models (Arai et al., 2010) and the former has also been shown to inhibit AD-like A $\beta$  and tau aggregation *in vitro* (Wischnik et al., 1996; Taniguchi et al., 2005). Future research should focus on several aspects in order to better understand the TDP-43 and LATE, then to find a potential therapeutic target. There are many ways to be explored, such as the common pathway of the formation of dementia-related protein; the synergy and interaction among A $\beta$ , tau, TDP-43 as well as other related pathological protein; the real role of progranulin in LATE and the mechanism of Methylene blue and dimebon therapy in LATE. In addition, more research is needed to clearly classify the relationship of TDP-43 pathological features with TDP-43 involved regions as well as corresponding clinical syndromes. It is of importance to address the following questions: why pathological change can also present in part of normal individuals? Is it a prediction of people who will develop age-related dementia? As the 35 kDa fragment of TDP-43 caused motor deficits, can LATE cases show motor syndromes in end-stage? No matter TDP-43 is a cause or an effect, what is the upstream or downstream target of TDP-43? Additional elucidation of the role of TDP-43 in ALS and FTLN may shine further light on its role in LATE as well. It is also important that further studies fully

explore clinical neuropathological correlations that may guide the diagnosis and treatment of individuals suffering from age-related dementia.

## AUTHOR CONTRIBUTIONS

GP and LZ conceived and designed the project. LZ and YC wrote the manuscript with inputs from other authors. ML and YW helped to revise the manuscript. All authors reviewed and edited the manuscript and approved the final version of the manuscript.

**Objectives:** Visuospatial dysfunction (VSD) is one of the most important symptoms for the diagnosis of dementia with Lewy bodies (DLB). The aim of this study was to validate a novel VSD questionnaire and determine the cutoff score for the screening for VSD in DLB.

**Methods:** This is a retrospective analysis of data from a project of the History-based Artificial Intelligent Clinical Dementia Diagnostic System (HAICDDS). VSD of non-demented control (NDC), Alzheimer's disease (AD), and DLB participants were analyzed and compared using the visuospatial questionnaire in the HAICDDS (HAI-VSQ), the Draw subscale in the Cognitive Abilities Screening Instrument (CASI-Draw), and the visuospatial subscale in Montreal Cognitive Assessment (MoCA-VS).

**Results:** A total of 440 individuals were studied, including 154 NDC, 229 AD, and 57 DLB participants. Compared to NDC or AD participants, DLB participants showed a higher total score on HAI-VSQ after adjustment for age. Using HAI-VSQ, a cutoff score  $\geq 2$  was useful for the screening for VSD in DLB with a sensitivity of 0.77 and a specificity of 0.94. Compared with CASI-Draw or MoCA-VS, HAI-VSQ was least influenced by gender, age, and education and had the highest correlation with the sum of boxes of the Clinical Dementia Rating scale. After adjustment for age, education, gender, and global cognitive function, HAI-VSQ significantly discriminated DLB from AD and NDC whereas MoCA-VS or CASI-Draw did not.

**Conclusion:** Our study showed that the newly designed simple questionnaire was a practical screening tool for VSD in DLB that can be applied in clinical practice as well as on a registration platform.

**Keywords:** visuospatial dysfunction, Alzheimer's disease, dementia with Lewy bodies, screening tools, cognitive abilities

## INTRODUCTION

Visuospatial dysfunction (VSD) is a common clinical symptom used for the diagnosis of cognitive impairment or dementia due to Alzheimer's disease (AD) (McKhann et al., 2011; Kim et al., 2017). Furthermore, VSD is the central symptom for the diagnosis of dementia with Lewy bodies (DLB) (McKeith et al., 2017). DLB is the second most-common type of degenerative dementia

and previous studies have provided evidence of VSD in patients with DLB (McKeith et al., 2017). Previous studies assessing VSD in patients with dementia revealed several important clinical information with particular relevance for its connection to DLB. For example, salient and initial VSD are essential for the diagnosis of DLB (McKeith et al., 2017). Besides, well-formed, detailed, and complex visual hallucinations (VH) are among the core diagnostic features for DLB and this striking feature starts early in the disease (McKeith et al., 2017). The presence of VSD may also identify patients whose syndrome is driven by DLB rather than by AD pathology (Hamilton et al., 2012). The presence of early and severe VSD increases the likelihood that patients will develop prototypical DLB syndrome (Hamilton et al., 2012). In the early stages of dementia, VSD is more profound in DLB than in AD but memory retrieval deficit is more prominent in AD than in DLB (Yoshizawa et al., 2013). Studies of VSD mainly focused on the clinical performance of perception of locations or objects (Culham et al., 2006). Unlike these types of performance, visuomotor dysfunction manifests in goal-directed or visual-guided behavior and is also regarded as part of the visuospatial system of the brain (Culham et al., 2006). Visuomotor function is compromised in AD compared to normal elderly (Tippett et al., 2007; Galati et al., 2011; Hawkins and Sergio, 2014). Pathophysiological studies of visuomotor dysfunction revealed that reciprocal communication between hippocampal, parietal, and frontal brain regions play an important role in transforming visual-spatial information into goal-directed actions (Galati et al., 2011; Hawkins and Sergio, 2014). Disrupting these connections could affect the skills for activities of daily living (Hawkins and Sergio, 2014). Several studies using visuospatial/visuomotor function tests of the performance of visual recognition, visual discrimination, visual attention, or visuo-perceptive integration in DLB compared to AD revealed that these skills are impaired in DLB compared with AD (Oda et al., 2009; Yamaguchi et al., 2011; Li et al., 2014).

Based on these studies and diagnostic criteria, VSD including impairment of visuomotor skills is important for the diagnosis of dementia including AD and DLB. Therefore, a simple screening tool for VSD would be useful in a clinical setting but VSD assessment in common informant-based dementia assessment tools is still lacking and unable to satisfy the clinical requirements. For example, in the Clinical Dementia Rating (CDR) scale, evaluation of VSD is embedded in the domain of orientation and only a few questions address navigating function (Hamilton et al., 2012) but no question addresses visuomotor function. Impaired visuomotor skills are also important in other domains that are characteristic of DLB or posterior cortical atrophy (PCA) (McKhann et al., 2011; McKeith et al., 2017). Furthermore, frequently-used cognitive screening tests for dementia or cognitive impairment, for example, Mini-Mental Status Examination (MMSE), Cognitive Abilities Screening Instrument (CASI), and Montreal Cognitive Assessment (MoCA), also do not include visuomotor skills (Folstein et al., 1975; Teng et al., 1994; Chen et al., 2016).

To solve this problem, the initial aim of our study was to validate a novel VSD questionnaire that contained frequently-asked questions or common complaints of visuospatial and

visuomotor symptoms obtained from caregivers or patients. In addition, we intended to use the simple questionnaire for investigating different presentations of VSD among the non-demented (ND) elderly, patients with neurodegenerative disorders including AD, DLB, or other disorders. Furthermore, during the consecutive data collection, the embedded auto-judgment program in the questionnaire continued to revise machine learning techniques to improve the ability of differential diagnosis of severity and subtypes of dementia.

## MATERIALS AND METHODS

This is a sub-study of the History-based Artificial Intelligent Clinical Dementia Diagnostic System (HAICDDS) project which is currently used as a registration platform in the Show Chwan Health System. Before the starting of the study, twenty-six participants with their informants were interviewed by neuropsychologists from 3 centers of the health system and the reproducibility was investigated using the interrater reliability analysis. The results revealed a high intra-class correlation coefficient of 0.830. The detailed procedure of this project was described in our previous reports (Lin et al., 2018; Chiu et al., 2019a,b). In this study, we analyzed the data of individuals with normal cognition (NC), mild cognitive impairment (MCI), and dementia due to DLB or AD.

### Diagnosis of AD or DLB

The diagnosis of DLB was made according to the revised consensus criteria for probable DLB developed by the fourth report of the DLB consortium (McKeith et al., 2017). According to these criteria, at least two of the following core features including fluctuation of cognition, VH, parkinsonism, and REM sleep behavior disorder (RBD) or one core features plus at least one indicative biomarker including abnormal dopamine transporter imaging (DaTabN), abnormal  $^{123}\text{I}$ -metaiodobenzylguanidine (MIBG), and REM sleep without atonia (RSWA) were necessary for the diagnosis of probable DLB. AD patients were diagnosed according to the criteria for probable AD developed by the National Institute on Aging and Alzheimer's Association Workgroup (NIA-AA) (Kim et al., 2017).

### Diagnosis of Non-demented Control (NDC) or Different Stages of Dementia

For the diagnosis of NDC, patients should have NC or MCI. NC was diagnosed with a global CDR (Morris, 1993) score of 0. MCI was diagnosed based on the criteria for MCI of the National Institute on Aging and Alzheimer's Association Workgroup on 2011 (Albert et al., 2011) as a change in cognition with impairment in one or more cognitive domains but no evidence of impairment in social or occupational functioning with a CDR score of 0.5 and the sum of boxes of CDR (CDR-SB) 0.5–4.0 (O'Bryant et al., 2008). The diagnosis of dementia was made according to the criteria for dementia developed by the NIA-AA (Kim et al., 2017). Participants with dementia had impairments in two or more cognitive domains as well as a decline in daily functions (at least one of the domains of community affairs, home

hobbies, and personal care with a CDR  $\geq 0.5$ ). Dementia severity was defined by a global CDR scale. A global CDR score of 0.5, 1, 2, and 3 was defined as very mild, mild, moderate, and severe dementia, respectively (Morris, 1993).

## Procedure of the Study

This is a retrospective analysis of data from the HAICDDS which is currently applied in three centers in Taiwan (two in central Taiwan and one in southern Taiwan). In the database, daily function was assessed using the Instrumental Activities of

Daily Living (IADL) Scale (Lawton and Brody, 1969). Cognitive function was assessed using the Cognitive Abilities Screening Instrument (CASI) (Teng et al., 1994) and the Montreal Cognitive Assessment (MoCA) (Chen et al., 2016). Cognitive tests for all patients were performed by trained neuropsychologists. VSD was assessed using the visuospatial subscale of CASI (CASI-Draw, total score 0–10), of MoCA (MoCA-VS, total score 0–5), and of the HAICDDS (HAI-VSQ, total score 0–12) which includes 7 visuospatial/visuomotor function questions (The original Chinese version of the questionnaire with tentative English translation is shown in **Appendix Table A1**). VSD of NDC, AD, and DLB were analyzed and compared. In performing HAICDDS, informants of the participants were interviewed by a well-trained neuropsychologist and were requested to fill out the original structured questionnaire to determine the severity of dementia or cognitive impairment.

## Statistics

The Chinese version of SPSS 22.0 for Windows (IBM, SPSS Inc., Chicago) was used for statistical analyses. For the determination of cut-off score for the differentiation from DLB to NCD, we want to maximize both the sensitivity and specificity therefore, the Youden's index was applied, which is maximum = sensitivity + specificity – 1. Comparisons of demographic data, neuropsychological tests, sum of boxes of CDR (CDR-SB), IADL, MoCA, MoCA-VS, CASI, CASI-Draw, HAI-VSQ, and sum of score of the Neuropsychiatric Inventory (NPI-sum) (Cummings, 1988) were compared between the different groups and analyzed using independent t-tests or one-way ANOVA with either Bonferroni or Dunnett T3 *post hoc* analysis according to the homogeneity of variance. Gender

Odds ratio (OR) was Adjusted for Age. NDC, Non-demented control, including normal cognition and mild cognitive impairment; AD, Alzheimer's disease; DLB, dementia with Lewy bodies; NA, Not applicable; NS, Non-significance; CDR-SB, Sum of boxes of the Clinical Dementia Rating Scale; HAI-VSQ, Visuospatial function questionnaire in the History-based Artificial Intelligent Clinical Dementia Diagnostic System (HAICDDS); IADL, Instrumental Activities of Daily Living; MoCA, Montreal Cognitive Assessment; CASI, Cognitive Abilities Screening Instrument; NPI, Neuropsychiatric Inventory; VH, Visual hallucinations; RBD, REM sleep behavior disorder; DaTabN\*, Abnormal dopamine transporter imaging among eight ND, 12 AD, and 17 DLB participants.

and DLB clinical features (fluctuation, VH, RBD, Parkinsonism, and abnormal dopamine transporter imaging) (McKeith et al., 2017) were analyzed with the chi-square test. Multivariable risk estimates (OR) for each question in HAI-VSQ, CASI-Draw, and MoCA-VSQ were adjusted for age, gender, education, and cognitive function and compared between AD/NDC, DLB/NDC, and DLB/AD groups. Pearson correlation coefficients were derived between age, education, gender, CDR-SB, IADL, CASI, MoCA, and NPI of the different diagnostic tools for VSD.

Ethical Consideration

The participants were selected from a register-based database of Show Chwan Health System. The study design was retrospective and the data were analyzed anonymously. The Committee for Medical Research Ethics of Show Chwan Memorial Hospital reviewed the project and the Data Inspectorate approved the study.

RESULTS

A total of 440 individuals were studied, including 154 NDC, 229 AD, and 57 DLB participants. One or more visuospatial symptoms were reported in 31.2% of NC, 81.7% of AD, and 91.2% of DLB participants. Mean age of the NDC group ( $71.3 \pm 9.2$ ) was significantly smaller than those of DLB ( $81.3 \pm 7.0$ ) or AD ( $80.2 \pm 7.2$ ) using one-way ANOVA ( $F = 65.58$ ;  $p < 0.001$ ). After adjustment for age, the dementia groups showed impaired responses to all questions compared to the NDC group (all  $p < 0.001$ ). Compared to NDC ( $0.4 \pm 0.6$ ) or AD ( $2.0 \pm 2.2$ ), the DLB ( $3.3 \pm 2.2$ ) group showed significantly increased total score of the HAI-VSQ after adjustment for age (both  $p < 0.001$ ). Using HAI-VSQ, a cutoff score  $\geq 2$  was useful for the discrimination of VSD in DLB and NDC with a sensitivity of 0.77, a specificity of 0.94, and an AUC of 0.91 (Figure 1).

Additionally, the DLB group demonstrated higher CDR-SB, NPI, and Lewy body clinical features, including fluctuation of cognition, VH, Parkinsonism, and RBD after adjustment for age (all  $p < 0.001$ ). The DLB group also demonstrated significant lower IADL, CASI, and MoCA compared to NDC or AD participants after adjustment for age (all  $p < 0.001$ ). Compared to NDC participants, AD patients showed significantly higher CDR-SB, were proportionally more often female, had a significantly higher total score of the HAI-VSQ, NPI, and significantly higher fluctuation after adjustment for age (all  $p < 0.001$ ). The AD patients also demonstrated lower education, IADL, MoCA, and CASI compared to NDC participants (Table 1).

Pearson correlation coefficients between age, education, gender, CDR-SB, IADL, CASI, MoCA, and NPI of different diagnostic tools for VSD are summarized in Table 2. The HAI-VSQ had weak to moderate correlation with MoCA-VS ( $r = -0.380$ ,  $p < 0.001$ ) or CASI-Draw ( $r = -0.467$ ,  $p < 0.001$ ). Furthermore, except for the non-correlation between HAI-VSQ with gender ( $r = -0.026$ ,  $p < 0.341$ ), other parameters were significantly correlated. In contrast to HAI-VSQ, MoCA-VS ( $r = 0.234$ ,  $p < 0.001$ ) and CASI-Draw ( $r = 0.187$ ,  $p < 0.001$ ) were

CDR-SB, Sum of boxes of the Clinical Dementia Rating Scale; IADL, Instrumental Activities of Daily Living; MoCA, Montreal Cognitive Assessment; CASI, Cognitive Abilities Screening Instrument; NPI, Neuropsychiatric Inventory; HAI-VSQ, Sum score of the visuospatial questionnaire in History-based Artificial Intelligent Clinical Dementia Diagnostic System (HAICDDS); MoCA-VS, Visuospatial domain in MoCA; CASI-Draw, Visuospatial domain in CASI.

weakly correlated to gender. Compared to MoCA-VS or CASI-Draw, HAI-VSQ had the lowest correlation with age or education and the highest correlation with CDR-SB.

The comparison of visuospatial subscales in HAI-VSQ, MoCA-VS, and CASI-Draw among NDC, AD, and DLB, the odds ratio (OR) adjusted for age, education, gender, and the cognitive state by CASI total score are summarized in **Table 3**. The HAI-VSQ significantly discriminated DLB from AD or NDC whereas MoCA-VS or CASI-Draw did not.

Visuospatial subscales of HAI-VSQ (A), MoCA-VS (B), and CASI-Draw (C) in different stages of dementia with Lewy bodies (DLB) and non-DLB are summarized in **Figure 2**. Among all participants, significantly increased HAI-VSQ (all  $p < 0.001$ ) and decreased CASI-Draw (all  $p < 0.05$ ) were noted as the severity of dementia increased. MoCA-VS was different in the CDR 0/0.5 stage compared to other stages (all  $p < 0.001$ ). Among DLB participants, HAI-VSQ showed significant differences in CDR 3 vs. CDR 2, CDR 3 vs. CDR 1, CDR 3 vs. CDR 0/0.5, and CDR 2 vs. CDR 0/0.5. CASI-Draw showed significant differences in CDR 0/0.5 vs. CDR 1, CDR 2, and CDR 3. MoCA-VS did not differentiate between any two stages according to CDR. Among non-DLB participants, significantly increased HAI-VSQ (all  $p < 0.001$ ) and decreased CASI-Draw (all  $p < 0.05$ ) were noted as the severity of dementia increased. Except for CDR 2 vs. CDR 3, significantly decreased MoCA-VS (all  $p < 0.005$ ) was noted as the severity of dementia increased.

## DISCUSSION

This study was a sub-study of the HAICDDS project, analyzing and comparing data between NDC, AD, and DLB groups with two main results. First, using HAI-VSQ, a cutoff score  $\geq 2$  discriminates VSD in DLB from NDC with high sensitivity (0.77), specificity (0.94), and AUC (0.91). To provide more objective evidence, we analyzed the correlation of the HAI-VSQ with dopamine transporter imaging among NDC and DLB groups and the result showed a high negative correlation of striatal background ratio (SBR) of dopamine transporter imaging with the HAI-VSQ with correlation coefficient -0.571 and  $p < 0.001$ . These findings have provided additional evidence that the HAI-VSQ has high correlation with DLB because of abnormal dopamine transporter imaging being the indicative biomarker for the diagnosis of DLB. Therefore, we provided a simple tool that can help clinicians to detect DLB more easily at the bedside or in

clinics. Additionally, HAI-VSQ is probably the first informant-based VSD questionnaire that includes not only visuospatial but also visuomotor questions. We found more severe VSD according to the questionnaire in patients with DLB compared to NDC or AD. In this study, one or more visuospatial or visuomotor symptoms were reported in 31.2% of NDC, and 81.7% of AD and 91.2% of DLB patients. In mild stages, symptoms were reported in 74.4% of AD and 80.8% of DLB patients in CDR = 0.5 or 1. These results are consistent with previous studies on VSD that showed common and early symptoms in AD as well as in DLB (Culham et al., 2006; Tippett et al., 2007; Oda et al., 2009; Galati et al., 2011; Yamaguchi et al., 2011; Hamilton et al., 2012; Yoshizawa et al., 2013; Hawkins and Sergio, 2014; Li et al., 2014). More severe VSD in DLB according to the HAI-VSQ compared to AD is also consistent with results from previous studies (Oda et al., 2009; Yamaguchi et al., 2011; Li et al., 2014).

Second, compared to MoCA-VS or CASI-Draw, HAI-VSQ had no correlation with gender and the lowest correlation with age and education. We considered this an important result because the current frequently-used dementia screening tools such as MoCA or CASI are too sensitive to age, gender, culture, and education. Therefore, a large variety of cut-off scores and adjustments are necessary for the screening of dementia or cognitive impairment when using these tools (Lin et al., 2002; Nasreddine et al., 2005; Chen et al., 2016). Furthermore, HAI-VSQ had the highest correlation with CDR-SB which had the highest correlation with dementia severity compared to the MoCA-VS or CASI-Draw scales.

In addition to above-mentioned findings, after adjustment for age, education, gender, and cognitive state by CASI total score, HAI-VSQ was significantly different in DLB patient than in NDC (OR = 4.28,  $p < 0.001$ ) or AD patients (OR = 1.48,  $p < 0.001$ ), and between AD patients and NDC participants (OR = 2.79,  $p < 0.001$ ). MoCA-VS or CASI-Draw showed no significant differences. This finding underlines the clinical applicability of the HAI-VSQ for the discrimination of DLB from AD or NDC and of AD from NDC participants. This also indicates that the information acquired from caregivers may be more useful or at least as useful as the cognitive performance of patients because the caregivers directly face the caring problems which might result in a higher impact of VSD on them.

Finally, we want to address the important issue that commonly-used informant-based questionnaires for the screening of dementia or cognitive impairment from normal elderly including CDR, AD8, or IQCODE are lacking or

**TABLE 3 |** Comparison of visuospatial subscales in HAICDDS (HAI-VSQ), MoCA (MoCA-VS), and CASI (CASI-Draw) among NDC ( $N = 154$ ), AD ( $N = 229$ ), and DLB ( $N = 57$ ) participants.

have only a few questions regarding VSD (Jorm et al., 1991; Morris, 1993; Galvin et al., 2005; Razavi et al., 2014). We are providing a simple informant-based visuospatial questionnaire for the clinical assessment of individuals with dementia. The purpose of our study was not using a

cut-off score for the discrimination of patients with language dysfunction from normal people. Instead, we want to provide an easy way for clinicians to be aware of the visuospatial as well as visuomotor problems of patients with dementia due to AD or DLB.

There are several limitations to this study. First, the questionnaire is an original Taiwanese version. More precise and colloquial translations will be necessary when translating the questionnaire to other language versions although we have preliminarily translated the questionnaire to English. Second, our study was conducted in only three centers in Taiwan and the questionnaire contained only seven questions. The findings of different presentations of VSD may not be generalizable to all individuals with NDC, AD, or DLB. Third, the comparison among different groups in our study was retrospective and cross-sectional. Therefore, a causal relationship between VSD and the underlying pathophysiologies of AD or DLB could not be investigated.

## CONCLUSION

In conclusion, our study showed that similar to our recently published language questionnaire (HAICDDS-Language) (Lin et al., 2018), the informant-based simple questionnaire was a practical screening tool and was more applicable than the visuospatial subscale of MoCA or CASI for the discrimination of NDC, AD, and DLB. We intend to design and validate several dementia-related simple questionnaires and hope that these rapid screening tools can be applied in clinical practice as well as in a registration platform for the screening of VSD as well as other cognitive dysfunctions. A further goal is to implement machine learning techniques to improve the accuracy and efficiency of these questionnaires.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation, to any qualified researcher.

Electroacupuncture Ameliorates  
Cognitive Impairment by Inhibiting  
the JNK Signaling Pathway in a  
Mouse Model of Alzheimer's Disease.  
*Front. Aging Neurosci.* 12:23.  
doi: 10.3389/fnagi.2020.00023

Electroacupuncture (EA) has become popular for its adjustable strength and frequency and easy quantification in the clinic and has demonstrated therapeutic potential for Alzheimer's disease (AD). However, the mechanism remains unknown. Abnormally activated c-Jun N-terminal kinase (JNK) has been closely related to the pathological process of AD. The aim of this study was to investigate the effect of EA on cognitive impairment and the role of the JNK signaling pathway in AD model amyloid precursor protein (APP)/presenilin 1 (PS1) mice. The memory and learning ability of each group was assessed using the Morris Water Maze (MWM). Immunofluorescence, immunohistochemistry and Western blot were performed to measure the expression of APP, JNK, phosphorylated (P-)JNK, mitogen-activated protein kinase 4 (MKK4), MKK7, c-Jun and caspase-3 in hippocampal tissue samples in APP/PS1 mice after EA intervention. Obvious cognitive deficits were observed in the AD model APP/PS1 mice in the MWM test and were associated with JNK signaling pathway activation and APP upregulation. Four weeks of EA significantly ameliorated the cognitive impairments and inhibited JNK signaling pathway activation and APP upregulation. Taken together, the findings demonstrated that EA can reverse cognitive deficits and substantially lower the burden of APP in AD model APP/PS1 mice, at least partially through inhibiting the JNK signaling pathway and regulating apoptosis signals. Therefore, EA may offer an effective alternative therapeutic approach for AD.

**Keywords:** electroacupuncture, Alzheimer's disease, APP/PS1 mice, cognitive impairment, JNK signaling pathway, apoptosis

## INTRODUCTION

Alzheimer's disease (AD), the most common cause of dementia, is a slowly progressive neurodegenerative disease that ultimately leads to impairments in several brain functions, such as learning and memory (McKhann et al., 2011). The patient's ability to live and socialize is severely impaired. The "World Alzheimer Report 2018" noted that is one new dementia patient every three

seconds in the world and that by 2050, there will be 152 million dementia patients worldwide. Therefore, AD has become a significant global social burden (Lozano et al., 2012).

The classic amyloid hypothesis states that the deposition of amyloid  $\beta$  (A $\beta$ ) protein (Morris et al., 1996; Pike et al., 2007), which is generated by  $\beta$ -amyloid precursor protein (APP) cleavage, is the major event in AD pathology. The aggregation of A $\beta$  initiates irreversible neurodegeneration, which leads to neuronal cell damage and even death (Emerit et al., 2004). Studies have shown that dying cells in the brains of AD patients, including neurons, are characterized by apoptosis (Bredesen et al., 2006).

c-Jun N-terminal kinases (JNKs) belong to the family of stress-activated protein kinases (Kim and Choi, 2010). The JNK pathway plays an important role in a variety of physiological and pathological processes that are mainly involved in apoptosis. JNK activation has been identified as a key element responsible for the regulation of apoptosis signals. Studies have shown that the early activation of JNK is always accompanied by neuronal apoptosis induced by the deposition of A $\beta$  in the brain, indicating that activation of the JNK signaling pathway is involved in the deposition of A $\beta$  and its induced neurotoxicity (Lagalwar et al., 2006; Tare et al., 2011; Li G. Q. et al., 2018). Therefore, abnormally activated JNK is closely related to the pathological process of AD (Ramin et al., 2011; Yarza et al., 2016).

Despite the development of diagnostic techniques for AD, effective and safe therapeutic interventions remain to be found. Because of its curative effects and few side effects, acupuncture has been practiced in more than 183 countries and areas. Compared with manual acupuncture (MA), electroacupuncture (EA) has become popular for its adjustable strength, frequency and easy quantification in the clinic (Pan et al., 2017; Li S. et al., 2018). Studies have also shown that the effect of acupuncture on the brain is integrated at multiple levels, and EA is progressively being used in more clinical practices (Sun et al., 2016; Wei et al., 2016; Chang et al., 2017). In recent years, acupuncture has been used for treating AD and reported to have effectiveness in improving cognitive function (Jiang et al., 2015; Cao et al., 2017; Ding et al., 2019). However, the possible mechanism of action of acupuncture or EA on cognition in AD patients remains uncertain, limiting the application of these studies to guide clinical practice. The mechanism of action of acupuncture must be explored.

Therefore, in this study, we investigated the effect of EA, focusing on the JNK pathway, to determine whether there is an important function of EA in the regulation of the JNK pathway and JNK-dependent apoptosis in AD and further elucidate the mechanism of the potential therapeutic effects of EA.

## MATERIALS AND METHODS

### Animals and Experimental Groups

Forty 7-month-old male APP/PS1 mice and ten age- and gender-matched C57BL/6 mice were sourced from Beijing HuaFuKang Biotech [Certificate number: SCXK (Jing) 2014-0004], weighing

$30 \pm 2$  g. The APP/PS1 mice were randomly divided into four groups: the model (AD) group, the model + SP600125 (AD + SP) group, the model + EA (AD + EA) group and the model + EA + SP600125 (AD + SP + EA) group, with ten mice in each group. The C57BL/6 mice served as the normal control (N) group. To avoid outside interference, all mice were housed separately in standard mouse cages under constant temperature ( $23 \pm 2^\circ\text{C}$ ) and constant humidity (40–60%), with free access to water and food. The study was conducted in strict accordance with the Animal Ethics Committee of Beijing University of Chinese Medicine. We made every effort to minimize the suffering of the animals during the experimental procedure. This animal experiment has been approved by Experimental Animal Ethics Committee of the Second Affiliated Hospital of Zhejiang University (No. 2015-084).

## Apparatus and Reagents

Reagents and apparatuses are displayed in **Table 1**.

### Methods of Intervention

EA treatment was performed on the AD + EA and AD + SP + EA groups on the acupuncture points Baihui (GV20) (located on the bregma, midpoint of the linking line of mouse ears), Yintang (GV29) (located in the forehead, the middle depression of the two eyebrows at the medial end), and Shuigou (GV26) (located on the face, at the upper one-third of the philtrum) (**Figure 1**, Tang et al., 2019). Baihui (GV20) and Yintang (GV29) received EA intervention for 20 min, with an intensity of 1 mA and a frequency of 1 Hz, followed by fast pricking of Shuigou (GV26). To immobilize the mice, We have made special bags based on the size of the mice. Ever since the mice crawled inside the bags, two clips would be performed to close the opening back of the bags, which absolutely control and immobilize the mice well. Since the first third of the bags were reticulated, experimental mice could breath properly.

SP600125 was injected intraperitoneally (30 mg/kg) into the AD + SP and AD + SP + EA groups before EA treatment.

**TABLE 1 |** Apparatus and reagents used in this study.

Apparatus	Source	Details
Disposable sterile acupuncture needle	Beijing Zhongyan Taihe Medical Instrument, Co., Ltd	Model: ZYTH2013030504, specification: 0.25 mm $\times$ 13 mm
Electroacupuncture apparatus	Peking University Institute of Science Nerve and Beijing Hua Wei Industrial Development Company	Model: HANS-LH202
Morris water maze	Shanghai Xinruan Information Technology, Co., Ltd	Model: XR-XM101
Image acquisition and analysis software	China Daheng Group, Inc	China Daheng Group, Inc., Beijing Image Vision Technology Branch
SP600125	Sigma-Aldrich, St. Louis, MO, United States	

**FIGURE 1 |** Locations of acupoints we applied in this study. Red points indicate the three governor vessel acupoints respectively: GV20, GV29, and GV26. **(A)**Top views of GV20, GV29, and GV26. **(B)** Locations of GV20, GV29, and GV26.

SP600125 (Sigma-Aldrich, St. Louis, MO, United States) is a JNK pathway blocker and was prepared with 2% dimethyl sulfoxide (DMSO) solvent.

Mice in the N, AD, and AD + SP groups received no EA treatment but were held and bound to ensure an equivalent trial condition. The intervention was performed once every other day for 4 weeks.

### Morris Water Maze (MWM)

Cognitive impairment was assessed using the MWM test, including a training trial and a probe trial to measure memory (D'Hooze and De Deyn, 2001; Vorhees and Williams, 2006). Throughout the training trials, the location of the platform was fixed in the center of the third quadrant (target quadrant) and submerged approximately 1 cm beneath the water surface. The training trial was repeated for five consecutive days. The mice were gently released from the first, second and fourth quadrants, sequentially, in each trial, at an equal distance to the center of the tank. The trial was terminated if the mouse failed to climb onto the platform within 60 s. Spatial acquisition performance was evaluated by assessing the escape latency to reach the platform. A 60-s probe trial was administered 24 h after the last training session. In the probe trial, the platform was removed from the pool, and the mice were placed in the first, second and fourth quadrants, sequentially. The swimming speed, frequency of crossing the platform in the target quadrant (the previous platform location), and percentage of time spent swimming in the third quadrant housing the platform within 60 s were measured by an automated analysis system.

### Sample Collection

Hippocampal sections were isolated and perfused with PBS and 0.2% Triton X-100 and then fixed in 4% paraformaldehyde for 24 h. The left brain sections were rapidly frozen at  $-50^{\circ}\text{C}$  and then transversely cut into 5- $\mu\text{m}$  slices.

In addition, seven mice in each group were anesthetized with chloral hydrate, and the hippocampus was collected. The obtained samples were rapidly frozen in liquid nitrogen and stored at  $-80^{\circ}\text{C}$  until use.

### Immunohistochemistry

Immunohistochemistry was performed on formalin-fixed, paraffin-embedded right brain hippocampal sections using three 5- $\mu\text{m}$  coronal hippocampal sections per mouse. Anti-mitogen-activated protein kinase kinase 7 (MKK7, 1:100) and c-Jun (60A8) rabbit mAb (1:70) were diluted in PBS, and the sections were incubated at  $4^{\circ}\text{C}$  overnight, washed, and then stained with biotinylated secondary antibody for 10 min. Positive expression was detected by staining the sections with DAB (DAB2031, MXB, China) for 10 min. Microscopy (BX53, Olympus, China) was performed, and images were obtained at  $100\times$  and  $400\times$  magnification. Information on the primary antibodies are displayed in Table 2.

### Immunofluorescence

Slices were incubated at  $4^{\circ}\text{C}$  with the anti-APP (1:150), anti-MEK4/MKK4 (1:75) and anti-caspase-3 (1:100) antibodies. After permeabilization and blocking overnight, appropriate secondary antibodies (IgG H&L) were used at a dilution of 1:200. After the sections were washed three times with PBS, they were incubated

with DAPI (C0065, Solarbio, China) for 10 min, followed by live imaging. The hippocampal images were captured and obtained with a confocal laser microscope (FV1000, Olympus, Japan) at 1000 × magnification. Information on the primary antibodies are displayed in **Table 2**.

## Western Blot (WB)

The extracted proteins were separated by electrophoresis with 10% SDS-PAGE. The gel was run at 80 V for 20 min and 120 V for 60 min and then transferred onto PVDF membranes at 4°C and 80 V for 1.5 h. The target proteins APP, P-JNK1/2, MKK4, MKK7, c-Jun and caspase-3 were measured by incubation with the primary antibodies against APP (1:2000), JNK1/2 (1:1000), P-JNK1/2 (1:500), MKK4 (1:2000), p-MKK4(1:500), MKK7 (1:1000), p-MKK7(1:500), c-Jun (1:1000) and caspase-3 (1:1000) at 4°C overnight. After the gels were washed three times with TBST, the corresponding secondary antibody was used at a dilution of 1:2000, 1:2000, 1:1000, 1:2000, 1:1000, 1:2000, 1:2000, 1:1000 or 1:2000, respectively, followed by visualization with an ECL kit (mixed with 1:1, PE0010, Solarbio, China). The exposure was completed in a dark room with a chemiluminescence gel imaging system (C600, Azure Biosystems, United States). Antibodies against GAPDH (primary antibody 1:5000 and secondary antibody 1:100000) were used as internal controls. Quantitative results are expressed as a ratio of target proteins to GAPDH and then compared to all groups to measure relative changes. Information on the primary antibodies are displayed in **Table 2**.

## Statistical Analysis

Statistical analysis was performed using IBM SPSS Statistics 20 software. Two-way ANOVA with repeated measures was used to analyze group differences in the training trial. The results of the probe trial and WB were analyzed by one-way ANOVA, and the least significant difference (LSD) pairwise comparison method was used among groups. Data are expressed as the means ± SD. Statistical significance was set at  $p < 0.05$ , and high statistical significance was set at  $p < 0.01$ .

**TABLE 2 |** Information on the primary antibodies used in this study.

Antibody	Host species	Antibody code	Company
Anti-APP antibody [Y188]	Rabbit	ab32136	Abcam, United Kingdom
Anti-JNK1 + JNK2 (phospho T183 + Y185) antibody	Rabbit	ab4821	Abcam, United Kingdom
Anti-JNK	Rabbit	9252S	CST, United States
Anti-MKK7 [EP1455Y]	Rabbit	ab52618	Abcam, United Kingdom

## RESULTS

### EA Intervention Ameliorates Cognitive Impairment in APP/PS1 Mice

In the MWM training trials, the mice in every group showed a downward trend in escape latency from day 1 to day 5 (**Figures 2A,B**). However, compared with the N group, the AD group showed worse spatial learning performance over all training sessions ( $P < 0.01$ ). Compared with the escape latency of the AD group, the escape latency of the AD + EA and AD + SP + EA groups was lower and significantly lower on days 4 and 5 ( $P < 0.01$ ). Compared with the AD + SP group, the AD + EA and AD + SP + EA groups also showed significantly lower escape latency on day 5 ( $P < 0.01$ ).

In the MWM probe trial on day 6, platform crossing frequency and time spent in quadrant III were tested (**Figures 2C,D**). A higher platform crossing frequency and greater amount of time spent in quadrant III indicate a higher level of memory maintenance. The platform crossing frequency in the AD group was significantly lower than that in the N group ( $P < 0.01$ ). However, compared with the AD group, the AD + EA and AD + SP + EA groups showed a significantly greater number of platform crossings ( $P < 0.01$ ). Furthermore, the AD + EA and AD + SP + EA groups spent more time in quadrant III than the AD + SP group ( $P < 0.01$ ). **Figures 2E–I** shows the representative strategies for searching for the platform of each group. The AD group showed an edge search strategy, suggesting that 7-month APP/PS1 mice displayed obvious impairment in learning and memory. The N group showed a search strategy that was similar to that of the AD + SP, AD + EA and AD + SP + EA groups.

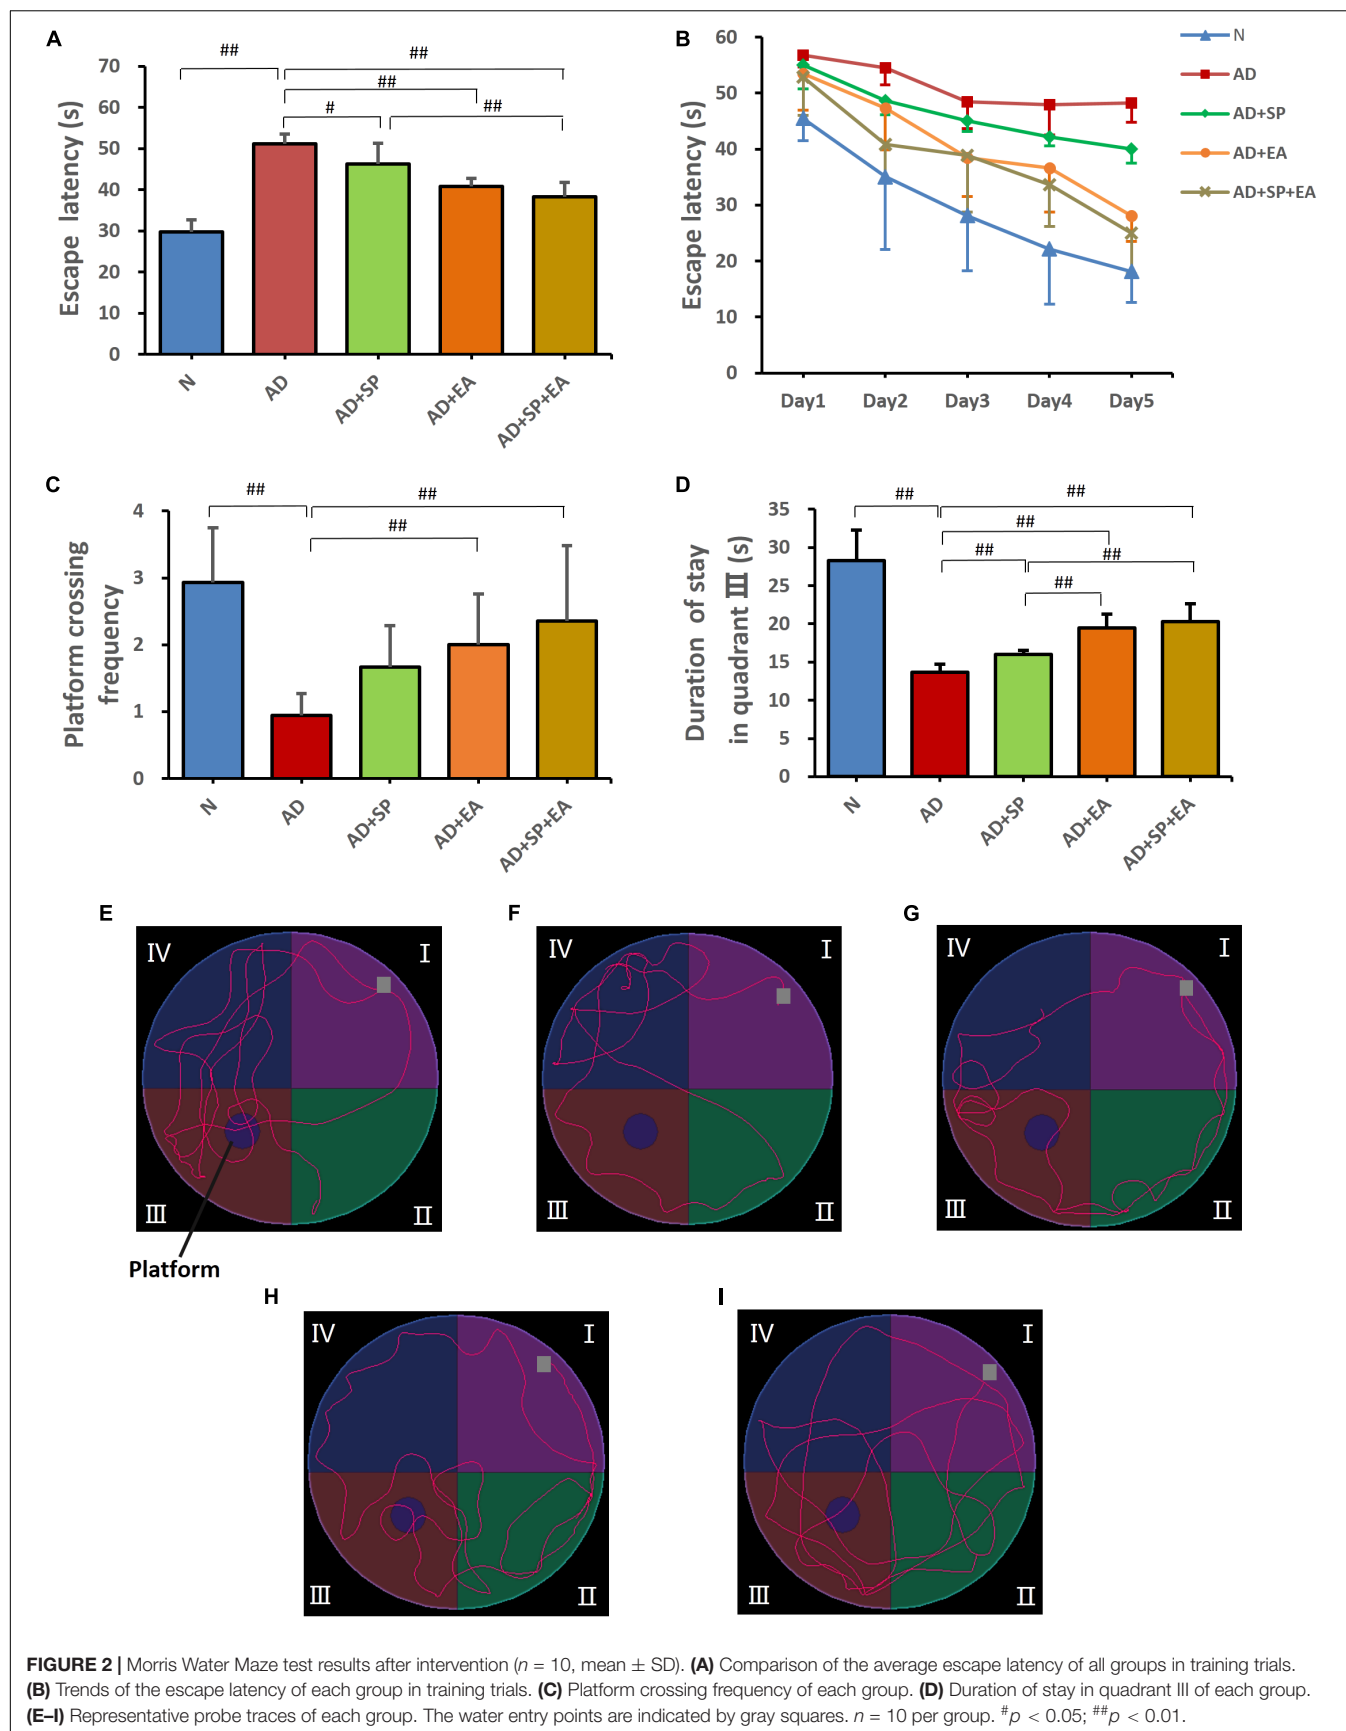

### EA Intervention Lowers the Burden of APP in the Hippocampus of APP/PS1 Mice

We next evaluated the distribution and accumulation of APP in the mouse brain hippocampus by immunofluorescence and WB. Immunofluorescence showed the expression of APP in the hippocampus, with obvious higher expression in the AD group (**Figures 3A–A2,B–B2**) that was decreased in the AD + SP, AD + EA, and AD + SP + EA groups (**Figures 3C–C2,D–D2,E–E2**). WB results showed notably higher accumulation of APP in the AD and AD + SP groups compared to that in the N group ( $P < 0.01$ ), while the AD + EA and AD + SP + EA groups showed lower expression of APP than the AD + SP group ( $P < 0.05$  and  $P < 0.01$ ). Furthermore, the AD + EA and AD + SP + EA groups showed lower expression of APP than the AD + SP group ( $P < 0.05$  and  $P < 0.01$ ) (**Figures 3F,G**). These results confirmed the efficacy of the EA intervention in decreasing the deposition of APP.

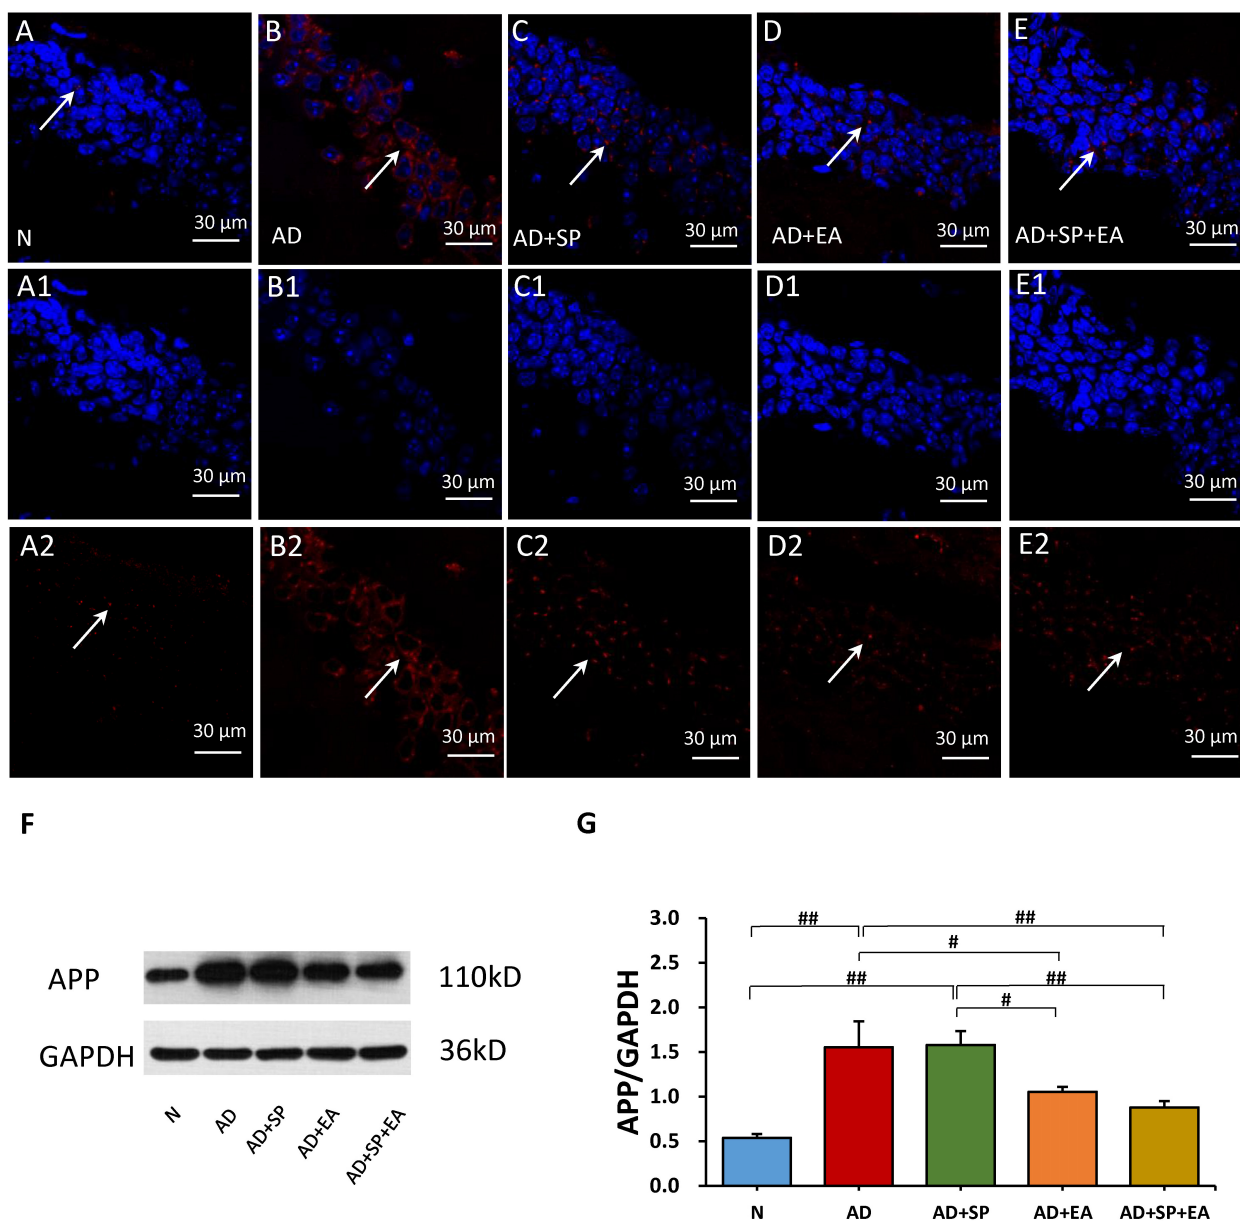

### EA Intervention Inhibits JNK Signaling Pathway Activation in the Hippocampus of APP/PS1 Mice

We hypothesized that the decrease in APP deposition is related to the JNK signal transduction pathway. To test

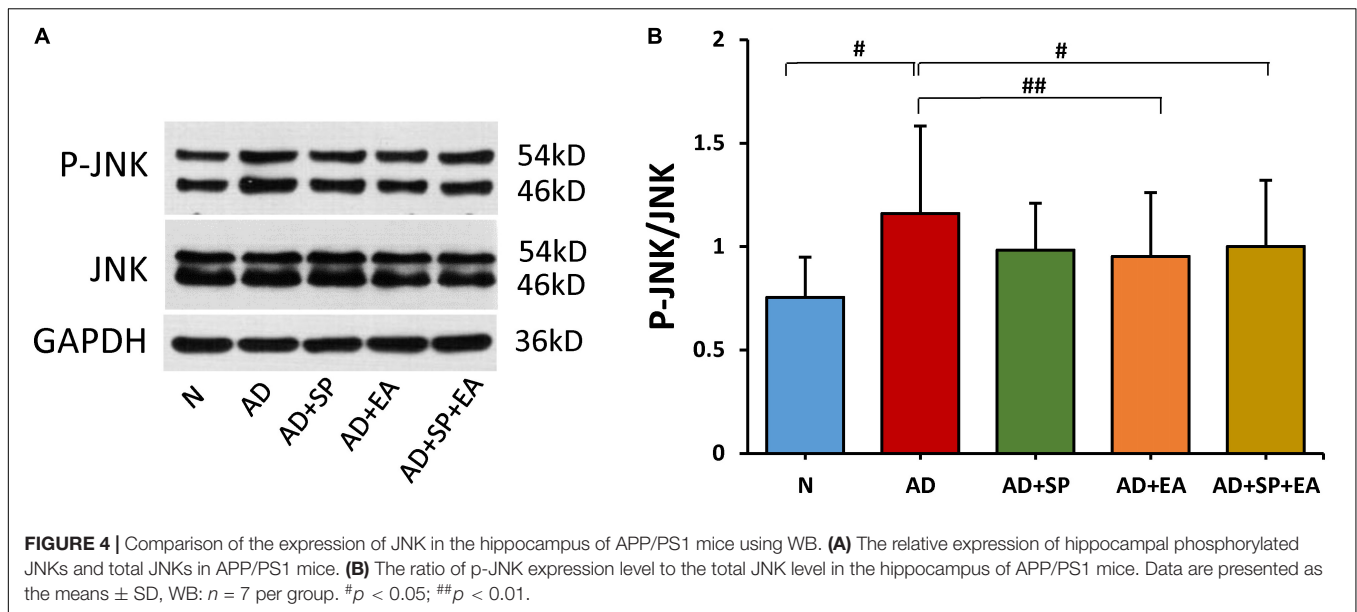

**FIGURE 2 |** Morris Water Maze test results after intervention ( $n = 10$ , mean  $\pm$  SD). **(A)** Comparison of the average escape latency of all groups in training trials. **(B)** Trends of the escape latency of each group in training trials. **(C)** Platform crossing frequency of each group. **(D)** Duration of stay in quadrant III of each group. **(E–I)** Representative probe traces of each group. The water entry points are indicated by gray squares.  $n = 10$  per group.  $^{\#}p < 0.05$ ;  $^{##}p < 0.01$ .

**FIGURE 3 |** Comparison of APP expression in the hippocampus of APP/PS1 mice in each group. **(A–E)** Comparison of APP expression using immunofluorescence. **(A1–E2)** Comparison of APP expression in the square frame of A–E in detail. APP: red; DAPI: blue; White arrows indicate positive expression of APP. **(F,G)** Comparison of APP expression using WB. Data are presented as the means  $\pm$  SD, WB:  $n = 7$  per group, immunofluorescence:  $n = 3$  per group.  $^{\#}p < 0.05$ ;  $^{\#\#}p < 0.01$ .

this possibility, we first detected the expression of JNK by WB. The result shows that the JNK phosphorylation in AD group was increased significantly when compared to N group ( $P < 0.05$ ). Here, decline trend of P-JNK phosphorylation were also seen after SP600125 intervention. However, as compared to AD group, EA resulted in significant reduction in P-JNK phosphorylation in the AD + EA and AD + SP + EA groups ( $P < 0.05$  and  $P < 0.01$ ). The results supported that EA mainly inhibited activation of JNK in AD (Figures 4A,B).

To further confirm the linkage between APP and the JNK signal transduction pathway, we detected the expression of MKK4, MKK7, c-Jun and caspase-3 in the mouse brain hippocampus by immunofluorescence, immunohistochemistry and WB. In the immunohistochemistry and immunofluorescence analyses, MKK4, MKK7, c-Jun and caspase-3 expression was obviously higher in the AD group than in the N group, but this expression decreased after the intervention in the AD + SP, AD + EA and AD + SP + EA groups (Figures 5A–J2, 6A–J2). WB results showed notably higher expression of p-MKK4,

p-MKK7, c-Jun and caspase-3 in the AD group compared to that in the N group ( $P < 0.05$  or  $P < 0.01$ ) (Figures 5K–M, 6K–M). Compared to the expression in the AD group, the expression of p-MKK7, c-Jun in the AD + EA and AD + SP + EA groups was significantly lower ( $P < 0.05$  or  $P < 0.01$ ) (Figures 5K,L, 6K,L). Furthermore, the AD + SP + EA group showed significantly lower expression of MKK7 and c-Jun than the AD + SP group. The results suggested that EA exerts its effects mainly by regulating MKK7 and c-Jun in the JNK pathway.

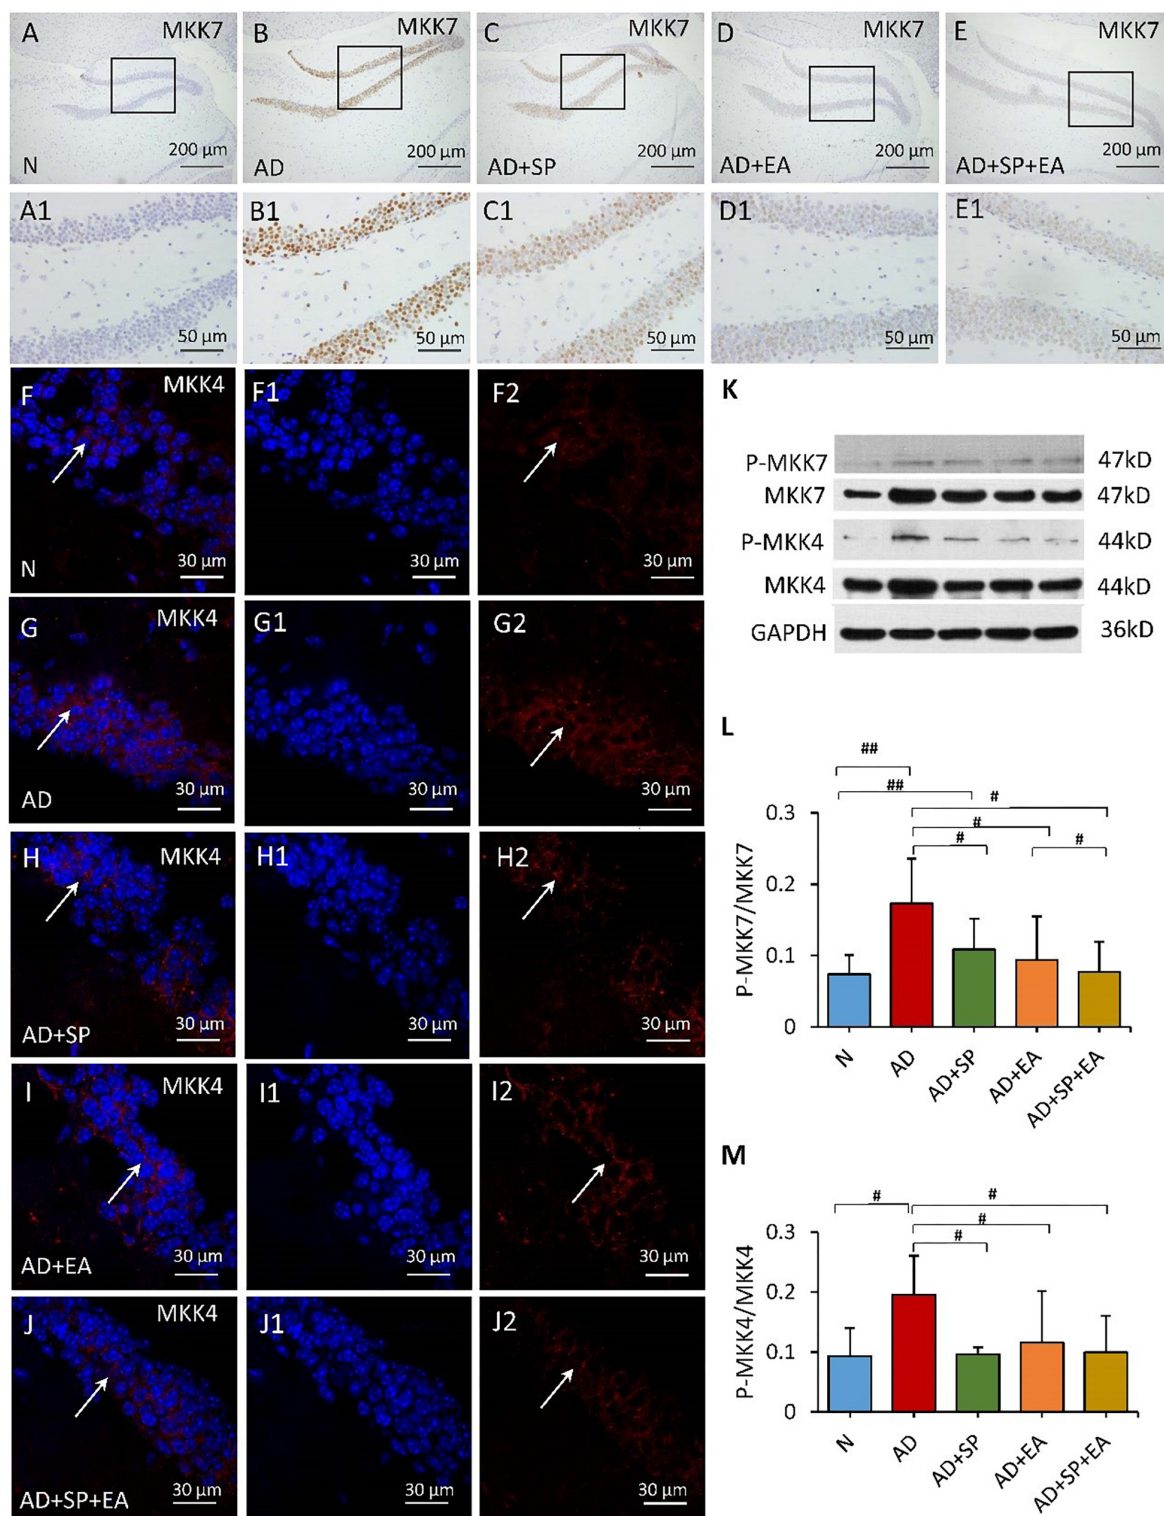

## DISCUSSION

In this study, EA treatment improved the learning and memory ability of AD model APP/PS1 mice, which is consistent with a previous study. EA also inhibited JNK activation and APP accumulation in APP/PS1 mice. The data suggested that EA treatment may effectively improve cognitive impairments in AD, at least partially by inhibiting the JNK signaling pathway.

AD is a multifaceted neurodegenerative disease that is clinically characterized by progressive deterioration of cognitive functions. Increasing evidence points to a pivotal role of the JNK signaling pathway in the development of AD. The JNKs, known as stress-activated protein kinases (SAPKs), belongs to the family of mitogen-activated protein kinases (MAPKs). JNKs are a family of multifunctional signaling molecules that are activated in response to a wide range of cellular stresses and are involved in the regulation of cell proliferation, differentiation and apoptosis (Dhanasekaran and Reddy, 2008). SP600125 is an anthrapyrazolone inhibitor that binds to JNK to inhibit phosphorylation and subsequently blocks the functional activation of JNK. Therefore, the JNK-specific inhibitor SP600125 may potentially reduce JNK activity to prevent neuronal degeneration (Sharma

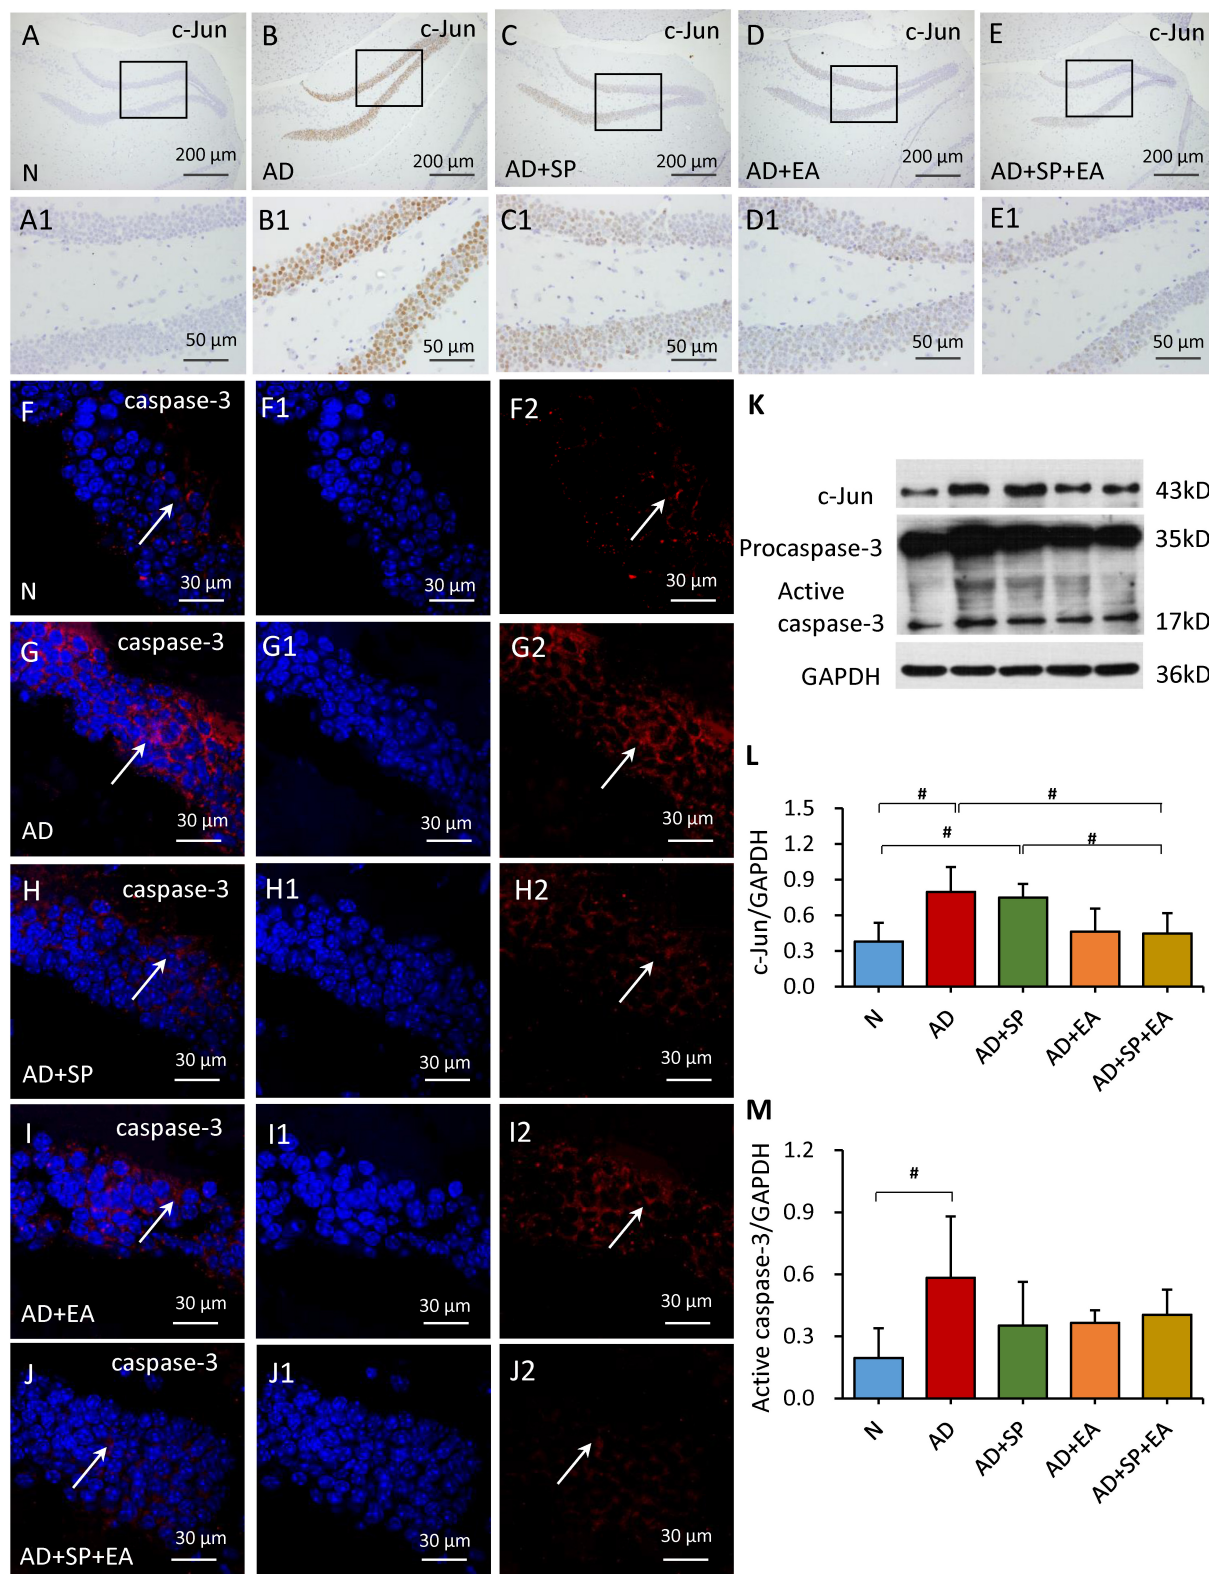

et al., 2010). In the present study, both EA and SP600125 ameliorated cognitive deficits by improving spatial learning and memory. More interestingly, the protective effect was more remarkable when the two interventions were combined. The JNK-specific inhibitor SP600125 may potentially reduce JNK activity to prevent neuronal degeneration (Sclip et al., 2011; Sherrin et al., 2011).

APP plays a pivotal role in the pathophysiology of AD. APP metabolism drives other pathological changes, including the accumulation of A $\beta$ . The accumulation of A $\beta$  plays the most important role in the pathogenesis of AD. The A $\beta$  stimulated microglial inflammatory responses engage MAPK pathways in AD. The major component of AD-associated amyloid-beta load is the 39- to 42-residue-long A $\beta$  peptide. In previous study, our team found that the EA treatment was effective in decreasing the A $\beta$  in AD mice, including A $\beta_{1-40}$  and A $\beta_{1-42}$  in hippocampus, cortex and serum (Wang X. et al., 2016). By reducing APP, it can indirectly reduce the production of A $\beta$  and alleviate the accumulation of A $\beta$ . Thus, therapy that targets APP metabolism is considered to be an effective approach to treat AD. According to our previous studies, EA treatment reduced APP expression by regulating  $\beta$ -site APP-cleaving enzyme 1 (BACE1) in APP/PS1 mice and regulated protein kinase A (PKA) and its associated substrates to change memory and learning abilities (Tang et al., 2019). In the present study, APP expression in the AD + SP group was not significantly different from that in the AD group, but APP expression in the AD + EA group was significantly reduced. Some investigations showed A $\beta$  activated the expression of BACE1 through the JNK pathway (Guglielmotto et al., 2011). BACE1 is an  $\beta$ -secretase, which cleaves the ectodomain of APP. However, the inhibition of JNK activation by SP600125 might decrease the BACE1, resulting in APP accumulation. In addition, SP600125 was injected intraperitoneally in this study, the effect of SP600125 might be weakened by the blood-brain barrier. These results suggest

that EA could promote the curative effect of SP600125. More importantly, the effects of EA might not be entirely mediated through the JNK signaling pathway and that EA effects multiple AD-associated pathways (Colombo et al., 2009; Guglielmotto et al., 2011). Acupuncture may enhance the cognitive function-improving effect of SP600125 in the treatment of AD (Mazzitelli et al., 2011; Zhou et al., 2015).

Numerous studies have reported an increase in the abnormal activation of JNK in both transgenic AD mouse models and AD patients. Indeed, aberrant activation of JNK has been implicated in the pathogenesis of AD (Lagalwar et al., 2006). We also found that the level of P-JNK was significantly higher in APP/PS1 mice. To date, three JNKs have been identified in cells, namely, JNK1, JNK2 and JNK3 (Sherrin et al., 2011; Petrov et al., 2016). Studies have shown unequivocal evidence that JNK1 and JNK2 are involved in apoptotic signaling (Busquets et al., 2019). Studies have also shown that the transcriptional activity promoted by Aβ<sub>1–42</sub> on BACE1 is transmitted by the activation of the JNK pathway. JNK activation regulates the phosphorylation of APP, leading to modulation of Aβ levels (Colombo et al., 2009). In this study, the P-JNK levels declined by varying degrees after the interventions. Notably, compared with SP600125, EA treatment has an significantly inhibitory effect on the activation of JNK, which may be due to the incomplete blocking of the blocker. However, EA works in many ways, which is also the advantage of EA, so its effect is not affected by blockers.

MKK4 and MKK7, two MAPK kinases, are key upstream factors of the JNK signaling pathway located in the cytoplasm. Both MKK4 and MKK7 are capable of dual phosphorylation of JNK and activation of JNK (Nakagawa et al., 2010). MKK4 can activate JNKs as well as p38MAPKs, whereas MKK7 specifically

activates JNKs (Haeusgen et al., 2011). In the present study, the expression of both p-MKK4 and p-MKK7 was greatly increased in APP/PS1 mice, and this increase was responsible for the high level of P-JNK. MKK4 has been reported to be primarily activated by environmental stresses, whereas MKK7 is primarily activated by cytokines. In addition, MKK7 is the only MKK containing three motifs within its regulatory domain (Haeusgen et al., 2010; Kragelj et al., 2015; Wang S. et al., 2016). The three interventions examined here led to substantially reduced MKK4 and MKK7 expression. Notably, EA in APP/PS1 mice significantly reduced the level of MKK7, indicating that EA treatment inhibits JNK through acting on MKK7 expression (Ho et al., 2006).

The JNK signaling pathway involves phosphorylation of c-Jun. JNK is a kinase of c-Jun, a specific transcription factor that promotes c-Jun phosphorylation and activates caspase cascade reactions to initiate cell apoptosis (Nishina et al., 2004). Both c-Jun and caspase are key downstream factors of the JNK signaling pathway (Kim et al., 2005). Studies have confirmed that activation of caspase-3 occurs in Aβ-induced neuronal apoptosis (Chu et al., 2015; Chang et al., 2016). The role of JNK signaling pathway in cell stress response is complex and diverse. Its activation promotes the occurrence of cell apoptosis, and its mechanism is related to the induction of FasL and TNFR1 expression and the activation of caspases family. According to some studies, JNK may be the upstream regulatory molecule of caspase-dependent apoptosis signal transduction pathway, and caspases act as the effector of apoptosis in the downstream of JNK (Choi et al., 1999). On the other hand, caspases can induce JNK phosphorylation by activating upstream protein kinases in the MAPKs pathway, leading to apoptosis (Newhouse et al., 2004). In addition, Caspase-3 has been shown to cleave

APP giving rise to amyloidogenic fragments including A $\beta$  (Gervais et al., 1999). In this study, the expression of both c-Jun and caspase-3 was significantly elevated in APP/PS1 mice, and this increase in expression was due to the high level of JNK phosphorylation and activation. After EA, the level of c-Jun in APP/PS1 mice was greatly reduced. Consistently, previous reports have shown that JNK2 has the highest affinity for c-Jun, as it contains the putative loop region that interacts with the JNK docking site on c-Jun. Furthermore, the level of caspase-3 showed a downward trend with EA treatment. Therefore, we demonstrate that JNK signaling pathway could be involved in anti-apoptotic effect of APP/PS1 mice. The results of this study highlighted that EA combined with the SP-induced (SP600125) could regulate the JNK signaling pathway and inhibit the production of caspase-3 of APP/PS1 mice, indicating the beneficial role of EA in neuron functional reconstruction and reducing the apoptosis. Collectively, our findings, along with previous reports, demonstrate that the inhibition of JNK activation by EA may occur through multiple targets.

In summary, this study provides essential preclinical evidence suggesting that EA reverses cognitive deficits and substantially lowers the burden of APP in AD model APP/PS1 mice, at least partially by inhibiting the JNK signaling pathway and regulating apoptosis signals (Yarza et al., 2016) (Figure 7). In addition, our findings indicated a moderate synergy between the EA and SP600125 interventions in APP/PS1 mice. Collectively, these data suggest that EA is effective at treating AD and may enhance the effect of drugs. Therefore, EA offers an effective alternative therapeutic approach for AD.

Potential pathogenic factors, other than well-known *APP*, *APOE4*, and *PSEN*, can be further identified from transcriptomics studies of differentially expressed genes (DEGs) that are specific for Alzheimer's disease (AD), but findings are often inconsistent or even contradictory. Evidence corroboration by combining meta-analysis and bioinformatics methods may help to resolve existing inconsistencies and contradictions. This study aimed to demonstrate a systematic workflow for evidence synthesis of transcriptomic studies using both meta-analysis and bioinformatics methods to identify potential pathogenic factors. Transcriptomic data were assessed from GEO and ArrayExpress after systematic searches. The DEGs and their dysregulation states from both DNA microarray and RNA sequencing datasets were analyzed and corroborated by meta-analysis. Statistically significant DEGs were used for enrichment analysis based on KEGG and protein-protein interaction network (PPIN) analysis based on STRING. AD-specific modules were further determined by the DIAMOND algorithm, which identifies significant connectivity patterns between specific disease-associated proteins and non-specific proteins. Within AD-specific modules, the nodes of highest degrees (>95th percentile) were considered as potential pathogenic factors. After systematic searches of 225 datasets, extensive meta-analyses among 25 datasets (21 DNA microarray datasets and 4 RNA sequencing datasets) identified 9,298 DEGs. The dysregulated genes and pathways in AD were associated with impaired amyloid- $\beta$  (A $\beta$ ) clearance. From the AD-specific module, Fyn, and EGFR were the most statistically significant and biologically relevant. This meta-analytical study suggested that the reduced A $\beta$  clearance in AD pathogenesis was associated with the genes encoding Fyn and EGFR, which were key receptors in A $\beta$  downstream signaling.

**Keywords:** Alzheimer's disease, meta-analysis, microarray analysis, RNA sequence analysis, bioinformatics

**Abbreviations:** A $\beta$ , amyloid- $\beta$ ; AD, Alzheimer's disease; BBB, blood-brain barrier; CMRgl, cerebral metabolic rate for glucose; DEGs, differentially expressed genes; DIAMOND, DISeAse Module Detection algorithm; eCBs, endocannabinoids; FDR, false discovery rate; IDE, insulin-degrading enzyme; KEGG, Kyoto Encyclopedia of Genes and Genomes; logORs, log<sub>e</sub> odds ratios; PPIN, protein-protein interaction network; PrP<sup>C</sup>, cellular prion protein; ROS, reactive oxygen species; RNA-Seq, RNA-sequencing; T2DM, type 2 diabetes mellitus; UPR, unfolded-protein response; UPS, ubiquitin-proteasome system.

## INTRODUCTION

Alzheimer's disease is a neurodegenerative disease that is the major cause of dementia worldwide (Alzheimer's Association, 2009). The AD brain is characterized by the distribution of amyloid plaques and neurofibrillary tangles, which are composed of A $\beta$  and hyperphosphorylated tau proteins, respectively (Wang and Mandelkow, 2016; Wang J. et al., 2017). The generation of A $\beta$  from amyloid precursor protein (APP) is a central theme in the field of AD. APP is a single transmembrane protein with a large extracellular domain that is generated in large quantities and efficiently metabolized. APP can be processed via non-amyloidogenic or amyloidogenic generation of A $\beta$  (Chow et al., 2010). A $\beta$  mainly exists in two forms, A $\beta$ <sub>40</sub> and a more hydrophobic A $\beta$ <sub>42</sub>, which consist of 40 and 42 amino acids, respectively (Marina et al., 2003). The A $\beta$  monomer is intrinsically disordered, and present as a dynamic conformational structure (Chen et al., 2017), which allows the monomer binds to numerous substrate with a high binding affinity. The monomers of A $\beta$  aggregate into oligomers, fibrils, and plaques, when a critical concentration of amyloid is reached due to dysfunctional homeostasis (Knowles et al., 2014). The soluble A $\beta$  oligomer is recognized as the major neurotoxic species, and exists in an equilibrium with fibrils (Yang et al., 2017). And the toxicity of A $\beta$  oligomers is inversely correlated with their oligomer size (Sengupta et al., 2016). A $\beta$  is directly neurotoxic and induces a series of cellular responses; for example, it can induce excitotoxic signaling by increasing glutamate release (Brito-Moreira et al., 2011), and alter Ca<sup>2+</sup> homeostasis and synaptic functions in neurons, astrocytes, and microglia (Parihar and Brewer, 2010). A $\beta$  located on the mitochondria generates ROS, thus increasing oxidative stress and disrupting oxidative phosphorylation (Caspersen et al., 2005). A $\beta$  also activates protein kinase to phosphorylate tau protein, resulting in the formation of neurofibrillary tangles (Hernández and Avila, 2008). The toxicity of both A $\beta$  and hyperphosphorylated tau proteins are dependent on one another; an absence of tau protein reduces A $\beta$ -induced memory impairment, while increased A $\beta$  levels promote tau pathology (Oddo et al., 2006; Roberson et al., 2007).

The amyloid cascade hypothesis was proposed in 1992, and depicts A $\beta$  as the causative factor in AD development (Hardy and Higgins, 1992). This hypothesis has genetic-based support, because mutations in genes related to A $\beta$  formation (*APP* and *PSEN*) and clearance (*APOE4*) induce early-onset AD (Rovelet-Lecrux et al., 2006; Kline, 2012; St George-Hyslop and Fraser, 2012). However, this hypothesis is challenged by two facts, although there are also counterarguments that have been proposed from other scientific findings. First, amyloid imaging reveals that A $\beta$  deposition also occurs in healthy aging subjects, suggesting that A $\beta$  deposition could be a normal phenomenon of aging (Edison et al., 2007). However, Esparza et al. (2013) suggested that A $\beta$  oligomer levels, which are the neurotoxic form of A $\beta$  deposition, are higher in AD brains compared with healthy subjects. Second, the degree of dementia does not correlate well with amyloid plaque formation in AD (Nelson et al., 2012). In fact, A $\beta$  oligomers may exert their neurotoxic effects much earlier, before the formation of amyloid plaques

(Broersen et al., 2010). Also, the drug development for the treatment of AD has been guided by the amyloid cascade hypothesis for the past two decades, although most anti-A $\beta$  drugs fail in clinical trials and no novel drugs have been brought to market since 2003 (Cummings et al., 2014). For example, Solanezumab (currently in a phase 3 trial) recognizes A $\beta$  at the 13 to 28 amino acid position and lowers amyloid levels, but does not show beneficial effects in subjects with mild AD (Honig et al., 2018). Verubecestat (currently in a phase 3 trial), a  $\beta$ -secretase inhibitor, reduces A $\beta$  levels in a dose-dependent manner (Kennedy et al., 2016). However, a recent clinical trial (Egan et al., 2019) indicated that verubecestat does not have clinical effects in AD subjects. The failure of development of anti-A $\beta$  drugs does not discredit amyloid as the central theme for AD treatment, because the sporadic AD is caused by the changes of genes which potentiate the neurotoxicity of A $\beta$  in the brain over years, rather than solely A $\beta$  overproduction. Indeed, the cerebral A $\beta$ <sub>42</sub> kinetics were modified by A $\beta$  accumulation (Potter et al., 2013), resulting in the disease preventative treatment required at least 95% lowering A $\beta$ <sub>42</sub> production if the treatment was started after A $\beta$  accumulation (Roberts et al., 2017). This suggests that the development of anti-A $\beta$  drugs should not be solely dependent on inhibition of A $\beta$ <sub>42</sub> production. However, the incomplete knowledge of AD pathogenic factors may hindered the investigation of AD (Scott et al., 2014), not just A $\beta$  production, but also the A $\beta$ -relevant receptors and their corresponding downstream signaling cascades.

Alzheimer's disease is a complex disorder, expressed as a malfunction of defects in multiple genes. The discovery of AD pathogenic factors can be revealed by transcriptome profiling approach [i.e., DNA microarray and RNA-Seq (Sutherland et al., 2011)] to identify DEGs in AD subjects compared with healthy subjects. DEGs are genes that are potentially associated with disease pathology. **Table 1** shows the publications using transcriptomic data and bioinformatics tools for identifying AD pathogenic factors. Puthiyedth et al. (2016) identified common DEGs from microarray datasets across six different brain regions. All datasets were integrated using the Colored ( $\alpha$ ,  $\beta$ )- $\kappa$  Feature set approach (Puthiyedth et al., 2015), and a few common DEGs were identified across the brain regions, revealing an AD-specific signature. Kawalia et al. (2017) used the BC3Net10 algorithm to infer AD gene regulatory networks. This network was generated by the integration of literature-based knowledge and data-driven analysis. Inferences did not solely depend on the network topology, but also integrated information about DEGs and AD-related genes, after systematic searching from databases. However, the DEGs obtained from different transcriptomic studies of AD are sometimes conflicting because of many factors, such as the use of different experimental designs or statistical methods between studies. The integration of these studies based on meta-analysis therefore resolves inconclusive results and obtains a generalization (Haidich, 2010). The results of meta-analysis are presented as logORs based on the number of dysregulation events in both disease and control samples. The effect sizes are integrated to assess the overall effect size based on either fixed- or random-effect models. Meta-analysis

R packages and genes are in italic font.

has been applied in genomic analyses to assess the effectiveness of a particular gene in AD. Moradifard et al. (2018) conducted a meta-analysis using the R package *RobustRankAggreg* to identify statistically significant DEGs in AD across six microarray datasets. The DEGs were further corroborated with three RNA-Seq datasets and input for biological enrichment analysis to reveal the miRNAs that regulate the DEGs. Furthermore, Wang Q. et al. (2017) conducted a meta-analysis using the R package *RankProd* to explore the molecular mechanisms of AD across seven microarray datasets. They found 37 DEGs commonly shared by six brain regions, and most of these DEGs were downregulated. The significantly enriched pathways of DEGs were associated with mitochondrial oxidative phosphorylation and synaptic vesicle function. However, both studies only focused on a single microarray platform (Affymetrix), and the meta-analysis of DEGs did not include the gene expression profiles from RNA-Seq. For the study by Moradifard et al., the DEGs from RNA-Seq were only used to validate the results of microarray datasets; that is, the DEGs common to both the RNA-Seq and microarray datasets, in the same dysregulated direction. It seems that the results of currently available meta-analyses of DEGs for identifying AD pathogenic genes are limited by the use of microarray platforms and the inability to integrate results from both microarray and RNA-Seq.

This study aimed to identify potential pathogenic factors based on the meta-analysis of transcriptomic data from different brain regions in AD. The meta-analysis was conducted according to PRISMA guidelines (Moher et al., 2009), including those for

dataset search, dataset selection, and statistical analysis. The raw transcriptomic data were retrieved from databases after a systematic search and were analyzed using a consistent workflow, from quality control and normalization to DEG determination. A statistical meta-analysis was performed when more than one study reported the same DEG. The DEGs that remained statistically significant after *P*-value adjustment were collected to perform a biological enrichment analysis and subgroup analysis, and to construct a PPIN. The network information and AD seed genes, which were obtained from the GWAS Catalog (Welter et al., 2014), were collected for the DISeAse Module Detection (DIAMoND) algorithm (Ghiassian et al., 2015) to examine the significance of the connectivity patterns among network components. This algorithm identified an AD-specific module from the network, and the nodes within the module with a high degree were treated as potential pathogenic factors. The overall study design is illustrated in **Figure 1**.

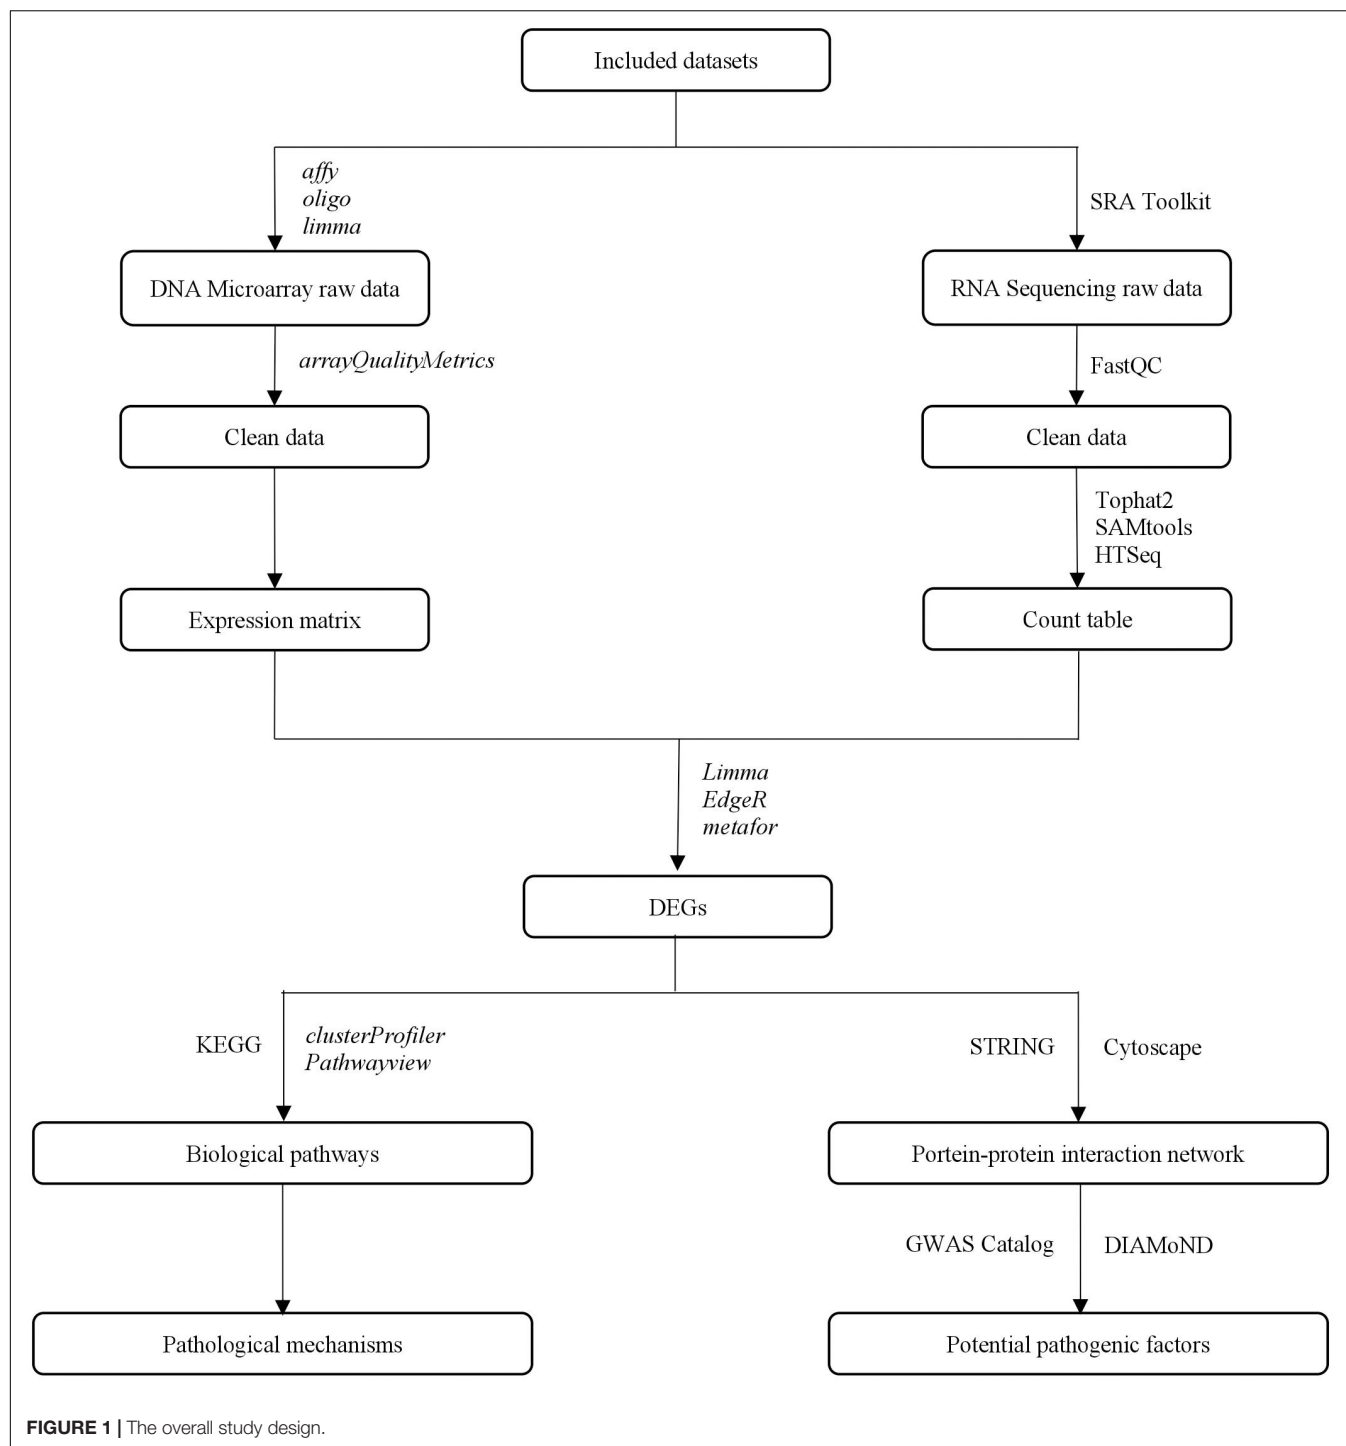

## MATERIALS AND METHODS

### Database Search and Dataset Selection

The datasets were collected from GEO<sup>1</sup> (Barrett et al., 2012) and ArrayExpress<sup>2</sup> (Kolesnikov et al., 2015) from their respective

<sup>1</sup><https://www.ncbi.nlm.nih.gov/geo>

<sup>2</sup><https://www.ebi.ac.uk/arrayexpress/>

**FIGURE 1** | The overall study design.

inception dates until January 6, 2019. The search strategy is shown in **Supplementary File S1**.

Raw DNA microarray and RNA-Seq data reporting the transcriptomes of brain regions from AD and healthy subjects were included. The datasets were excluded if they were (1) not case-control studies; (2) focused on other neurodegenerative diseases; (3) demonstrated treatment effects on AD; or (4) used cell-line or artificial AD models. Sample details were

collected if they were provided. If the datasets contained several comparisons, DEGs were determined from each comparison independently.

## Data Processing

Each microarray dataset was processed consistently and independently using R packages from Bioconductor. Each dataset was processed through background correction, quantile

normalization, and log<sub>2</sub>-transformation of the averaged expression value of duplicate probes, using the *affy* (Gautier et al., 2004), *oligo* (Carvalho and Irizarry, 2010), or *limma* (Ritchie et al., 2015) package. For each dataset, the quality of each array was assessed using the *arrayQualityMetrics* (Kauffmann et al., 2009) package. The array was omitted from the subsequent analysis if it was detected as an outlier in any of the three metrics provided by the package. The gene expression ratios between AD and healthy subjects were determined for each dataset using the *limma* package. Genes with an adjusted *P*-value (by FDR) of less than 0.05 were considered to be statistically significant DEGs. The DEGs were annotated using the gene annotation table provided by GEO and ArrayExpress. The probes with missing gene symbols were removed. When multiple probes were annotated with the same gene symbol on the same array, the probe with the highest expression value was kept.

The raw sequence data were converted to FASTQ format using the SRA Toolkit (version 2.9.2) (Leinonen et al., 2011). Quality control on FASTQ was conducted using FastQC (version 0.11.8) (Andrews, 2010): (1) sequences with less than 80% of bases with at least quality of 25 were filtered; and (2) the bases with quality less than 25 were trimmed. The cleaner FASTQ files were aligned to the *Homo.sapiens* reference genome, GRCh38.94 (downloaded from Ensemble), using TopHat (version 2.1.1) (Kim et al., 2013). The aligned sequences were sorted based on the aligned position to the reference genome using SAMtools (version 1.9) (Li H. et al., 2009). After sorting, the count-based gene expression was obtained using HTSeq (version 0.8.0) (Anders et al., 2015), and the reads with alignment scores less than 10 were omitted. Differential expression was performed using the *edgeR* (Robinson et al., 2009) package for R software. RNA-Seq datasets were processed on a Linux-based HP ProLiant DL580 Gen8 workstation [Inter® Xeon® E7-4820 CPU v2 @ 2.00 GHz; 4 processors with 32 total cores enabled; 128 GB RAM].

## Meta-Analysis, Biological Enrichment Analysis, and Subgroup Analysis

The list of DEGs and their dysregulation states (i.e., upregulated or downregulated) from each study were processed using the *meta* for Chung et al. (2015) package for R software. The meta-analysis was conducted under a random-effects model, and their outcomes were logORs with *P*-values. For each gene in the *i*-th study, the effect ( $\theta_i$ ) based on the numbers of dysregulation events in both AD and control samples was first calculated, then the overall effect was computed according to formula  $\frac{\sum w_i \theta_i}{\sum w_i}$ , where  $w_i$  is the weight and is equal to  $1/v_i$ , where  $v_i$  is the sample variance. The genes with logORs above or below 0 were considered upregulated or downregulated, respectively. The *P*-values were adjusted by FDR, and DEGs with adjusted *P*-values less than 0.05 were regarded as statistically significant. After meta-analysis, the statistically significant DEGs were used to perform a biological enrichment analysis. The enrichment analysis was conducted by the hypergeometric test using the *clusterProfiler* (Yu et al., 2012) package for R software,

based on the KEGG<sup>3</sup> (Kanehisa et al., 2012). The statistically significant DEGs after meta-analysis were collected as input for the enrichment analysis to identify biological pathways among them. The pathways with FDR-adjusted *P*-values less than 0.05 were considered statistically significant.

The DEGs were split into different subgroups based on which brain regions they were from, to compare expression profiles among brain regions. According to Roth et al. (2006), brain regions can be hierarchically clustered into three major branches based on cytological differences. The first branch includes the cerebellum. The second branch is sub-categorized into three sub-branches; the first sub-branch includes the putamen and nucleus accumbens, the second sub-branch includes the amygdala and hippocampus, and the third sub-branch includes the cerebral neocortex. The third branch includes the thalamus, brain stem, and spinal cord. Biological enrichment analysis was also conducted in each subgroup.

## Protein–Protein Interaction Network and Potential Pathogenic Factors

After meta-analysis, statistically significant DEGs were used to construct a PPIN based on the data from STRING (version 11<sup>4</sup>; Szklarczyk et al., 2011). Only interactions with the highest confidence (0.9) were kept. The PPIN was visualized using Cytoscape (Shannon et al., 2003). Disease-associated genes are not topologically interacted into a dense network module because disease can be the consequence of perturbation in many functional units. AD seed genes were retrieved from the GWAS Catalog (Welter et al., 2014)<sup>5</sup> using the key word “AD” and the following selection criteria: a significance *p*-Value cutoff of no more than  $1 \times 10^{-8}$ . Genes with official gene symbols were kept as AD seed genes. The PPIN information (e.g., edge list in the co-expression network) and AD seed genes were put into the DIAMOND algorithm (Ghiassian et al., 2015) to evaluate the significance of the connections that each node had with the seed genes in the biological network. In each iteration until the stopping condition was satisfied, the node with the lowest connectivity *P*-value was treated as the most significantly connected node for output. The nodes within the module that had a high degree (>95th percentile) were treated as potential pathogenic factors.

## Risk of Bias

All studies were collected according to the publication information of datasets. If there was more than one publication for one dataset, the publication with the earlier publication year was selected. The risk of bias for the included studies was evaluated according to MIAME (Minimum information about a microarray experiment) (Brazma, 2009) and MINSEQE (Minimum information about a high-throughput nucleotide sequencing experiment<sup>6</sup>, proposed by FGED Society in 2012) guidelines by two authors (SY and HZ), independently.

<sup>3</sup><http://www.genome.jp/kegg/>

<sup>4</sup><https://string-db.org/>

<sup>5</sup><https://www.ebi.ac.uk/gwas/>

<sup>6</sup><http://fged.org/projects/minseqe/>

Disagreements between the authors were resolved by discussion with the third author (SWL). The MIAME and MINSEQE guidelines are designated to report the quality of DNA microarray and RNA-Seq studies, respectively. And the quality of transcriptomic parts of included studies was assessed, including raw data collection, result presentation, sample annotation, experimental design, array annotation, and data processing pipeline. Items with low risk were counted +1, suggesting high reproducibility; items with unclear risk were counted 0, suggesting ambiguous reproducibility; and items with high risk were counted -1, suggesting low reproducibility.

## RESULTS

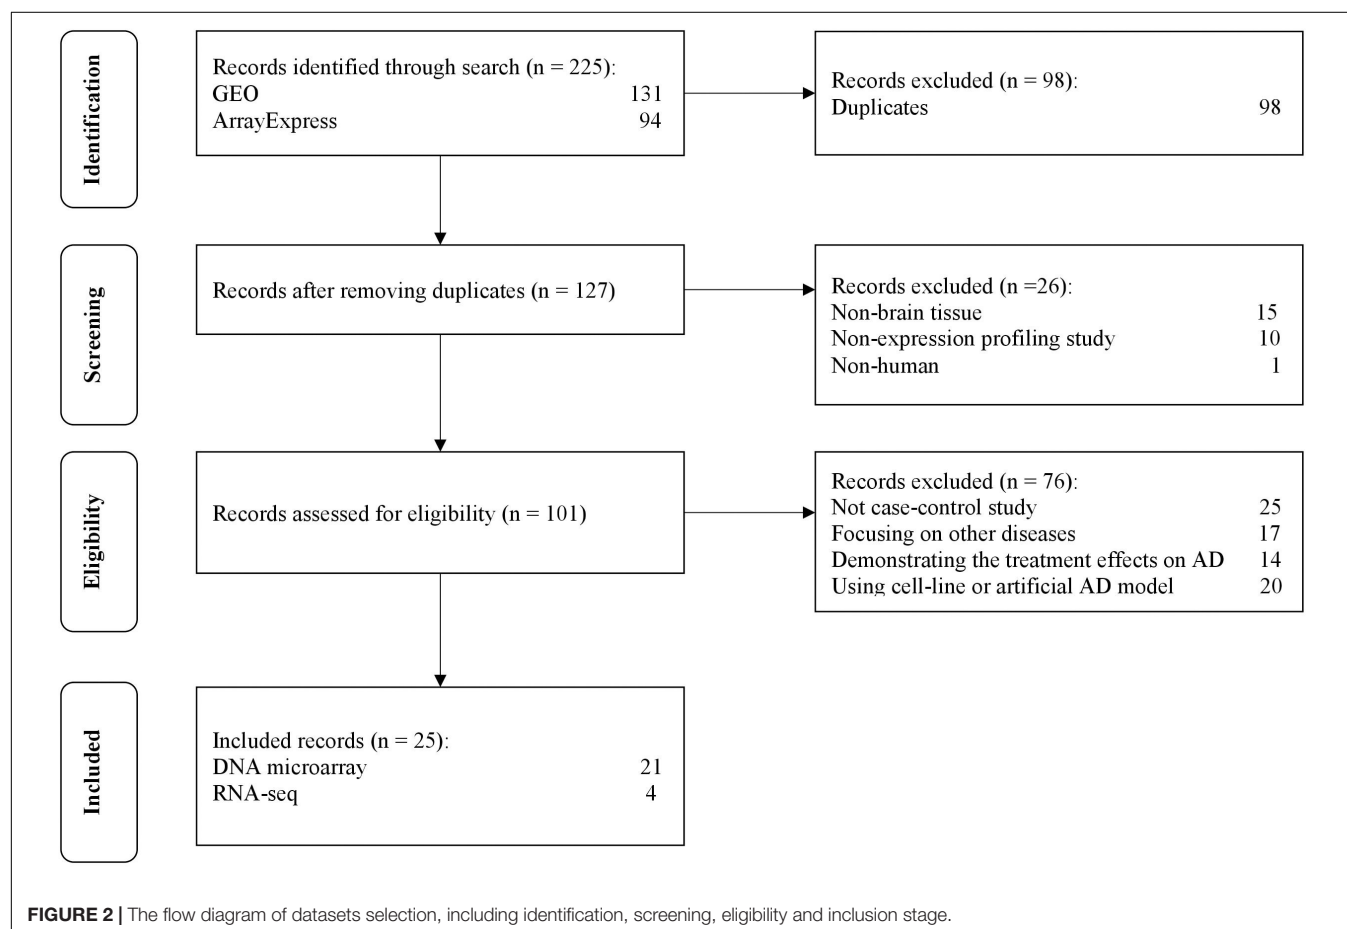

### Included Datasets

The selection process of the datasets is shown in **Figure 2**. A total of 225 datasets were initially identified from GEO and ArrayExpress. After removing duplicated datasets and datasets that met the exclusion criteria, 25 datasets (21 for microarray and 4 for RNA-Seq) met the eligibility criteria. The dataset characteristics are shown in **Table 2**. Among the included datasets, the hippocampus ( $n = 8$ ) was the most extensively

studied brain region, followed by the entorhinal cortex and prefrontal cortex ( $n = 3$ ).

### Preprocessing of Datasets and Determination of Differentially Expressed Genes

After the selection process of the datasets, all included datasets contained complete transcriptomic raw data, and were undergone a quality control as a prioritization procedure. In the included microarray datasets, the quality of the normalized dataset was assessed using the R package *arrayQualityMetrics*. Different numbers of arrays were identified as outliers and omitted in the subsequent analysis (**Table 2**). In the included RNA-Seq datasets, the reads were mapped to the *Homo.sapiens* reference genome (GRCh38.94) after sequence quality assessment. The mapping rates were above 95% for the RNA-Seq datasets. From the mapped reads, the genes were counted to determine DEGs. After preprocessing steps, different numbers of DEGs were determined from each comparison, ranging from 0 to over 10,000 (**Table 3**). There were 21,064 DEGs in all comparisons that compared AD brain samples with healthy brain samples, and 16,810 DEGs (79.76%) were reported in at least two comparisons (**Supplementary File S2**). In the meta-analysis of DEGs, 9,298 DEGs were found to be

statistically significant (**Supplementary File S3**); 4,960 genes were downregulated and 4,338 genes were upregulated. The most reported downregulated DEGs were *DPP6* and *FXYD7*, which were reported in 16 comparisons; *RHOQ* was the most reported upregulated DEG among all 15 reported comparisons. A loss of *DPP6* or *FXYD7* is reported to dysregulate neuronal excitation (Hoos et al., 2013; Cacace et al., 2019), while *RHOQ* is reported to enhance A $\beta$  oligomerization (Aguilar et al., 2017). Multiple DEGs involved in A $\beta$  clearance were found statistically significant in meta-analysis (**Table 4**). These DEGs could be categorized into UPS, autophagy, and UPR, implying the downregulated A $\beta$  clearance. The statistically significant DEGs in UPS and autophagy were mostly downregulated, while those in UPR were mostly upregulated, proposing a dysfunctional homeostasis. The impaired A $\beta$  clearance resulting from dysfunctional homeostasis is suggested to induce A $\beta$  accumulation in sporadic AD, in contrast with the overproduction of A $\beta$  in familial AD (Mawuenyega et al., 2010; Potter et al., 2013).

However, several genes involved in A $\beta$  clearance were not found statistically significant in meta-analysis, although they were reported as DEGs in separated comparisons. The heat shock proteins work coordinately with UPS for protein clearance,

remodeling the misfolded proteins before the degradation by UPS. Both systems are upregulated to restore dysfunctional homeostasis at the beginning (Kästle and Grune, 2012). However, the genes for most heat shock proteins, such as *ATXN1*, *ATXN3*, and *ATXN7*, were not statistically significant (**Supplementary File S3**), suggesting that the early event of AD might not be truly reflected. *PICALM* and *SQSTM1* which are involved in autophagosome formation (Moreau et al., 2014; Ntsapi and Loos, 2016), were not reported as DEGs in the meta-analysis. Several autophagic marker genes, *MAP1LC3B* and *ATG12*, associated with autophagosomal function (Ma et al., 2010), were also found as a statistically insignificant in the meta-analysis. The expression of *TREM2* was upregulated, which was contradictory to the role of *TREM2* reported in autophagy (Lucin et al., 2013), but consistent with that reported in A $\beta$  plaque-activated microglia (Yuan et al., 2016; Yin et al., 2017). Meanwhile, those genes involved in A $\beta$  plaque-activated microglia, *MS4A4A*, *PLCG2*, and *ABI3*, were also found significantly upregulated in the meta-analysis.

On the enrichment analysis, AD itself was identified as significant (**Figure 3A**). In the AD pathway, components related to the mitochondrial respiratory chain were downregulated,

while components related to  $\text{Ca}^{2+}$  channels that transport  $\text{Ca}^{2+}$  from the ER into the cytoplasm were upregulated (**Figure 3B**). Several AD-related pathways, including proteasome, oxidative phosphorylation, and retrograde endocannabinoid signaling pathways, were also identified as statistically significant; most components in these pathways were downregulated (**Figures 3C–E**). Downregulation of the proteasome decreases the clearance of  $\text{A}\beta$  (Hong et al., 2014), while downregulation of oxidative phosphorylation decreases the efficacy of the mitochondrial respiratory chain, suggesting hypometabolism in the AD brain (Mosconi et al., 2008). The genes (e.g., *MFN1*, *OPA1*, and *DNM1L*) involved in mitochondrial fusion and fission were downregulated (Westermann, 2012), disturbing mitochondrial biogenesis to adopt energetic demands. The aberrant mitochondria were removed by the process, mitophagy. However, the genes responsible for mitophagy, *PINK1* and *PRKN* (Narendra et al., 2008), were downregulated, which further increased the burden of damaged protein clearance. The regulation of genes involved in oxidative phosphorylation in mitochondria was severely impaired in the present study, including genes for NADH dehydrogenase, succinate dehydrogenase, cytochrome *c* reductase, and cytochrome *c* oxidase in the electron transport chain. eCBs are signaling molecules used among nearby cells over short distances, and they modulate neuronal transmission. There is a high density of cannabinoid receptors in presynaptic terminals

in the hippocampus and limbic cortex, indicating a role for cannabinoids in cognitive information processing (Zou and Kumar, 2018). A disruption of eCB signaling has been reported in AD, which influences neurotransmitter release (Basavarajappa et al., 2017). In the current study, most members of the retrograde endocannabinoid signaling pathway were downregulated, interfering with the role of eCBs in the release of glutamate and GABA in synapses.

## Subgroup Analysis

Among 77 comparisons, 15 investigated the amygdala and hippocampus of AD subjects, while 28 focused on the cerebral cortex (Table 5). Statistically significant DEGs for each subgroup analysis are shown in **Supplementary File S4**. There were 2,260 DEGs that were reported as significant in the amygdala and hippocampus, while 6,636 DEGs were reported as significant in the cerebral cortex. Among the 1,390 commonly found DEGs, 359 upregulated and 1,020 downregulated DEGs were consistently found in two subgroups. Eleven DEGs were upregulated in one subgroup but downregulated in another subgroup. The most highly upregulated and downregulated DEGs were *S100A6* and *STMN4*, respectively, in both subgroups. The protein calcyclin (encoded by *S100A6*) is a calcium-binding protein that is highly expressed in astrocytes surrounding A $\beta$

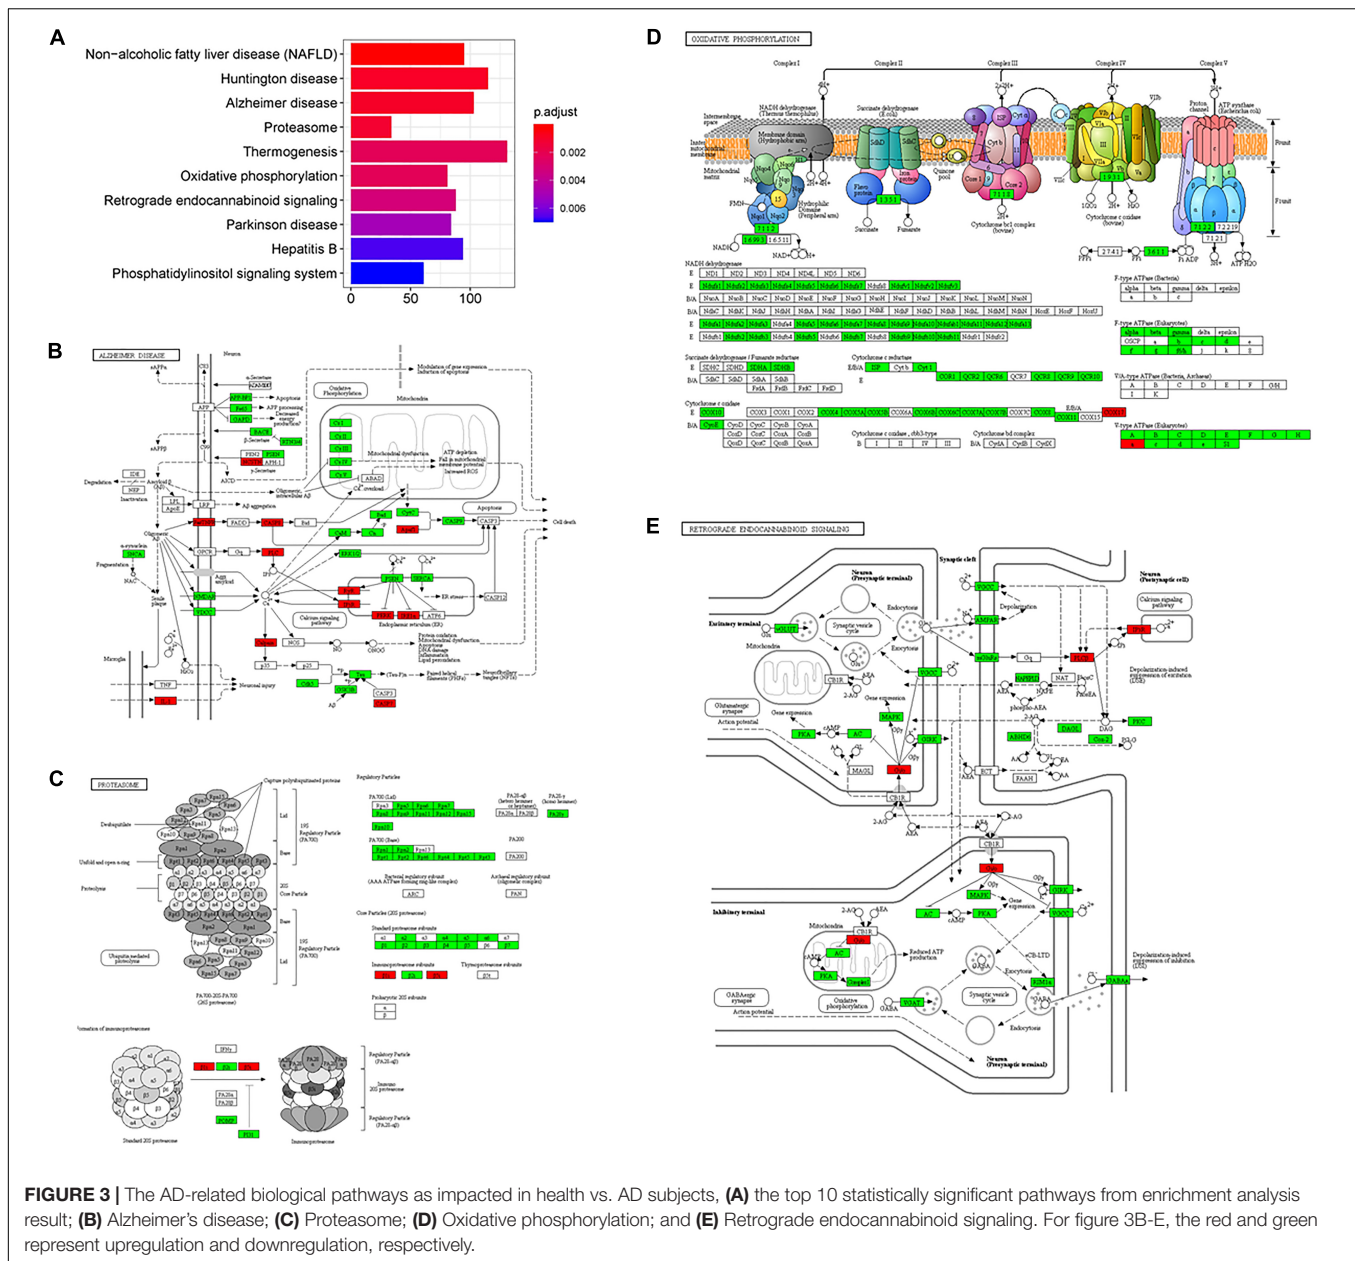

deposits, and is involved in neuronal death via zinc depletion (Bartkowska et al., 2017). The protein stathmin (encoded by *STMN4*) binds tubulin to mediate microtubule dynamics, and dysregulation of stathmin-mediated microtubule stability induces memory loss (Uchida et al., 2014).

In the subgroup enrichment analyses, the pathways for proteasome and retrograde endocannabinoid signaling were found in both subgroups (Figures 4, 5). For the subgroup of the amygdala and hippocampus, the synaptic vesicle cycle was identified as statistically significant, and most components in this pathway were downregulated (Figure 4F). Downregulated synaptic functions decrease the release of neurotransmitters from neurons, inducing memory-related symptoms in AD. For the subgroup of the cerebral cortex, several synaptic signaling pathways were identified in AD, including the MAPK signaling pathway, dopaminergic synapses, and the insulin signaling pathway; the components in these pathways were mostly downregulated (Figures 5D–F). The role of the MAPK effector, JNK, is to dissociate Beclin 1 from Bcl-2 to mediate autophagy, and downregulation of JNK reduces autophagy ability (Zhou et al., 2015). The loss of dopaminergic synapses in the ventral tegmental area reduces the release of dopamine toward the cortex and hippocampus, and is reported to be associated with memory loss in AD before the formation of amyloid plaques (Nobili et al., 2017). Although all AD datasets collected in this study did not report suffering from T2DM, the dysfunctional insulin signaling was identified, suggesting an effect of A $\beta$  in insulin signaling pathway. A $\beta$  shares a common sequence with insulin, antagonizing the regulatory effects of insulin (Folch et al., 2018). In the canonical insulin signaling pathway, insulin binds receptors to activate Akt for mediating downstream effects, e.g., translocating glucose receptors to cellular membrane, activating mTOR for autophagy regulation, and inhibiting GSK3 $\beta$  for tau protein phosphorylation. Losing the regulatory effects of insulin may induce dysfunctional autophagy and tau protein hyperphosphorylation, potentiating AD development. The increased level of free insulin due to A $\beta$  blockage reduces A $\beta$  clearance via IDE, because insulin has a higher affinity to IDE than A $\beta$  (Farris et al., 2003). On the other hand, the AD progression reduces the transport of insulin across BBB, decreasing insulin signaling in brain (Stanley et al., 2016).

In the present study, several datasets focused on the hippocampus and entorhinal cortex because these two regions suffer the most significant neuronal loss in the early stage of AD, while no significant neuronal loss is observed in these regions during normal aging. The transcriptome from these brain regions therefore represents the chronic response to the causes and consequences, or the treatment, of AD.

## Quality Assessment of Studies

MIAME and MINSEQE guidelines were used to assess the transcriptomic analysis of studies (Blalock et al., 2004, 2011; Liang et al., 2007; Berchtold et al., 2008; Bronner et al., 2009; Williams et al., 2009; Nunez-Iglesias et al., 2010; Tan et al., 2010; Durrenberger et al., 2012; Antonell et al., 2013; Fischer et al., 2013; Janssen et al., 2013; Miller et al., 2013; Zhang et al., 2013; Hokama et al., 2014; Narayanan et al., 2014; Magistri

**FIGURE 3 |** The AD-related biological pathways as impacted in health vs. AD subjects, **(A)** the top 10 statistically significant pathways from enrichment analysis result; **(B)** Alzheimer's disease; **(C)** Proteasome; **(D)** Oxidative phosphorylation; and **(E)** Retrograde endocannabinoid signaling. For figure 3B-E, the red and green represent upregulation and downregulation, respectively.

et al., 2015; Scheckel et al., 2016; Wang et al., 2016; Lachen-Montes et al., 2017; Friedman et al., 2018; Nativio et al., 2018; Stopa et al., 2018) that published the datasets that were used in the present study. The results of quality assessments are shown in **Figure 6**. Among the 19 studies that published the microarray datasets, 80% did not provide the brain sample size or the weight used for RNA extraction for sample annotation and experimental variables, and only two studies provided sufficient information about experimental design, including quality control of samples. Furthermore, the annotations of array designs, including microarray quality indicators, were not fully reported for most studies (95%). For 40% of the studies, experimental and data processing details, including normalization methods and cut-offs for DEGs, were not fully reported. Among the four

studies that published the RNA-Seq datasets, no study provided the brain sample size or the weight used for RNA extraction, or the details of experimental parameters used for RNA-Seq procedures. Furthermore, half of the studies did not provide sufficient information about experimental and data processing protocols, including the cut-offs for DEGs.

The relatively low quality of the studies indicates the insufficient information related to transcriptomic analysis provided in the studies, raising the reproducibility issue. Also, the transcriptomic results might be influenced, blurring some pathological events in the postmortem AD brains. The genes encoded heat shock proteins (e.g., *ATXN1*, *ATXN3*, and *ATXN7*) were not found statistically significant in the meta-analysis, while the multiple genes involved in neuroinflammation (e.g., *CXCL3*,

*IFNG*, *IL6*, *IL13*, and *CXCL9*) (Garwood et al., 2011) were only reported as DEGs in one dataset, and therefore were not collected for meta-analysis. Although both heat shock proteins recruitment and neuroinflammation are associated with AD development, their pathological roles in AD development might not fully reflected in this study.

Construction of a Protein–Protein Interaction Network to Identify Potential Pathogenic Factors

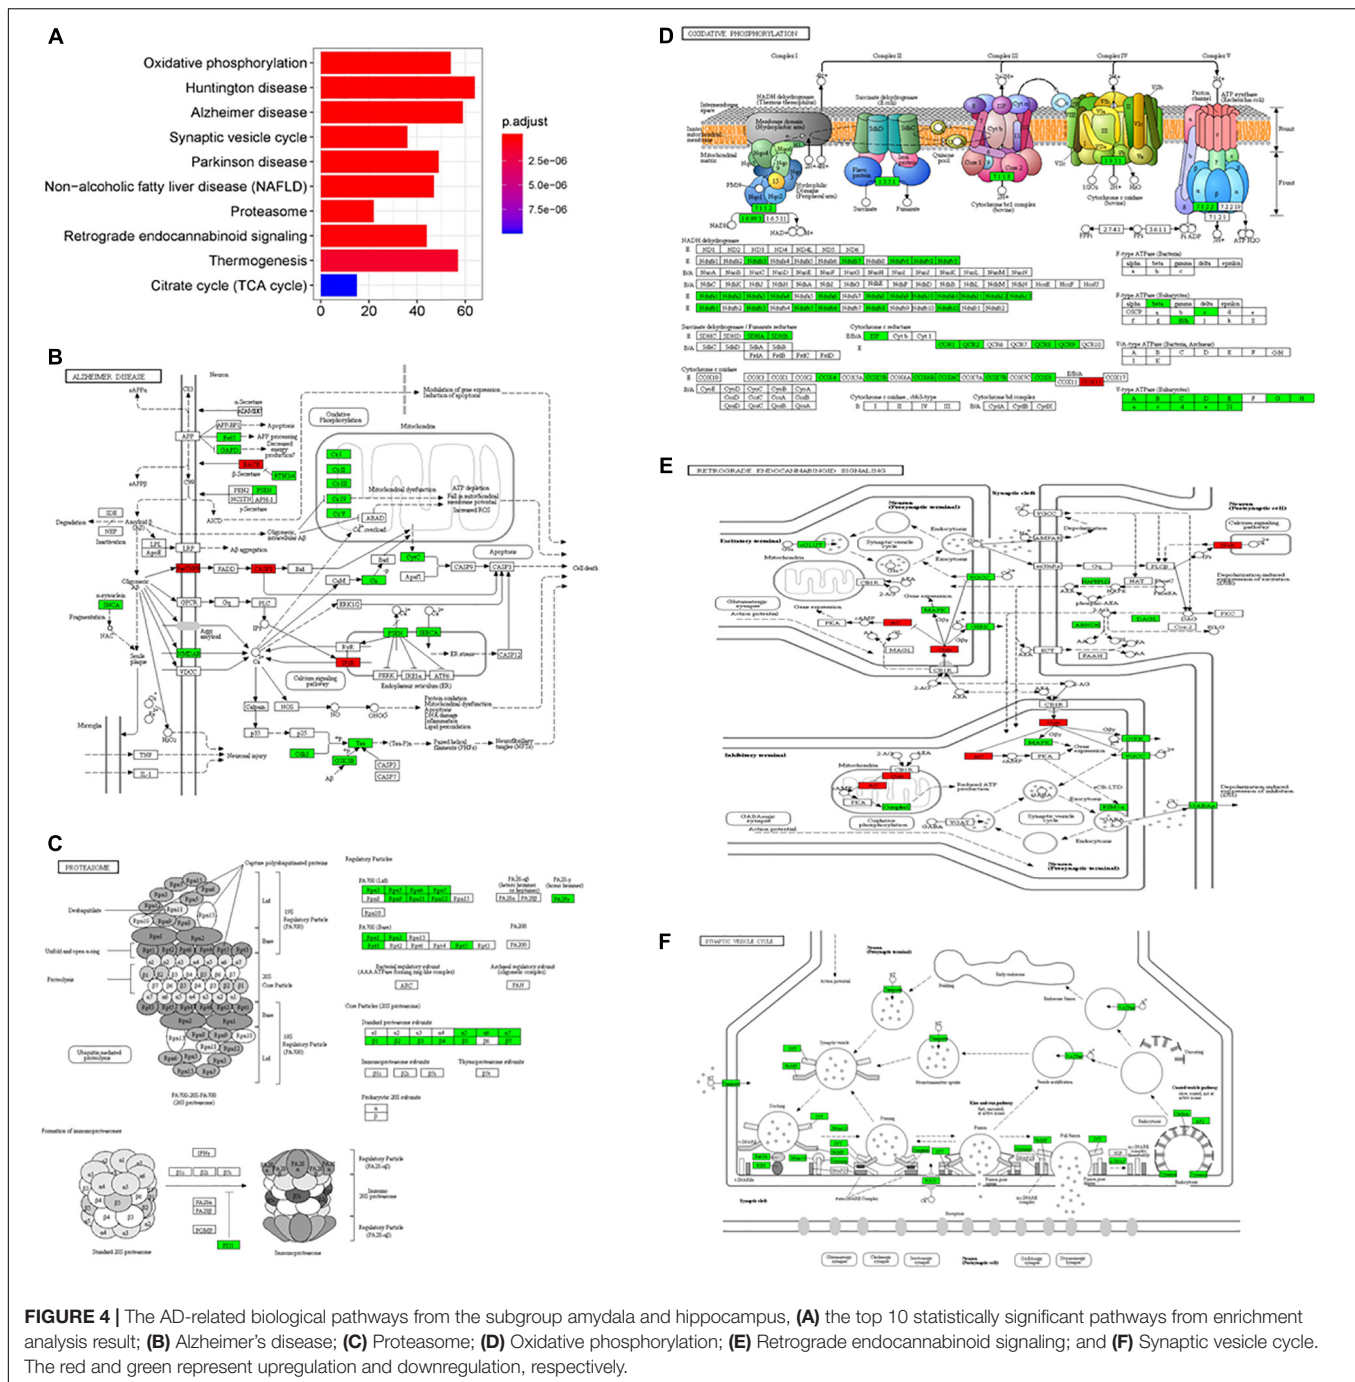

The DEGs from the meta-analysis were used to retrieve the corresponding proteins in interactions according to STRING. The PPIN consisted of 4,781 nodes (2,083 upregulated nodes and 2,698 downregulated nodes) and 51,076 edges (Figure 7A) and there were 105 AD seed genes (Supplementary File S5) retrieved from the GWAS Catalog. The PPIN exhibited scale free topology with the degree distribution following a power law distribution ( $y = 3779.2x^{-1.481}$ ) and the most proteins were closely linked. In the PPIN, polyubiquitin-C (encoded by *UBC*) and E3 ubiquitin-protein ligase RBX1 (encoded by *RBX1*), were the two proteins with the highest degree (372 and 222, respectively). These proteins were downregulated and are parts of UPS for protein degradation. The dysfunctional proteasome is regarded as an early event of AD (Manavalan et al., 2013), e.g., the decreased proteasomal clearance enhances mitochondrial dysfunction (Braun et al., 2015).

The PPIN for each protein pair was extracted for the subsequent DIAMOnD algorithm with AD seed genes to obtain a disease module. Not every seed gene was biologically linked to AD; some were involved in AD comorbidity disease. Among the disease modules (Figure 7B), the two nodes with a high degree (>95th percentile) were selected as potential pathogenic factors, and included EGFR and Fyn. The EGFR was the Aβ oligomer receptor, in which Aβ oligomer is regarded as the causative toxic species. The hydrophobic residues of Aβ oligomers are more easily accessible and interacting with cellular proteins, compared

with Aβ fibrils (William et al., 2011). Fyn is involved in Aβ signal transduction and tau protein phosphorylation, and is changed in synaptic signaling pathways, including MAPK signaling pathway. These two proteins are both Aβ-relevant receptors, mediating the Aβ oligomers downstream neurotoxicity.

DISCUSSION

We used a meta-analysis approach based on DNA microarray and RNA-Seq datasets from multiple brain regions to reveal potential pathogenic factors of AD. Perturbations in the genes involved in the proteasome, oxidative phosphorylation, and retrograde endocannabinoid signaling pathways were identified. The proteasome is required to degrade the damaged proteins to maintain the cellular functionality. The decreased proteasome activity results in an accumulation of ubiquitinated and damaged proteins (Ciechanover, 2015). The ubiquitination degradation of APP by the proteasome includes several key genes, such as *PRKN*, *NEDD8*, *PSMC1*, *UCHL1*, and *UCHL3* (Bedford et al., 2008; Chen et al., 2012; Zhang et al., 2015; Nomura et al., 2016). Tau-specific ubiquitin–proteasome related genes, including *UBE2D2* (Shimura et al., 2004) and *STUB1* (Saidi et al., 2015), were also downregulated. The downregulation of these genes might result in impaired Aβ and phosphorylated tau protein clearance (Table 4). The oligomeric Aβ itself disrupts the catalytic activity of proteasome (Tseng et al., 2008), forming a positive feedback loop to worsen the Aβ clearance by proteasome. The disrupted catalytic activity of proteasome may also lose its inhibition of presenilin complex, which is the catalytic complex for γ-secretase, enhancing Aβ production (Chadwick et al., 2012). The accumulated Aβ, located on the mitochondria, deleteriously impairs oxidative phosphorylation, decreasing ATP production in the mitochondria (Chen and Du Yan, 2007; Moreira et al., 2010). The ATP-dependent proteins (i.e., the Ca<sup>2+</sup> pumps located on the endoplasmic reticulum (ER) and ATP-dependent ion pumps) are unable to maintain their physiological functions,

The red and green represent upregulation and downregulation, respectively.

interfering neurotransmitter release and memory formation (Sudhof, 2012). The ATP-dependent molecular chaperones are also failed to work coordinately with UPS to remodel the misfolded proteins (Mattoo and Goloubinoff, 2014).

The reduced activity of proteasome enhances the burden of A $\beta$  clearance on the autophagy and UPR. Autophagy is the process of degrading redundant cellular components by delivering them to lysosomes and forming autophagosomes. Beclin 1 (encoded by *BECN1*) is an essential component of autophagosomal structure (Jaeger and Wyss-Coray, 2010), but

its autophagy function is inhibited by interacting with Bcl-2 (encoded by *BCL2*) leading to cellular death (Marquez and Xu, 2012). The downregulation of *BECN1* and upregulation of *BCL2* in the present study indicated autophagic flux failure. Autophagy is inhibited by the upregulation of *mTOR* and activated by the downregulation of *TFEB* (Caccamo et al., 2010; Polito et al., 2014). The downregulation of *mTOR* and upregulation of *TFEB* in the present study induced the formation of immature autophagosomes, impairing A $\beta$  clearance. In addition, the downregulation of *mTOR* is associated with

**FIGURE 6 |** The overall quality assessment for **(A)** 19 studies for DNA microarray and **(B)** 4 studies for RNA-seq. Green color represents low risk of bias, which the authors clearly provided the information with full detail. Yellow color represents unclear risk of bias, which the authors provided the information without full detail. Red color represents high risk of bias, which the authors did not provide the correct information.

The two top pathogenic factors determined in the present study, Fyn and EGFR, are key receptors in A $\beta$  downstream signaling. Fyn is a protein tyrosine kinase belonging to the Src family, and it mediates synaptic plasticity in the central nervous system (Kaufman et al., 2015). The soluble A $\beta$  oligomer binds to PrP<sup>C</sup> with high affinity (Laurén et al., 2009), and interrupts the PrP<sup>C</sup>'s autoinhibitory mechanism (Wu et al., 2017), overactivating Fyn to increase glutamate release (Trepanier et al., 2012). Overactivation of Fyn, however, alters NMDA receptor function and intracellular Ca<sup>2+</sup> homeostasis, rendering neurons vulnerable to A $\beta$ -induced neurotoxicity. The A $\beta$ -activated Fyn can phosphorylate downstream tau proteins at Tyr18 (Lee, 2004), and tau proteins participate in transporting Fyn to post-synaptic densities around glutamate receptors (Ittner et al., 2010). Fyn is a key protein that links between extracellular A $\beta$  and intracellular tau protein, and unites these two pathologies in AD. The activity of Fyn is gene-dose-dependent (Um et al., 2012); that is, downregulation of *FYN* reduces A $\beta$ -induced neurotoxicity, while upregulation of *FYN* exacerbates A $\beta$ -induced neurotoxicity. In

previous studies, overexpression of *FYN* has also been reported to accelerate synaptic loss, making Fyn inhibition a potential therapeutic treatment for AD (Chin et al., 2004; Chin, 2005). Saracatinib (AZD0530) is a Src kinase inhibitor that is being tested clinically for the treatment of AD. Saracatinib blocks Fyn activation to rescue memory deficits, and exhibits well-tolerated effects in mild-to-moderate AD subjects (Nygaard et al., 2015). A recently published clinical trial (VanDyck et al., 2019) revealed that saracatinib does not slow the decline in the CMRgl, and does not exhibit beneficial effects on several cognitive assessments, compared with the placebo group. However, a trend for slowing the reduction of volumetric measure in brain is observed, and a *post hoc* exploratory analysis deduces a statistically significant decline in CMRgl in the entorhinal cortex. Although the frequent adverse event of saracatinib, e.g., diarrhea, may limit the feasibility of increasing 125 mg daily to a higher dosage, the authors proposed that a higher dosage of saracatinib may be beneficial to slow decline of CMRgl in AD participants, who have greater tolerability.

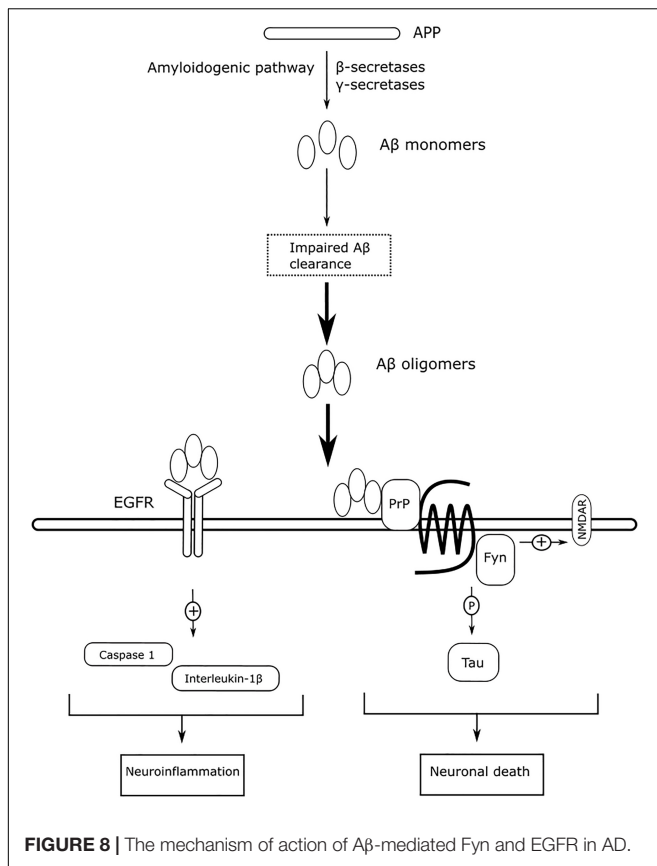

EGFR is more commonly associated with cancer than with AD. However, the expression of EGFR is statistically correlated with the expression of  $\gamma$ -secretase, suggesting a significant role of EGFR in AD (Zhang et al., 2007). EGFR is widely distributed in the hippocampus and cerebral cortex (Fu et al., 2003), and EGFR signaling exerts neurotrophic functions to regulate synaptic architecture in the central nervous system (Oyagi et al., 2011). The expression of *EGFR* is reported to be upregulated in the brains of AD animals, and overactivation of EGFR by A $\beta$  oligomers induces memory loss (Wang et al., 2012). The overactivation of EGFR can also be induced by the prolonged UPR (Papa and Germain, 2011). The levels of overactivated EGFR can be suppressed by treatment with the EGFR inhibitor gefitinib to rescue memory loss. Activation of EGFR also induces downstream neuroinflammatory cascades in response to A $\beta$ -induced neurotoxicity. Afatinib, an orally available EGFR tyrosine kinase inhibitor, inhibits EGFR activation to alleviate neuroinflammation by reducing caspase 1 activation and interleukin-1 $\beta$  levels in neurodegenerative diseases (Chen et al., 2019). Antagonizing A $\beta$ -induced activation of EGFR may have beneficial effects to slow memory loss and alleviate neuroinflammation. **Figure 8** summarizes the mechanism of action of A $\beta$ -mediated Fyn and EGFR in AD, as described above.

Besides the genes involved in A $\beta$  downstream neurotoxicity, the genes related to amyloid clearance proteins (e.g., *ECE1* and *NEU1*) are reported as pathogenic factors of AD by other studies. Endothelin 1 (encoded by *ECE1*) is implicated in A $\beta$  degradation and downregulation of *ECE1* enhances A $\beta$  deposition (Pacheco-Quinto and Eckman, 2013). However, upregulation of *ECE1* was

found in the present study, suggesting that the pathophysiological role of *ECE1* was not solely involved in A $\beta$  metabolism, but also associated with the increase A $\beta$ -induced vasoconstriction in AD (Palmer et al., 2013). Sialidase (encoded by *NEU1*) is a lysosomal enzyme for A $\beta$  clearance through lysosomal exocytosis (Annunziata et al., 2013). Deficit of *NEU1* causes A $\beta$ -induced proteasome inhibition, which was consistent with our results. Disruption of A $\beta$  clearance proteins may be the secondary events of AD progression, rather than the primary cause. Increasing evidences show a correlation between T2DM and higher risk of developing AD, through increasing BBB permeability by chronic peripheral inflammation (Holmes et al., 2009). The BBB leakage was supported by the dysregulated genes in this study, including *OCN*, *TJP1*, *CDH5*, and *CTNBN1*, which encode the tight junction proteins. The compromised BBB can be exacerbated by chronic hypertension (Santos et al., 2017) and microbial pathogens (Li H. et al., 2018), and alters peripheral immune cell trafficking to the brain and induces neuroinflammation. The neuroinflammation is mediated by p38 (encoded by *MAPK14*), which is a protein found in MAPK pathway. p38 is also a kinase to phosphorylate tau protein, making p38 as a potential pathogenic factor of AD. However, upregulation of p38 was not observed in this study, since p38 participates in numerous cellular events not only neuroinflammation. This can be supported by that although the inhibition of p38 alleviates neuroinflammation in AD (Yasuda et al., 2012; Ashabi et al., 2013), most p38 inhibitors are failed in clinical trials due to off-target effects. A gene converting glucose into lactate in glycolysis, *LDHA*, is regarded as a relevant pathogenic factor in AD, although it may

not be specific to AD pathogenesis. Overexpression of *LDHA* is reported to prevent neurons from Aβ neurotoxicity by shifting mitochondrial glucose metabolism to lactate production, and decreasing ROS production (Newington et al., 2012). However, elevated lactate level may be detrimental to neurons (Harris et al., 2016). Although the expression of *LDHA* was insignificantly downregulated in this study, the opposing neuroprotective and neurotoxic effects of *LDHA* suggested that neurons might have its own defense mechanism against Aβ in the early onset of AD.

The strength of this study is the integration of transcriptomic data from both DNA microarrays and RNA-Seq using a systematic search and consistent workflow. However, there are some limitations. First, the articles that published the datasets did not provide full details of the experimental procedures, making the transcriptomic results less reliable and more difficult to repeat. In addition, the transcriptomic data retrieved from postmortem brain tissue using different methods might be biased. For example, laser-microdissection mainly targets neuronal soma, but may miss transcripts transporting to the pre- or post-synapses. Lacking of sufficient information about disposal of transcriptomic analysis, resulting in relatively low quality of the selected studies, might raise a reproducibility issue. Second, the confounding factors of postmortem brain tissues include age, sex, and postmortem interval, and may blur the results, e.g., neuroinflammation. Third, most included datasets in this study focused on hippocampus and entorhinal cortex, in which the brain region AD are believed to start. However, AD might start

differently from those two brain regions, e.g., the impaired UPS as an early AD event was reported in brainstem (Irmeler et al., 2012). Transcriptomic analysis in different regions of postmortem AD brains would provide more novel insights of AD development.

## CONCLUSION

This meta-analytical study suggested that the reduced Aβ clearance in AD pathogenesis was associated with the genes encoding Fyn and EGFR, which were key receptors in Aβ downstream signaling.

## DATA AVAILABILITY STATEMENT

The raw data of this paper are available in the public database, GEO and ArrayExpress. The data that support the findings of this paper are available in the published article and its additional files.

## AUTHOR CONTRIBUTIONS

SL and SY conceived and designed the study and wrote the manuscript. SY and HZ extracted and analyzed the data. SL and HZ verified the data and revised the manuscript. All authors read and approved the final version of the manuscript.

## FUNDING

Part of this authors' work and publication fees of this paper were supported by a grant (MYRG2019-00159-ICMS) received from the University of Macau.

## ACKNOWLEDGMENTS

We thank Bronwen Gardner, Ph.D., from the Edanz Group ([www.edanzediting.com/ac](http://www.edanzediting.com/ac)) for editing a draft of this manuscript.

## SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fnins.2020.00209/full#supplementary-material>

**FILE S1 |** The search strategy used in the database GEO and ArrayExpress.

Wei S, Gao L, Jiang Y, Shang S, Chen C, Dang L, Wang J, Huo K, Wang J and Qu Q (2020) The Apolipoprotein E  $\epsilon$ 4 Allele-Dependent Relationship Between Serum Lipid Levels and Cognitive Function: A Population-Based Cross-sectional Study. *Front. Aging Neurosci.* 12:44. doi: 10.3389/fnagi.2020.00044

**Objectives:** Till now, the effect of serum lipid levels on cognitive function is still controversial. The apolipoprotein E (APOE)  $\epsilon$ 4 allele is the most critical genetic risk factor for Alzheimer's disease (AD) and cognitive impairment. Additionally, APOE  $\epsilon$ 4 allele has a major impact on lipid metabolism. The aim of this study was to investigate the APOE genotype-dependent relationship between peripheral serum lipid levels and cognitive impairment.

**Methods:** A total of 1,273 subjects aged 40–86 years participated in this cross-sectional study. Serum lipid levels and the APOE genotype were detected. Mini-Mental State Examination was used to diagnose the cognitive impairment or not. Univariate and multivariate analyses were used to analyze the relationships between APOE genotype, serum lipid levels, and cognition function.

**Results:** After controlling for all possible covariates, a significant interaction between low serum high-density lipoprotein and the APOE  $\epsilon$ 4 allele on cognitive impairment (Wald's  $\chi^2 = 4.269$ ,  $df = 1$ , OR = 20.094,  $p = 0.039$ ) was found in the total participants. In APOE  $\epsilon$ 4 carriers, low serum high-density lipoprotein was positively associated with cognitive impairment (Wald's  $\chi^2 = 8.200$ ,  $df = 1$ , OR = 60.335,  $p = 0.004$ ) and serum high-density lipoprotein levels were positively correlated with Mini-Mental State Examination score ( $r = 0.217$ ,  $df = 176$ ,  $p = 0.004$ ). There was no significant correlation between serum total cholesterol (TC), low-density lipoprotein, triglycerides (TG) levels, and cognitive impairment in either the total participants or APOE  $\epsilon$ 4 carriers/non-carriers.

**Conclusions:** *APOE*  $\epsilon 4$  carriers, but not non-carriers, with lower serum high-density lipoprotein had a higher prevalence of cognitive impairment and a lower Mini-Mental State Examination score. These results suggest that the *APOE*  $\epsilon 4$  allele may affect the relationship between serum lipid levels and cognitive impairment. However, the specific mechanism needs to be further elucidated.

**Keywords:** Alzheimer's disease, total cholesterol, high-density lipoprotein, low-density lipoprotein, triglyceride, apolipoprotein E, risk factors

## INTRODUCTION

Alzheimer's disease (AD) is the most common type of dementia, and its prevalence has been increasing rapidly in China (Jia et al., 2014). A recent study revealed that, in China, the total annual socioeconomic costs of AD patients were US \$167.74 billion in 2015 and were predicted to reach US \$1.89 trillion in 2050, imposing an immense burden on patients and their families (Jia et al., 2018). Due to the complexity of the pathogenesis of AD, there are currently no unified and effective approaches for preventing or curing AD.

In the brain, amyloid- $\beta$  ( $A\beta$ ) accumulation and the formation of insoluble extracellular senile plaques are pathological hallmarks of AD.  $A\beta$  is produced by the endoproteolysis of amyloid precursor protein (APP). When cleaved by  $\beta$ -secretase and  $\gamma$ -secretase, APP is mainly hydrolyzed into the 38–43 amino acid residue  $A\beta$  peptide (De Felice and Ferreira, 2002), and senile plaques are mainly composed of amyloid  $A\beta_{40}$  and amyloid  $A\beta_{42}$  (Masters et al., 1985). Researchers have found that reducing cellular cholesterol levels appears to inhibit  $\beta$ -secretase and  $\gamma$ -secretase activity and, thus, decrease the amount of  $A\beta$  secreted by neurons (Wahrle et al., 2002; Subasinghe et al., 2003). The responsiveness of  $A\beta$  production to cholesterol levels suggests that cholesterol metabolism plays an essential role in the pathogenesis of AD (Hartmann et al., 2007). However, there are still no consistent results of epidemiological studies concerning the role of cholesterol as a risk factor for AD, although some studies have demonstrated that elevated cholesterol increases the risk of AD development, particularly in middle-aged individuals (Kivipelto et al., 2001; Whitmer et al., 2005). Other researchers have failed to confirm this result (Reitz et al., 2004; Tukiainen et al., 2012).

Apolipoprotein E (*APOE*)  $\epsilon 4$  is the most important genetic risk factor for AD. *APOE* is a polymorphic protein involved in the development of late-onset AD, although the mechanism has not been fully elucidated (Siest et al., 2000). There are three alleles of *APOE* (E2, E3, and E4) that produce three homozygous (E2/2, E3/3, and E4/4) and three heterozygous (E2/3, E2/4, and E3/4) isoforms (Zannis and Breslow, 1981). Pathophysiological studies show that *APOE* immunoreactivity exists in senile plaques, indicating a significant role of *APOE* in the metabolism of  $A\beta$  (Kim et al., 2009; Castellano et al., 2011), which is thought to initiate toxic events and further have distinct functions in regulating tau hyperphosphorylation, synaptic plasticity, cell signaling, lipid transport and metabolism, and neuroinflammation

(Yu et al., 2014; Giau et al., 2015). Additionally, *APOE*  $\epsilon 4$  has a major impact on lipid metabolism (Mahley, 1988). The *APOE* gene modulates serum concentrations of lipid and lipoproteins according to its high affinity for binding to cell-surface lipoprotein receptors. Previous research has reported that carriers of *APOE*  $\epsilon 4$  have a higher risk of hyperlipidemia (Dallongeville et al., 1992).

Considering that the *APOE* genotype plays an important role in both AD pathogenesis and lipid metabolism, we investigated the effects of the *APOE* genotype on the relationships between peripheral serum lipid levels and cognitive impairment in Chinese middle-aged and elderly subjects from Qubao village in the suburbs of Xi'an, northwest China.

## MATERIALS AND METHODS

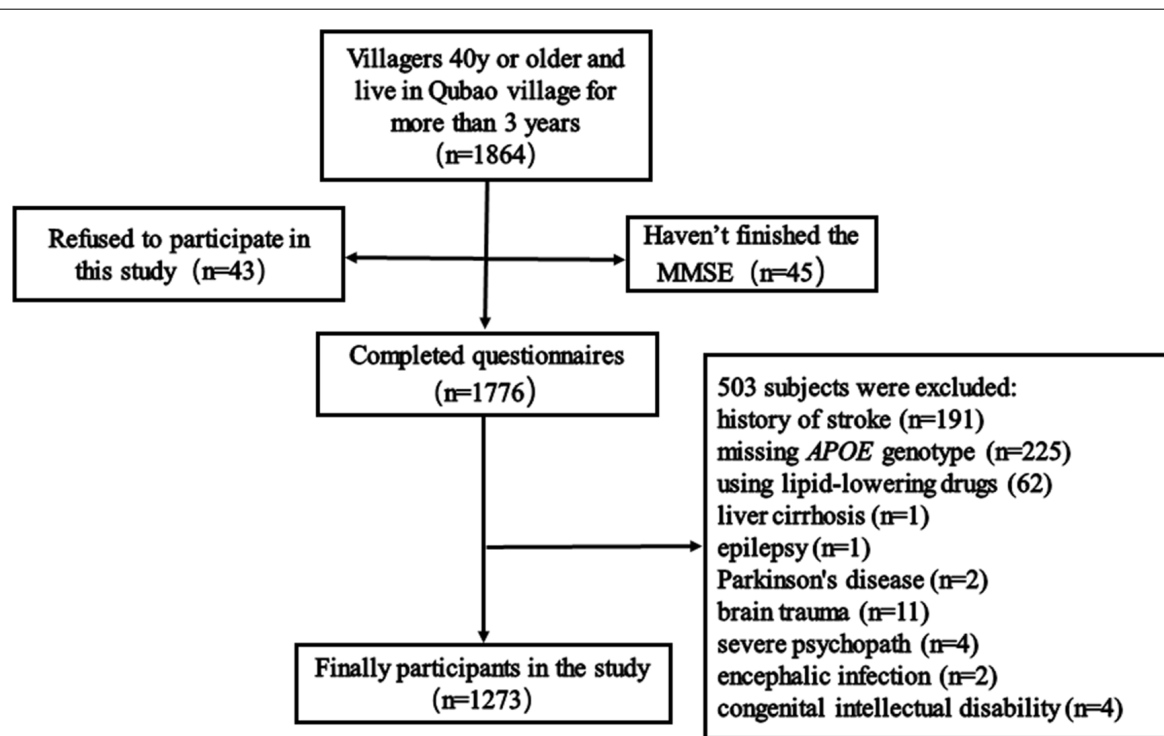

### Participants

Between December 2016 and April 2017, 1,865 subjects were recruited from Qubao village in the suburbs of Xi'an, China. Inclusion criteria were as follows: being 40 years old or older; having lived in Qubao for more than 3 years; agreeing to participate in the study and completing the questionnaire; and having venous blood collected. The exclusion criteria were as follows: (1) participants who had used lipid-lowering drugs in the last 3 months; (2) participants who had severe liver, kidney, thyroid, and hematopoietic system diseases; (3) participants who had suffered from a clear history of acute cerebrovascular disease, including stroke; (4) participants who had suffered from severe nervous system diseases that can cause cognitive impairment, including infection, Parkinson's disease, epilepsy, congenital intellectual disability, and craniocerebral operations; (5) participants who had suffered from other physical and chemical factors that led to cognitive impairment (drug poisoning, alcoholism, and carbon monoxide poisoning); (6) participants who had suffered from severe psychopathy, including schizophrenia, bipolar disorder, severe depression or anxiety; and (7) participants without a complete MMSE score, biomarkers, or covariates. Considering all the inclusion and exclusion criteria, 1,273 subjects were included in our study (Figure 1).

### Questionnaire Survey

All of the participants were asked to complete the questionnaire survey in a structured in-person interview given by trained interviewers. The questionnaire included basic information (gender, age, education, and marital status), lifestyle (exercise,

**FIGURE 1 |** Flow chart of participant selection. Qubao village: the suburbs of Xi'an in northwest China. APOE, apolipoprotein E.

smoking, and alcohol consumption), and medical history (hypertension, diabetes, dyslipidemia, cerebrovascular disease, and heart disease). The definitions of hypertension and diabetes are consistent with those in our previous articles (Jia et al., 2018). According to the diagnostic criteria of Chinese adult dyslipidemia prevention guide (2007 edition; Joint Committee for Developing Chinese guidelines on Prevention and Treatment of Dyslipidemia in Adults, 2007), people who meet any of the following criteria can be defined as dyslipidemia: high total cholesterol (TC):  $TC \geq 5.18$  mmol/L; high low-density lipoprotein (LDL-c):  $LDL-c \geq 3.37$  mmol/L; low high-density lipoprotein (HDL-c):  $HDL-c < 1.04$  mmol/L; high triglycerides (TG):  $TG \geq 1.70$  mmol/L. In addition, anthropometric measurements of participants were taken at the scene, including blood pressure, pulse rate, height, weight, and waist and hip circumference. The body mass index (BMI) was weight (kg) divided by the square of height in meters, and the waist-hip ratio was the waist circumference divided by the hip circumference.

## Diagnosis of Cognitive Impairment

The Mini-Mental State Examination (MMSE) questionnaire was completed by the participants to assess global cognitive function. The MMSE was chosen by Katzman et al. (1988) based on a Chinese version that had been shown to have good sensitivity and specificity. Participants with scores below the cutoff value were considered to have cognitive impairment. The cutoff values were as follows: scores  $\leq 17$  for illiteracy, scores

$\leq 20$  for participants who only finished primary school, and scores  $\leq 24$  for participants with junior high school or above level of education.

## Biochemical Assessment and APOE Genotype Detection

After completing the questionnaire, 10 ml of blood was extracted from the elbow vein of each participant under the condition of fasting for more than 8 h, which was put into a purple-top EDTA-anticoagulant tube and a red-top non-anticoagulant tube. The red-top tube blood samples were sent to the biochemical laboratory of the First Affiliated Hospital of Xi'an Jiaotong University for biochemical assessment [HDL-c, LDL-c, TG, TC, and fasting blood glucose (FBG)]. The concentrations of serum HDL-c, LDL-c, TC, TG, and FBG levels were tested by enzymatic method using an automated biochemical analyzer (C501, Roche, Sweden). The purple-top tube blood samples were centrifuged within 2 h after collection at a rate of 3,000 revolutions per second for 10 min, and all of the samples were stored in the refrigerator at  $-80^{\circ}\text{C}$  for future analysis. An extraction kit (Tiangen Co. Beijing, China) was used to extract DNA from the frozen EDTA-anticoagulant blood according to the manufacturer's protocol. Using human genome DNA as a template, the 244-bp length of the target DNA fragment that included two polymorphic sites at amino acid residues 112 and 158 (Mahley and Rall, 2000) was amplified by a PCR thermocycler. All PCR products were detected by Sanger

sequencing (Sangon Company, Shanghai, China) to finally determine the *APOE* genotype.

## Statistical Analyses

SPSS 18.0 software (SPSS Inc., IBM, Chicago, IL, USA) was used to analyze all of the data. First, participants were divided into a dyslipidemia group and a non-dyslipidemia group. In addition, according to the *APOE* genotype, the participants could also be divided into *APOE*  $\epsilon 4$  non-carriers (E2/2, E2/3, and E3/3) or *APOE*  $\epsilon 4$  carriers (E2/4, E3/4, and E4/4). Unpaired Student's *t*-tests and the mean  $\pm$  SD were used for data that were approximately normally distributed; the Mann-Whitney *U* test and the median (quartiles) were used for skewed data distributions, and the Pearson  $\chi^2$  test and percentages were used for categorical data. A *p*-value of  $<0.05$  (two-tailed) was considered statistically significant.

Then, a  $\chi^2$  test or Fisher's exact test was used to compare the differences in cognitive impairment between serum lipid groups in the total participants and in the subgroups according to *APOE*  $\epsilon 4$  status. For multivariate analysis, binary logistic regression was used to correct for covariates, including gender, age, education years, smoking, drinking, physical activity, medical history, FBG, mean arterial pressure (MAP), pulse rate, and BMI.

Finally, partial correlation analysis was used to research the correlations between MMSE score and serum lipid levels in the subgroups according to the *APOE*  $\epsilon 4$  status. The covariates included age, sex, education years, smoking, drinking, intensity of physical activity, BMI, log-transformed FBG, MAP, pulse rates, and heart disease.

## RESULTS

### Demographic Characteristics of the Study Samples

A total of 1,273 subjects ranging from 40 to 86 years old (mean  $57.1 \pm 9.7$  years) were included in the study, including 755 (59.3%) women. Participants with dyslipidemia comprised 59.2% (754) of the total population. Ninety-nine (7.8%) subjects met the diagnostic criteria of cognitive impairment, and a total of 189 people (14.8%) were *APOE*  $\epsilon 4$  carriers. **Table 1** shows the demographic characteristics of the total participants. There were significant differences in gender, education, smoking, hypertension, diabetes mellitus status, MAP, pulse rate, FBG level, BMI, and *APOE*  $\epsilon 4$  carrier status between the dyslipidemia group and the normal lipids group.

### The Current Prevalence of Cognitive Impairment Between the Normal Serum Lipids Group and the Dyslipidemia Group

As shown in **Figure 2**, in the total samples, the current prevalence of cognitive impairment was not significantly different between the normal serum lipids group and the dyslipidemia group. The stratified analyses according to *APOE*  $\epsilon 4$  status showed that the current prevalence of cognitive impairment was still not significantly different between any of the serum lipid groups in *APOE*  $\epsilon 4$  carriers or non-carriers.

### Multivariate Analysis of the Relationship Between Serum Lipid Parameters and Cognitive Impairment in the Total Samples

To eliminate the influence of covariates, binary logistic regression analysis was performed. In the total samples, after adjusting for age, gender, and education, no significant correlation was found between high TG, high TC, high LDL, low HDL levels, and cognitive impairment (**Table 2**, Model 1). When continuing to bring other covariates into the binary logistic regression models, the results were approximately the same (**Table 2**, Model 2). However, with the binary logistic regression analysis of the interaction between the serum lipids and *APOE* genotype on cognitive impairment, we found that the interaction between low HDL and *APOE*  $\epsilon 4$  status was positively correlated with cognitive impairment (Wald's  $\chi^2 = 4.269$ , *df* = 1, OR = 20.094, 95% CI = 1.167–346.056, *p* = 0.039), and the interaction between other serum lipid parameters (high TG, high TC, and high LDL levels) and *APOE*  $\epsilon 4$  status had no significant effect on cognitive impairment (**Table 2**, Model 3).

### The Effects of the *APOE* $\epsilon 4$ Allele on Cognitive Impairment and Serum Lipid Levels

Univariate analysis showed that compared with *APOE*  $\epsilon 4$  non-carriers, serum TC, TG, and LDL levels were higher and HDL levels were lower in *APOE*  $\epsilon 4$  carriers [TC:  $5.36 \pm 0.94$  mmol/L vs.  $5.15 \pm 0.99$  mmol/L, *df* = 1,271, *p* = 0.008; TG:  $1.48$  (1.09, 2.15) mmol/L vs.  $1.29$  (0.96, 1.80) mmol/L, *p* < 0.001; LDL:  $2.82 \pm 0.62$  mmol/L vs.  $2.61 \pm 0.66$  mmol/L, *df* = 1,271, *p* < 0.001; HDL:  $1.53 \pm 0.32$  mmol/L vs.  $1.60 \pm 0.34$  mmol/L, *df* = 1,271, *p* = 0.007], and the prevalence of dyslipidemia was also significantly higher in *APOE*  $\epsilon 4$  carriers [132 (69.8%) vs. 622 (57.4%), *df* = 1, *p* = 0.001]. The current prevalence of cognitive impairment was not significantly different between *APOE*  $\epsilon 4$  carriers and non-carriers. Other covariates (age, gender, degree of education, smoking, drinking, intensity of physical activity, hypertension, diabetes mellitus, coronary heart disease, MAP, and BMI) also showed no significant difference between the two groups (**Table 3**).

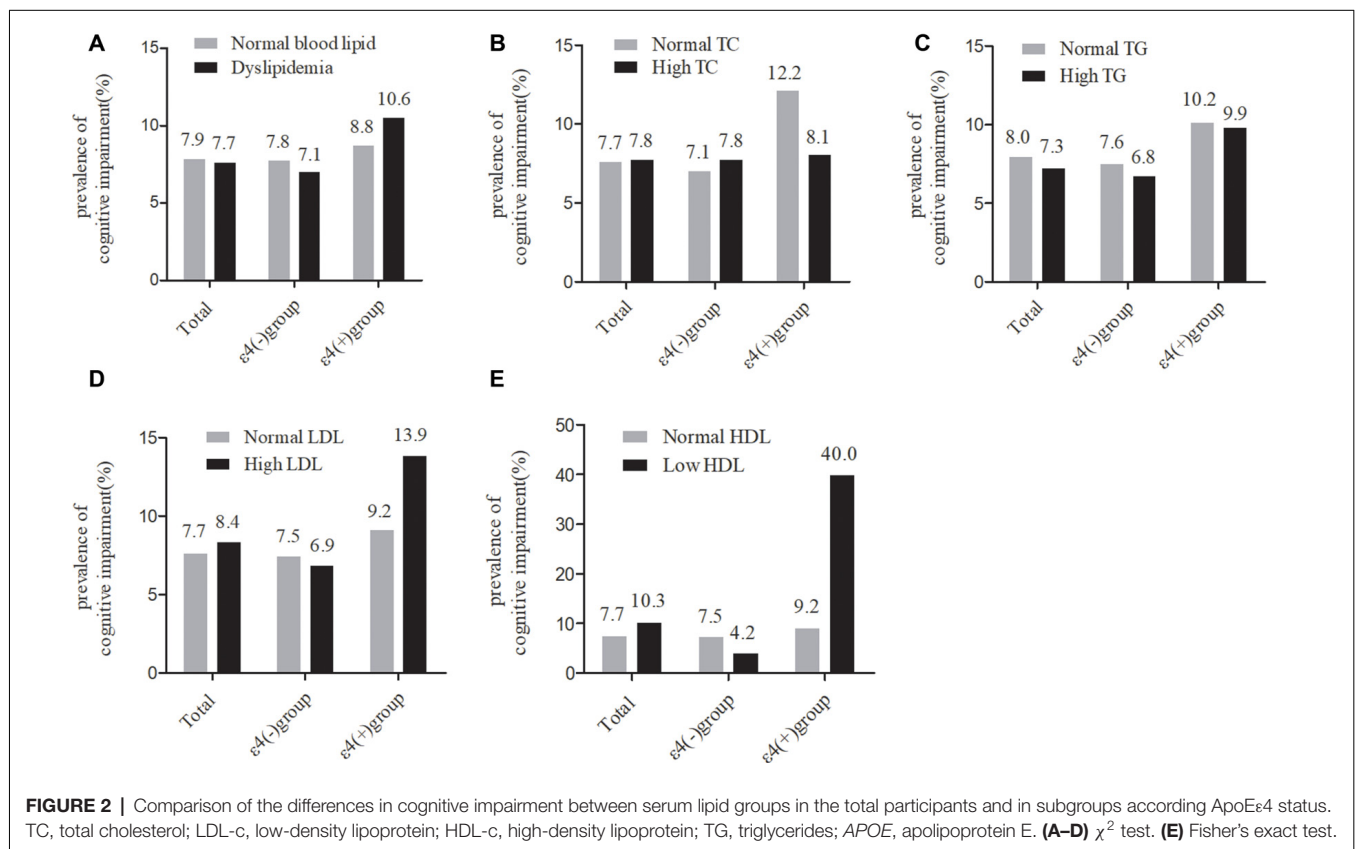

### Stratified Multivariate Analysis of the Relationship Between Serum Lipids and Cognitive Impairment According to *APOE* $\epsilon 4$ Status

Because the *APOE*  $\epsilon 4$  allele had effects on the relationship between serum lipid levels and cognitive impairment, stratified binary logistic regression analyses were performed according to *APOE*  $\epsilon 4$  status. In *APOE*  $\epsilon 4$  carriers, low HDL was positively correlated with cognitive impairment (Wald's  $\chi^2 = 8.200$ , *df* = 1, OR = 60.335, 95% CI = 3.646–998.364, *p* = 0.004; **Table 4**, Model 5). However, such a correlation disappeared among *APOE*  $\epsilon 4$  non-carriers (Wald's  $\chi^2 = 0.057$ , *df* = 1, OR = 0.776, 95% CI = 0.097–6.221, *p* = 0.811; **Table 4**, Model 7). For other serum lipid parameters (high TC, high TG, and high LDL levels), there was no significant correlation with cognitive

impairment in either APOE ε4 carriers or non-carriers (Table 3, Models 5 and 7).

## Stratified Multivariate Analysis of the Correlations Between Serum Lipids and MMSE Score According to APOE ε4 Status

To further confirm our results, stratified partial correlation analysis was separately performed to research the correlations

between serum lipids and MMSE score in APOE ε4 non-carriers and carriers. When adjusting for age, sex, education, smoking, drinking, intensity of physical activity, BMI, log-transformed FBG, MAP, pulse rates, and heart disease, MMSE scores positively correlated with serum HDL level ( $r = 0.217$ ,  $df = 176$ ,  $p = 0.004$ ) but not with LDL, TG, or TC levels in APOE ε4 carriers. In APOE ε4 non-carriers, no correlations were found between MMSE scores and any of the serum lipids (Figure 3).

## DISCUSSION

In this cross-sectional study, we found a significant interaction effect between low HDL and the APOE  $\epsilon 4$  allele on cognitive impairment in the total participants. In APOE  $\epsilon 4$  carriers, low serum HDL-c levels were positively associated with cognitive impairment, and participants with higher HDL levels had higher MMSE scores. No correlation was found between cognitive impairment/MMSE score and any of the serum lipids in APOE  $\epsilon 4$  non-carriers.

Although studies have shown that lipid metabolism is involved in the pathogenesis of AD (Hartmann et al., 2007; Anstey et al., 2008), and the effect of lipid levels on cognitive function has attracted the attention of many researchers, there is still no consistent conclusion. A previous study showed that high midlife TC levels can increase the risk of AD in older people (Anstey et al., 2017). In contrast, another study showed that higher TC levels were associated with better memory functioning in very elderly subjects without the APOE  $\epsilon 4$  allele (West et al., 2008). One study showed that increased serum LDL levels were

Binary logistic regression model was used for data analysis, *df* = 1. Models 4 and 5 were analyzed in *APOE*  $\epsilon 4$  carriers. Models 6 and 7 were analyzed in *APOE*  $\epsilon 4$  non-carriers. *APOE*  $\epsilon 4$  carrier status: dummy coded with  $\epsilon 4$  carriers = 1, non-carriers = 0. Models 4 and 6 were adjusted for age, gender, and education years. Models 5 and 7 were adjusted for age, gender, education years, smoking, drinking, intensity of physical activity, body mass index, log-transformed fasting blood glucose, mean arterial pressure, pulse rate, and heart disease. TC, total cholesterol; LDL-c, low-density lipoprotein; HDL-c, high-density lipoprotein; TG, triglycerides; *APOE*, apolipoprotein E.

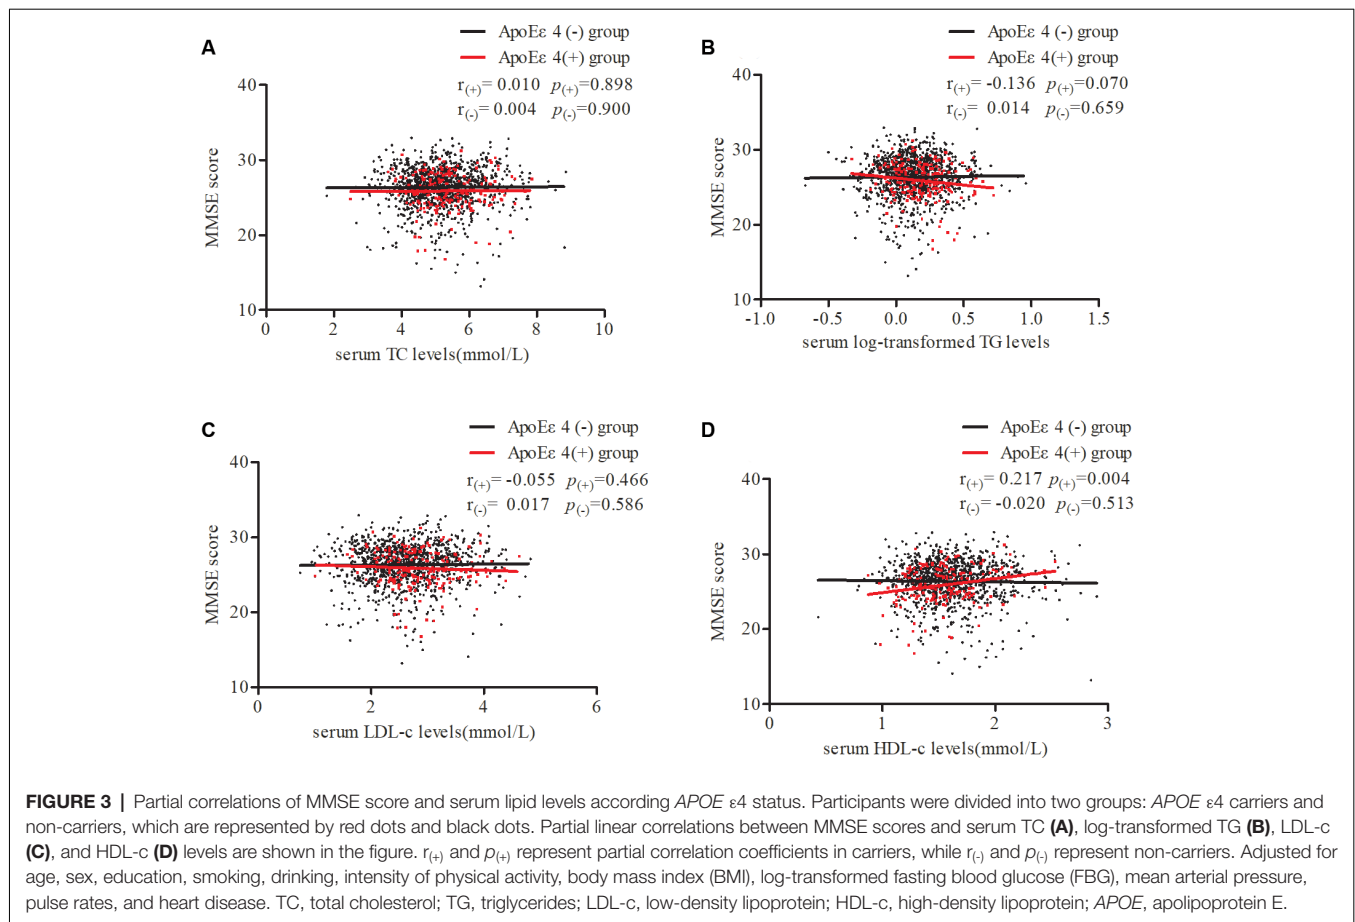

independently associated with AD (Chen et al., 2019), and one study showed that higher LDL levels were associated with better memory performance (Leritz et al., 2016). Katsumata et al. (2013) reported that HDL levels and lower TG/HDL-C ratios were associated with better memory performance, while other studies have shown no association between HDL and AD (Li et al., 2005). Therefore, to study the relationship between lipids and cognition, stratified analysis was separately performed according to the *APOE* genotype. Our study found that low HDL was associated with cognitive impairment in *APOE*  $\epsilon 4$  allele carriers, while TC, LDL, and TG levels were not associated with cognitive function.

Some possible mechanisms might explain the positive correlation between HDL levels and cognitive function. First, it has been shown that ApoA-I, the main component of HDL, is highly efficient at cholesterol efflux in the CSF (Demeester et al., 2000), resulting in increased membrane fluidity that could enhance the  $\alpha$ -secretase cleavage of APP at the cell membrane. As mentioned above, increased  $\alpha$ -secretase activity can reduce the production of A $\beta$ . Second, apoA-I/HDL can bind to A $\beta$  and make the clearance of A $\beta$  by astrocytes and/or microglia more efficient (Sagare et al., 2012), leading to a decrease in A $\beta$  aggregation and cytotoxicity. Third, it is well established that the antioxidant and anti-inflammatory effects of HDL play an important role in cardiovascular diseases (Barter et al., 2007), so the same disease mechanism may also affect neurodegenerative diseases (Lewis et al., 2010). Finally, the main role of HDL is lipid metabolism, which can reverse lipoprotein transport from the arterial wall of the brain (Mulder and Terwel, 1998), leading to a decrease in ischemic lesions that are involved in the development of cognitive decline and dementia (Kalaria, 2000).

However, the difference in the relationship between HDL and cognitive function between *APOE*  $\epsilon 4$  carriers and *APOE*

$\epsilon 4$  non-carriers remains to be addressed. We hypothesized that in *APOE*  $\epsilon 4$  carriers, there may be two reasons for the positive association between cognitive function and HDL levels. First, this study showed lower levels of HDL in *APOE*  $\epsilon 4$  carriers, suggesting that *APOE* exerts isoform-specific effects on HDL metabolism in humans. Using C57BL/6 *APOE*<sup>−/−</sup> mice, Hopkins et al. (2002) reported that compared with *APOE*  $\epsilon 3$ , the presence of *APOE*  $\epsilon 4$  was less efficient at transferring ApoA-I from chylomicron remnants to HDL, resulting in lower plasma HDL levels and smaller HDL volumes. The reduced HDL levels may be associated with eventual cognitive decline, which has been confirmed by some previous studies (van Exel et al., 2002; Zuliani et al., 2010). However, pathophysiological studies have shown that *APOE*  $\epsilon 4$  can directly lead to cognitive decline without HDL involvement by affecting A $\beta$  clearance, tau hyperphosphorylation, synaptic plasticity, cell signaling, and neuroinflammation (Yu et al., 2014; Giau et al., 2015). The combination of these two mechanisms may lead to the emergence of a positive relationship between HDL levels and cognitive function in *APOE*  $\epsilon 4$  carriers. However, in *APOE*  $\epsilon 4$  non-carriers, without *APOE*  $\epsilon 4$  as a risk factor, the effect of HDL alone on cognitive function might not be sufficiently apparent, leading to the result that there was no significant relationship between HDL and cognitive function. Of course, the abovementioned ideas are only our reasonable speculation, and the specific mechanism remains to be further studied.

Consistent with our findings, one community-based study with 2,356 participants showed no correlation between TC levels and the risk of dementia or AD (Elias et al., 2005). In contrast, the 3C study (Schilling et al., 2017) and another 14-year cohort study (Toro et al., 2014) found a positive correlation, and a meta-analysis (Anstey et al., 2017) also showed that high midlife

TC levels increase the risk of late-life AD. However, the lipid measurements in these studies were not from cross-sectional studies and were performed significantly earlier than the onset of AD by at least 13 years, and some of the cholesterol levels were measured in midlife and not late life. A previous study of 444 men from the Finnish cohorts of the Seven Countries (Notkola et al., 1998) showed that the TC levels of men in midlife who subsequently developed AD were significantly higher than those of normal men. However, because cholesterol levels decline with age, in the preclinical manifestations of AD stage, the TC levels of those eventually developing AD decreased more rapidly and were eventually lower in late life than those of normal men. This study was a cross-sectional study in Chinese middle-aged and elderly subjects, and all lipid measurements were clustered around the time of the study, which may explain the lack of correlation between TC levels and cognitive impairment.

Some limitations should be mentioned. First, the study is a cross-sectional study, so it can only explain the correlation between blood lipids and cognition; however, the causal relationship between them is difficult to explain, and randomized controlled trial is necessary in the future to see if increasing HDL-c plasma levels can prevent cognitive decline in the at-risk population of *APOE*  $\epsilon 4$  carriers and thus clarify the causal relationship. Second, the serum lipids were only detected at

a single time point, not allowing for an evaluation of the dynamic changes. In addition, our study focused on elderly individuals in the Chinese Han population in Northwest China, and the diagnosis of cognitive impairment was based on the Chinese version of the MMSE, so the generalizability of our findings may be limited in other ethnic or age groups, and multi-center and large population studies need to be performed to validate our results. Third, with the numbers of patients with cerebrovascular diseases increasing, the incidence rate of vascular dementia (VaD) rises year by year. VaD has become the second leading cause of dementia after AD itself (Lobo et al., 2000). In this study, we have excluded people with a clear history of acute cerebrovascular disease, including stroke. However, owing to lack of standard diagnostic procedures and biomarkers simultaneously (Formichi et al., 2010), it is still hard to rule out the possibility that some cases with cognitive impairment may be vascular dementia or mixed dementia (AD+VaD; Jellinger, 2005). So, further studies involving AD biomarkers need to be performed to elaborate the conclusion more deeply and accurately.

## CONCLUSION

In summary, by measuring serum lipids and cognitive function, this cross-sectional study found that in *APOE*

$\epsilon 4$  carriers, but not *APOE*  $\epsilon 4$  non-carriers, low serum HDL-c levels were positively associated with cognitive impairment and that those with higher HDL levels had higher MMSE scores. These data indicated that the *APOE*  $\epsilon 4$  allele may affect the relationship between serum lipid levels and cognitive impairment. However, this relationship needs to be further elucidated.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation, to any qualified researcher.

## ETHICS STATEMENT

This study and its protocol were approved by the Medical Ethics Committee of the First Affiliated Hospital of Xi'an Jiaotong University. All participants were required to sign a written informed consent form before participating in the study.

Several lines of evidence point to alteration in brain metabolic homeostasis in Parkinson's disease (PD) and levodopa-induced dyskinesia (LID), yet the metabolic mechanism in different brain regions underlying PD and LID remains largely unknown. The present study aimed to uncover the metabolic pathways across anatomical regions in the brain of PD and LID. Using an NMR-based metabolomic approach, we generated the metabolomics profiling data from six different brain regions of PD rats and following the onset of LIDs. The diversity of metabolite patterns across the brain and its relation to PD and LID were further investigated through principal component analysis (PCA) and multivariate general linear model. Compared with control rats, dopamine loss in PD rats produced a marked and persistent metabolic disturbance in neurotransmitter metabolism and energy pathway, resulting in a metabolic imbalance among different brain regions. In LID rats, levodopa replacement did not restore the midbrain-striatum metabolic crosstalk and metabolic disturbance throughout the brain was involved in levodopa related involuntary movements. Most notably, the midbrain and right cortex were identified as the primary regions of metabolic abnormalities in PD and LID rats. Neurochemical differences in metabolic phenotypes were mainly defined by various neurotransmitters including glutamate, glutamine and aspartate. Accordingly, we found that the PD and LID rats exhibited lower levels of synaptophysin (SYP), a marker for synaptic plasticity, compared with control rats. These findings provide key insights into the metabolic mechanism underlying PD and LID by defining brain-region specific metabolic phenotype, with implications for developing targeted therapies.

## INTRODUCTION

Parkinson's disease (PD) is a common age-related neurodegenerative disorder due to the loss of dopaminergic neurons in the substantia nigra par compacta (SNpc) thereby leading to the dopamine depletion in the striatum (Huang et al., 2019). The clinical symptoms of PD are mainly classified into motor abnormalities characterized by static tremor, rigidity, bradykinesia, postural instability and non-motor symptoms, such as cognitive impairment and gut dysfunction (Lee et al., 2019). So far, L-3,4-dihydroxyphenylalanine (L-dopa) remains to be the most effective drug for symptomatic treatment of Parkinson (Smith et al., 2014). However, the adverse effects of long-term L-dopa treatment vary, such as levodopa-induced dyskinesia (LID), which appears in approximately 40% of PD patients after 5 years L-dopa therapy and up to 90% within 10 years (Pourmirbabaei et al., 2019; Sellnow et al., 2019). Furthermore, the uncontrollable LID has been reported to dramatically affect the quality of patients' life and greatly augment the cost of health care for which no satisfying treatment is available (Dodel et al., 2001; Chapuis et al., 2005; Hechtner et al., 2014). In light of this urgent medical need for rapidly aging populations, there is an urgent need to identify the mechanism underlying PD and LID.

Metabolic abnormality has long been considered to be involved in a lot of diseases, such as neurodegenerative diseases including PD (Shao and Le, 2019) and Alzheimer's disease (Van Bulck et al., 2019), diabetes mellitus (Del Coco et al., 2019), chronic obstructive pulmonary disease (Lamonaca et al., 2017). <sup>1</sup>H-NMR based metabolomics has proven to be a key for the characterization of metabolic profiles relevant to brain function and disease (Ivanisevic and Siuzdak, 2015). Our previous studies demonstrated that metabolic abnormalities in the brain participated in DM-associated cognitive dysfunction (Zheng et al., 2017) and pathogenesis of Alzheimer's disease (Zheng et al., 2018b). And increasing evidence in recent researches has supported the idea that metabolic abnormality may be causal to PD and LID, though it is unclear how metabolic disruption affects striatal activity *in vivo*. In our previous study, <sup>1</sup>H NMR based metabolomics was applied to evaluate the metabolic signatures and pathways involved in the onset and progression of PD, which indicate that neuron loss and motor function impairment in induction PD mice may be linked to overactive glutamate-glutamine cycle and altered membrane metabolism in the striatum (Lu et al., 2018). There is, however, a dearth of information on understanding the metabolic and cellular mechanisms underlying motor impairment in LID.

Historically, studies of PD and LID have been focused on the striatum, since it is acknowledged that the dopamine depletion in the striatum result from degeneration of dopaminergic neurons is the main cause of PD (Hornykiewicz, 2006; Huang et al., 2019), and the prevailing hypothesis is that subsequent replacement with levodopa causes excessive direct pathway activity in the striatum. For example, Cenci et al. (1998) analyzed the correlations between the dyskinetic symptoms of LID and neurotransmitter-related mRNA expression in

the basal ganglia and found that striatal overexpression of prodynorphin- and glutamic acid decarboxylase participated in the occurrence of LID. Santini et al. (2007) found hyperactivation in the striatal medium spiny neuron of cAMP/PKA/DARPP-32 and ERK signaling played a critical role in L-dopa induced dyskinesia. Crucially, L-dopa replacement has little effects on axial symptoms of PD, indicating that disruptions in another neurotransmitter metabolism other than dopamine, even other brain regions beyond the striatum could mediate these PD and levodopa-evoked behaviors. Again, some indirect evidence supports this hypothesis: once LID develops, a given dose of levodopa relieves parkinsonism but produces dyskinesia.

If other brain regions were indeed involved in the onset and progression of PD and LID, then targeted therapies could be more effective than levodopa alone. Therefore, the creation of a detailed map of the human neural metabolic pathway across different brain regions will help to build a knowledge base to unravel complex brain functions. In the present study, we took advantage of a <sup>1</sup>H NMR-based metabolomics approach to characterize the involvement of region-specific metabolic phenotype in the brain of PD and following LID rats.

## MATERIALS AND METHODS

### Animals

Male Sprague-Dawley rats (180–220 g) purchased from the SLAC Laboratory Animal Company Limited (Shanghai, China) were housed under the standard laboratory conditions (controlled temperature/humidity condition, a normal 12/12-h light/dark schedule with the lights on at 08:00 a.m.), in the Laboratory Animal Center of the First Affiliated Hospital of Wenzhou Medical University (Wenzhou, China). All rats were given free access to standard chow and water during the whole experimental process. All experimental operations were performed strictly in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care and Use Committee of Wenzhou Medical College (wydw2018-015).

### 6-Hydroxydopamine (6-OHDA) Rat Model of PD and Levodopa-Induced Dyskinesia

Animals were weighed and randomly divided into control ( $n = 8$ ) and lesion groups ( $n = 20$ ). All rats in lesion group stereotaxically received 4  $\mu$ l of 6-OHDA (4  $\mu$ g/ $\mu$ l, dissolved in 0.9% physiological saline involving 0.2% ascorbic acid) injection at each coordinate in the right medial forebrain bundle (MFB) and the rats in control group received sham-operation with physiological saline at the same locations. The coordinates calculated by the rat brain atlas were as previously reported (Xie et al., 2014): AP  $-4.4$  mm, ML  $-1.2$  mm, DV  $-7.8$  mm; AP  $-3.7$  mm, ML  $-1.7$  mm, DV  $-7.8$  mm. The tooth bar was set to  $-2.4$  mm. After 3 weeks of lesioning, rats in the lesion group received intraperitoneal injection of apomorphine to induce contralateral rotations, and rats with at least seven full contralateral turns/min were selected as successful PD rats (Yang et al., 2012). The successful PD rats were then randomly divided into PD group ( $n = 10$ ) and LID group ( $n = 10$ ). In the next

3 weeks, rats in LID group received a daily intraperitoneal injection of L-dopa (15 mg/kg) together with benserazide (3.75 mg/kg) for 3 weeks (Zhang et al., 2014) and the rats in Con and PD group were given equal vehicle during the same period. The body weights of rats were constantly monitored during the process of the study.

## Behavioral Test

The onset and severity of LID were evaluated according to a highly validated abnormal involuntary movements (AIMs) scale on days 1, 4, 7, 10, 14, 17 and 20 of L-dopa/benserazide treatment (Lundblad et al., 2002; Mellone et al., 2019). Briefly, AIMs were conducted from 20 min to 120 min after L-dopa or vehicle administration and each rat was continuously observed for 1 min every 20 min each time. The AIMs scores were recorded from 0 to 4 according to the incidence of three subtypes of AIMs (axial, limb and orolingual): 0 = absent; 1 = present less than or equal to 30 s; 2 = present more than 30 s; 3 = present continuously but suppressible by external stimulus; 4 = present continuously but not suppressible by external stimulus.

The forelimb function test is a widely used behavior test to assess the forelimb motor function of rats. The test was performed at days 3, 8, 13, 18 of L-dopa/benserazide treatment and all the process was carried out in a glass beaker (diameter = 22 cm, height = 35 cm) to record the number of wall contacts of right/left forelimb of rats. 1 h after L-dopa or vehicle administration, the forelimb function test was evaluated 5 min every 20 min for four times. The final value was shown as the percentage wall contacts of the contralateral forelimb of 6-OHDA lesion (left forelimb) compared with total wall contacts of bilateral forelimbs (Schallert et al., 2000).

## Immunofluorescence Staining

Three rats of each group were processed for immunofluorescence staining studies. In brief, rats were anesthetized with 10% chloral hydrate (0.35 ml/100 g) first after the last L-dopa administration and then perfused transcardially with normal saline followed by a fixing solution containing 4% paraformaldehyde for 30 min. The brains were carefully removed, fixed in 10% buffered formalin overnight, and embedded in paraffin. The brain tissues were cut into coronal sections with a thickness of 5  $\mu$ m. The paraffin sections were incubated with Anti-Synaptophysin (SYP) antibody (Abcam, 1:200) overnight at 4°C and rinsed in PBS followed by incubation with Alexa Flour<sup>TM</sup> 488 goat anti-rabbit IgG (H + L; Invitrogen, 1:500). Subsequently, sections were rinsed again in PBS, stained with DAPI (Southern Biotech) and observed using a fluorescence microscope (Nikon, Tokyo, Japan).

## Sample Collection and Metabolite Extraction

The remaining rats were sacrificed by decapitation after a 3-weeks L-dopa administration, with the whole brain tissue dissected into midbrain, cortex, striatum, hippocampus, cerebellum, and hypothalamus immediately. All the brain tissues were put into liquid nitrogen at once and then stored at -80°C until use. The metabolite extraction was referred to as our

previous method (Liu et al., 2018). Briefly, the frozen tissues were weighted into an Eppendorf tube, Following the homogenization by electric homogenizer with ice-cold methanol (4.0 ml/g) and ultrapure water (0.85 ml/g). The mixture was homogenized again with 2 ml/g of chloroform, then again with 2 ml/g of chloroform and 2 ml/g of ultrapure water using a vortex mixer, placed on ice for 15 min, and centrifuged at 10,000 g for 15 min at 4°C. Finally, the supernatant was carefully transferred into a new Eppendorf tube, lyophilized for 24 h, and stored at -80°C until NMR analysis.

## NMR Spectroscopy

The lyophilized extract was dissolved into 0.6 ml of 99.5% D<sub>2</sub>O containing 0.05% of sodium trimethylsilyl propionate-d<sub>4</sub> (TSP), in which D<sub>2</sub>O provided a field-frequency lock, and TSP was used as the chemical shift reference. All <sup>1</sup>H NMR spectra of brain tissue were acquired on the Bruker Avance III 600 MHz NMR spectrometer with a 5-mm TXI probe (Bruker BioSpin, Rheinstetten, Germany) at 298 K. The one-dimensional <sup>1</sup>H NMR spectra of right striatum and SN were acquired using a standard single-pulse sequence with water signal presaturation (ZGPR) with number of scans (256), acquisition time (2.65 s/scan), data points (64 k), spectral width (12,000 Hz) and relaxation delay (6 s). Then, the <sup>1</sup>H NMR spectra were referenced to the TSP peak at 0.0 ppm and manually adjusted phase and baseline using Topspin (v2.1 pl4, Bruker Biospin, Germany).

## Data Processing of NMR Spectra and Multivariate Pattern Recognition

NMR spectra were reduced to integrated regions with a width of 0.01 ppm (bin) corresponding to the region of  $\delta$  10–0.5. The regions of 4.7–5.2 ppm (water) was removed to eliminate artifacts related to the residual water resonance. The remaining spectral segments were then normalized to the total sum of the spectral intensity to partially compensate for differences in the concentration of many metabolites in the samples. Before multivariate data analysis, the integral values were mean-centered and Pareto-scaled (Shao et al., 2014). NMR data sets were imported into SIMCA-P + 12.0 software (Umetrics, Umea, Sweden) for multivariate statistical analysis, including principal component analysis discriminant analysis (PCA-DA) and partial least squares-discriminant analysis (PLS-DA). And another data reduced to integrated regions with a width of 0.0015 ppm width corresponding to the region of  $\delta$  10–0.5 were used for quantitative analysis.

## Real-Time RT-PCR

The Real-time RT-PCR procedure and data analyses were carried out as previously described (Yang et al., 2019). The total RNA was extracted from the right cortexes using standard TRIzol reagent (Invitrogen, Carlsbad, CA, USA) and converted into cDNA following the instruction of PrimeScript<sup>TM</sup> RT reagent Kit (Takara, RR037A). Individual samples were measured in triplicate. Real-time-PCR was performed on an ABI 7500 Fast Real-Time PCR system using TB Green<sup>TM</sup> Premix Ex Taq<sup>TM</sup> II (RR820A). Primer sequences as follows: Actin (5'-ACCCGCGAGTACAACCTTC-3'/5'-ATGCCGTGTT

CAATGGGGTA-3'), SYP (5'-GCTAAAAGCAGGAGGGCGTA-3'/5'-GCACAGGAAAGTAGGGGGTC-3'). Relative expression levels were measured with the  $2^{-\Delta\Delta C_t}$  method.

## Statistical Analysis

Independent sample *t*-test or one-way ANOVA was applied to compare the difference among different groups. Statistical analyses were performed using SPSS (version 25, IBM, USA). Data were exhibited as mean  $\pm$  SEM and *P*-values less than 0.05 were considered statistically significant.

## RESULTS

### Behavior Tests in Experimental Models of PD and LID

To mimic dyskinesia of PD patients, male SD rats were unilaterally injected with 6-OHDA in the right MFB, causing a nearly complete depletion of ipsilateral dopamine, while the rats in Con group were got same Sham-operation but injected with vehicle (**Figures 1A,B**). Three weeks later, motor symptoms were validated using apomorphine-induced rotation test (**Figure 1C**). Then the LID rats were intraperitoneally administrated L-dopa (15 mg/kg, i.p.) with benserazide (3.75 mg/kg, i.p.) once a day for 3 weeks and observed progressive AIMs. Forelimb function test was conducted at days 3, 8, 13, 18 after L-dopa/benserazide treatment, results showed that the percent of left forelimb use of total wall contacts of rats in Con group is around 50%, while the percent of left forelimb use was significantly reduced in PD rats with a partial lesion of the nigrostriatal pathway. After the treatment of L-dopa, the percent of left forelimb use of rats in the LID group was significantly increased compared to that in the PD group ( $P < 0.05$ , **Figure 1D**). These results suggested that PD rats showed reduced forelimb motor function, and L-dopa treatment is quite effective in alleviating PD behavioral symptoms.

However, we found that L-dopa treatment caused both dyskinesia and contralesional rotations. Abnormal involuntary movements (AIMs) score, a standard behavior performance score system for dyskinesia, was significantly higher in the 6-OHDA-lesioned rats after 3 weeks of L-dopa administration (**Figure 1E**). We observed that AIMs immediately appeared at 20 min after L-dopa injection and did not attenuate until 80 min and then faded away after 120 min. Besides, we continuously monitor the total AIMs scores at days 1, 4, 7, 10, 14, 17 and 20 of L-dopa/benserazide treatment (**Figure 1F**). The results showed that total AIMs scores of LID rats gradually increased with time went by, while that of rats in Con and PD group had no obvious changes.

In addition, we also questioned whether the growth of rats was affected by the disease. A repeated-measures ANOVA revealed a significant time and treatment interaction effect in the body weight ( $P = 0.01$ ). To be specific, the bodyweight of PD rats was significantly reduced after 6-OHDA administration, compared with the control group. After L-dopa administration for 3 weeks, the bodyweight of LID rats increased significantly compared with PD rats ( $P < 0.05$ , **Figure 1G**), while no significant difference was found between Con and LID rats.

### NMR-Based Metabolic Profiling of Different Brain Regions

In order to characterize the dynamic changes of metabolites throughout the brain, NMR-based metabolic profiling of different brain regions was performed among control, PD and LID rats. Typical  $^1\text{H}$ -NMR CPMG (600 MHz) spectra of different brain regions (midbrain, cortex, striatum, hippocampus, cerebellum, and hypothalamus, respectively), obtained from control, PD and LID rats are presented in **Figure 2**. Assignments were performed according to our previous studies (Zheng et al., 2017, 2018a) using the Chenomx NMR suite 7.0 (Chenomx Inc., Edmonton, AB, Canada). A total of 20 metabolites were identified, which can be detected in all six brain regions (**Figure 2**). Although the NMR spectra appeared similar among different brain regions, there were striking differences in peak intensities for different brain regions. The metabolites identified included lactate, alanine, GABA, NAA, glutamine, glutamate, dimethylamine, aspartate, creatine, choline, glycerol-phosphocholine, taurine, Myo-inositol, glycine, Glu/Gln, Inosine, ADP/AMP, fumarate, AMP and IMP.

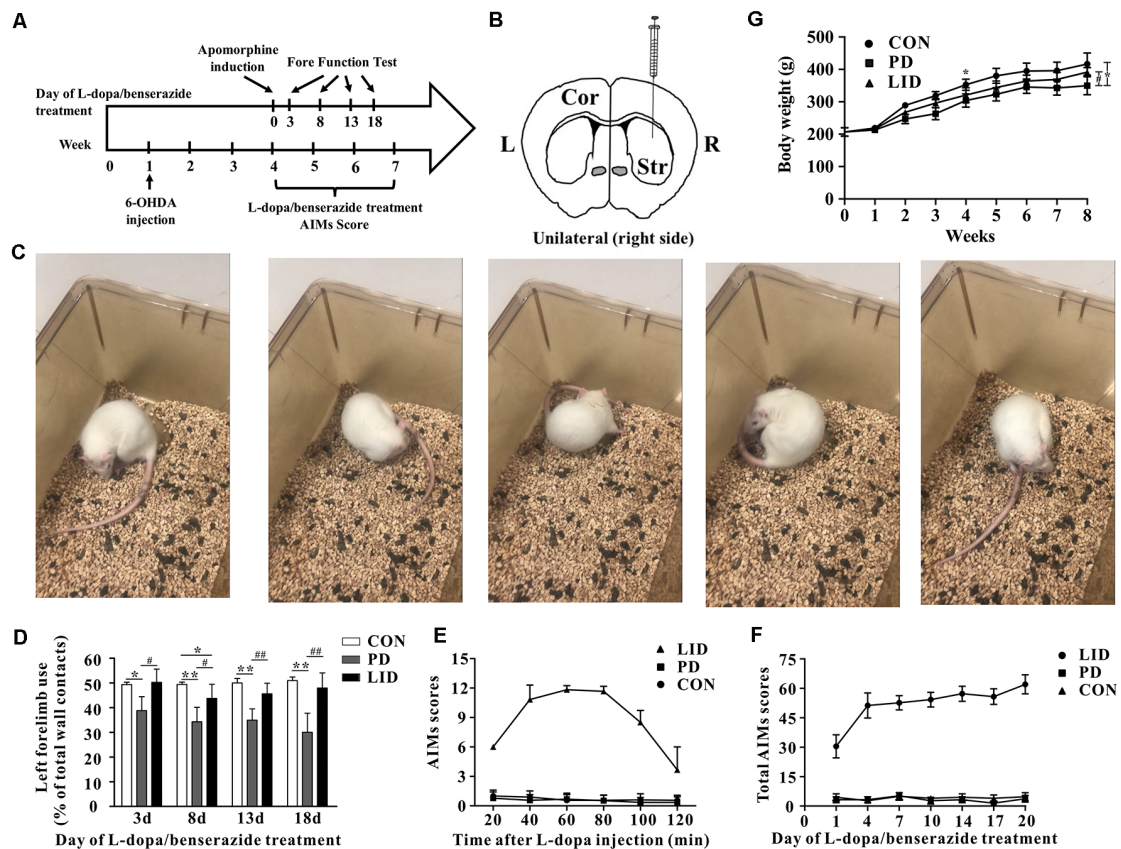

### Multivariate Analysis of NMR Data

After the pre-processing of the NMR spectra, including the bucketing process and total sum normalization to minimized small differences due to sample concentration among samples, NMR data was subjected for multivariate statistical analysis including unsupervised (PCA) and supervised (PLS-DA) multivariate statistical methods. As a first attempt, the PCA was used to quantitatively compare the global metabolomics profiling data collected from the six different brain regions of control (**Figure 3A**), PD (**Figure 3B**) and LID (**Figure 3C**) rats. The PCA score plot obtained for control rats revealed good separation among the different brain regions, especially along the first principal component PC1 (with PC1 and PC2 accounted for 43.6% and 18.1% of the total variance, respectively, **Figure 3A**). PCA score plot obtained for PD and LID rats showed similar, distinct separation among different brain regions (**Figures 3B,C**). As showed in **Figure 3**, the metabolic pattern in the striatum appeared as separate significantly from other brain regions, especially along the second principal component PC2. Whereas the midbrain and right cortex distribution was significantly different both in PD and LID rats compared with control rats, indicating midbrain-cortex crosstalk was involved in the behavioral symptoms of PD and LID.

### Brain Regional Specific Metabolic Disturbance Was Involved in Parkinson's Disease

To further explore discriminating features and potential biomarkers in brain function and disease, the supervised PLS-DA analyses were applied for six different brain regions from three groups (**Figure 4**). Moreover, a mixed-model analysis was applied to evaluate the effects of dopamine loss and L-dopa replacement on metabolite alterations in the PD and LID rats and the detailed results were shown in **Figure 5** and listed in **Supplementary Tables S1–S6**. As predicted, a clear separation between control and PD rats was observed

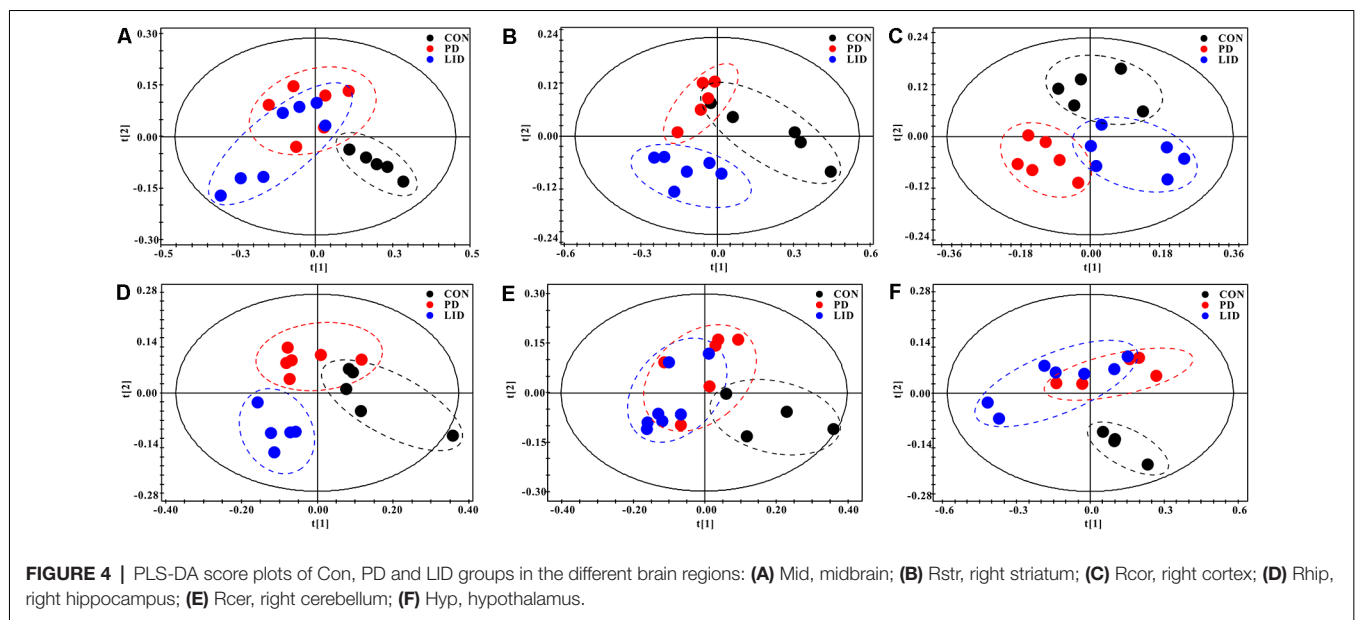

**FIGURE 1 |** Behavior performance of the experimental models of Parkinson's disease (PD) and levodopa-induced dyskinesia (LID). **(A)** The time scale of the experiments: 6-OHDA lesioning, L-dopa/benserazide treatment, and behavioral tests. **(B)** Schematic of stereotaxic injection of 6-hydroxydopamine (6-OHDA), the rats in the control group received sham-operation with physiological saline at the same location ( $n = 8-10$  for each group). **(C)** Apomorphine-induced rotation test. **(D)** Forelimb function tests at days 3, 8, 13, 18 of L-dopa/benserazide treatment. **(E)** AIMs 120-min time-score plot of three groups after L-dopa injection. **(F)** Total AIMs scores plot of three groups at Days 1, 4, 7, 10, 14, 17 and 20 of L-dopa/benserazide treatment. **(G)** Body weight over time of rats from three groups. \*Means the difference between Con group and experimental groups ( $t$ -test); # means the difference between PD and LID group ( $t$ -test). \* $P < 0.05$ , \*\* $P < 0.01$ ; # $P < 0.05$ , ## $P < 0.01$ .

**FIGURE 2 |**  $^1\text{H}$  NMR spectra of different brain sections obtained from control, PD and LID rats: Mid, midbrain; Cor, cortex; Str, striatum; Hip, hippocampus; Cer, cerebellum and Hyp, hypothalamus. 1. Lactate (Lac); 2. Alanine (Ala); 3. GABA; 4. N-acetyl aspartate (NAA); 5. Glutamine (Gln); 6. Glutamate (Glu); 7. Dimethylamine; 8. Aspartate (Asp); 9. Creatine (Cre); 10. Choline (Cho); 11. Glycerol-phosphocholine (GPC); 12. Taurine (Tau); 13. Myo-inositol (Myo); 14. Glycine (Gly); 15. Glu/Gln; 16. Inosine (Ino); 17. ADP/AMP; 18. Fumarate (Fum); 19. AMP; 20. IMP.

in the midbrain (Figure 4A) and striatum (Figure 4B). Accordingly, using hierarchical clustering on the profile of the identified 21 metabolites, the metabolic profile of midbrain

and striatum was strictly separated between control and PD rats, several interesting metabolite clusters became apparent as well (Figures 5A,B). One of these clusters contained glutamate

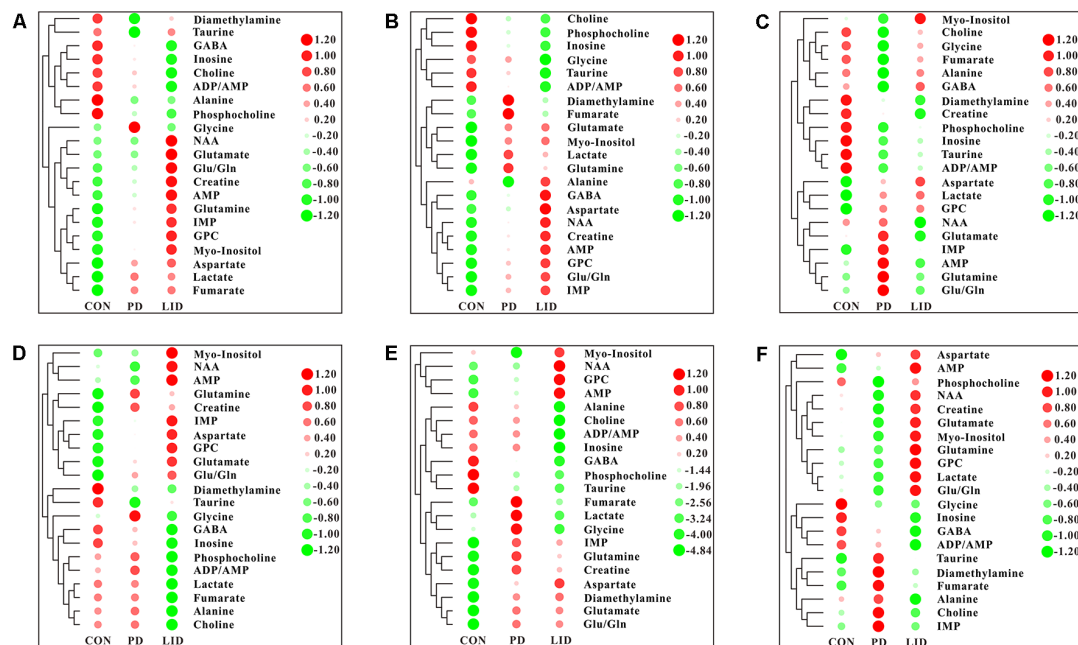

and glutamine, and this alteration in the glutamate metabolism pathway reflected neurotransmitter homeostasis in the brain (Bak et al., 2006). In addition, various products of energy metabolism pathways (e.g., taurine, lactate, and fumarate) in the striatum were altered in PD rats (Figure 5B).

Surprisingly, the metabolic profile of PD rats was also separated significantly in the other four brain regions: right cortex (Figure 4C), hippocampus (Figure 4D), cerebellum (Figure 4E) and hypothalamus (Figure 4F), respectively. The potential biomarkers, which are responsible for the separation were observed in the corresponding heatmap, respectively (Figures 5C–F). In summary, nine assigned metabolites with a significant difference were identified between Con and PD rats ( $P < 0.05$ ), including lactate, glutamine, GABA, aspartate, glycerol-phosphocholine, fumarate, Glu/Gln, glycine and taurine. Of note, the midbrain and cortex were the main brain regions that underwent significant metabolic disruption between the Con group and PD groups. These observations suggest that dopamine loss in PD rats produces a marked and persistent metabolic disturbance in neurotransmitter metabolism and energy pathway, resulting in a metabolic imbalance among different brain regions.

## L-Dopa Induces Brain Regional Specific Metabolic Disturbance During LID

The standard model predicts that by increasing striatal dopamine, L-dopa is hypothesized to restore the normal balance of striatal activity. To test the metabolic activity of the whole brain during LID, PLS-DA analyses were also performed for control and LID rats (Figure 4). PLS-DA score plots showed an even better separation in all the six brain regions than that observed comparing control and PD rats, especially in the midbrain (Figure 4A), striatum (Figure 4B), and right cortex (Figure 4C). Quantitative analysis on the metabolites from control and LID groups with  $T$ -test, total 10 significantly changed metabolites were detected between Con and LID rats, namely lactate, phosphocholine, aspartate, glycerol-phosphocholine, GABA, fumarate, glutamine, Myo-inositol, AMP, and alanine (Figure 5, Supplementary Tables S1–S6). Counter to our expectation, we found that the striatal metabolism was not restored in response to L-dopa, furthermore, during LID, relatively higher lactate, aspartate, glutamine, AMP and Myo-inositol was observed in midbrain and striatum, compared with that of the control group (Figures 5A–C). These findings confirmed that L-dopa replacement did not

**FIGURE 5 |** Heatmap displaying the identified metabolites in six different brain regions obtained from the brain of Con, PD and LID rats: **(A)** Mid, midbrain; **(B)** Rstr, right striatum; **(C)** Rcor, right cortex; **(D)** Rhip, right hippocampus; **(E)** Rcer, right cerebellum; **(F)** Hyp, hypothalamus.

restore the midbrain-striatum metabolic crosstalk and metabolic disturbance throughout the brain was involved in levodopa related involuntary movements.

## Glutamate-Glutamine Metabolic Cycle in Parkinson's Disease and LID

Since these results point toward neurotransmitter dysregulation as an underlying feature both in PD and LID, we sought to assess how the glutamate-glutamine cycle was affected by the disease in different brain regions (Figure 6). Remarkably, we found that the concentration of glutamate in the PD and LID groups was higher than that in the Con group, except for the hypothalamus in the PD group and the right cortex in the LID group (Figure 6A). Besides, the PD rats had a higher glutamine concentration than Con rats in all six brain regions, especially in the right cortex and right cerebellum (Figure 6B). The concentration of glutamine varied in the LID group compared to the Con group, which was significantly increased in the midbrain and right cerebellum ( $P < 0.05$ ). More interestingly, compared with the Con rats, the PD rats had a significantly higher concentration of aspartate in the midbrain, right cortex, right cerebellum and right hypothalamus, and a significantly increased of aspartate concentration occurred in all brain regions of the LID rats (Figure 6C). These results provide further evidence that glutamate-glutamine metabolism is dysregulated in PD and LID.

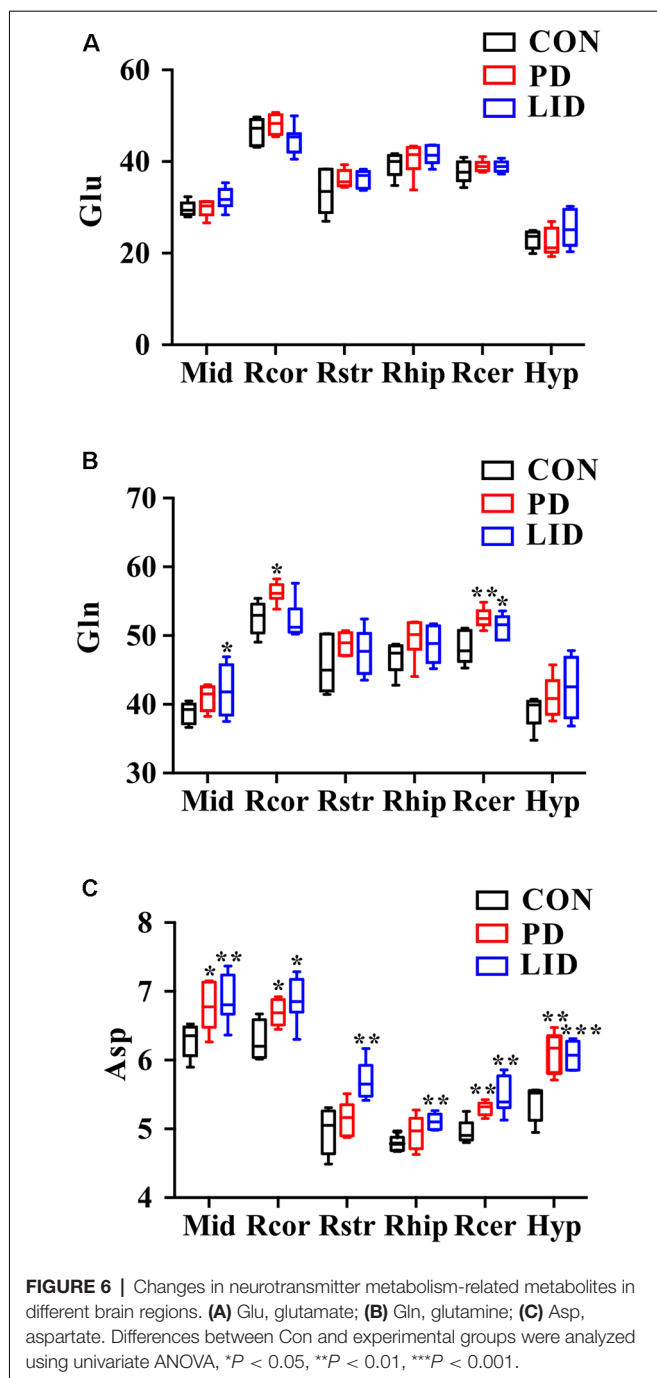

## Synaptic Plasticity Is Impaired in Parkinson's Disease and LID

It was noticed that there was a disorder of neurotransmitters in the PD and LID rats, we wondered if the synaptic plasticity,

which controls the release and recycle of neurotransmitters was also involved in the PD and LID disease. SYP, a standard presynaptic marker, which was responsible for synapse formation and neurotransmitter recycle (Wu et al., 2015). Immunofluorescence staining was performed to visually evaluate the expression of SYP in the right cortex of PD and LID rats. The immunofluorescence staining results showed that the density of SYP in the right cortex of PD and LID rats was lower than that in the Con rats (Figure 7A). Accordingly, the results of real-time RT-PCR also showed that the gene expression of SYP in the right cortex of PD and LID rats was significantly decreased compared to Con rats (Figure 7B).

## DISCUSSION

The potential metabolic mechanisms of PD and LID are not largely elucidated and keep a great challenge for the therapy of PD (Wang et al., 2014). In the present study, the  $^1\text{H}$  NMR-based metabolomics approach was performed to present the first widespread investigation of metabolic profile throughout the brain in a 6-OHDA-unilaterally-lesioned rat model. We found that: (1) dopamine loss in PD rats produces a marked and persistent metabolic disturbance in neurotransmitter metabolism and energy pathway, resulting in a metabolic imbalance among different brain regions; (2) L-dopa replacement did not restore the midbrain-striatum metabolic crosstalk and metabolic disturbance throughout the brain was involved in levodopa related involuntary movements; and (3) further multivariate general linear model identified that a significant perturbation of Glu-Gln-GABA cycle in midbrain and

right cortex of both PD and LID rats, accompanied by reduced synaptic plasticity.

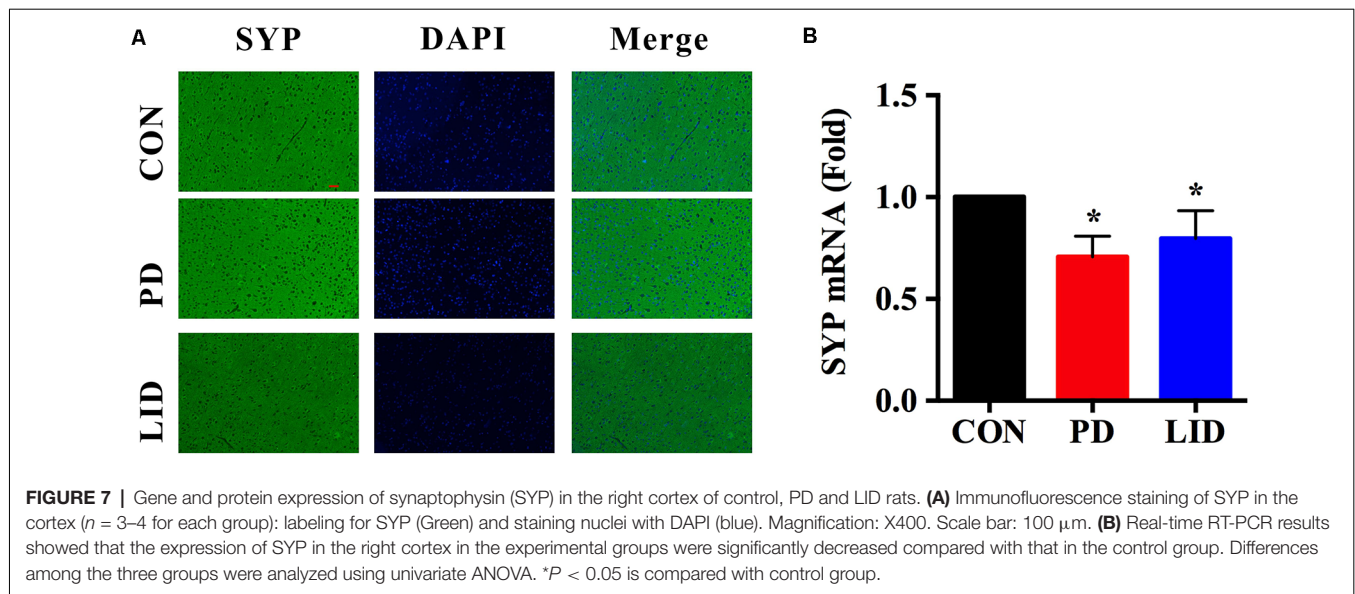

Although many investigators have posited that energy metabolism is critical to maintaining the normal brain function (Bélanger et al., 2011), previous studies of the metabolic mechanism of PD and LID had largely focused on the midbrain and striatum, while the global metabolic profile in the adult brain has not been extensively described. Consistent with a midbrain-striatum mediated mechanism of behavior modulation, the pattern of energy metabolism in midbrain and striatum we

identified in the current study is in-line with what described in numerous studies of both human and rodent models (Zheng et al., 2016, 2017). Notably, we found a significantly increased lactate level in the right striatum of 6-OHDA-lesioned PD and LID rats' respect to Con rats, which confirms previous studies that identified lactate served as a spare energy substrate and was critical in the brain function (Proia et al., 2016). Besides, the concentration of alanine of LID rats was significantly decreased compared with Con rats. Interestingly, compared with Con rats, the fumarate level was significantly decreased in the right cortex of PD rats and in the right hippocampus of LID rats. Taken together, these results suggest that while regional specific metabolic disturbance is a feature of PD, L-dopa replacement did not restore the midbrain-striatum metabolic crosstalk may still contribute to levodopa-evoked facilitation of movement in LID.

The multivariate analysis performed on brain metabolic profile also identified a significant difference in the levels of glutamate (Glu), glutamine (Gln) and aspartate (Asp) in PD and LID rats with respect to control rats. Glu is the main excitatory neurotransmitters which can enhance neuronal excitability whereas GABA is the primary inhibitory in the central nervous system (Rage et al., 1992). Glutamate is the metabolic precursor of GABA, which can be in turn transferred into synthesize glutamate through the TCA cycle (Petroff, 2002). Recent publications indicate that the Glu-Gln-GABA cycle is involved in a variety of neurological disorders (Zheng et al., 2016, 2017; Lu et al., 2018; Zott et al., 2019). In the present study, the Glu levels showed no significant differences among three groups, however, the concentrations of Gln were brain region-specific, for example, compared with Con rats, the Gln level increased in all brain regions of PD rats and most significantly in the right cortex and right cerebellum, and it significantly increased in the midbrain and right cerebellum of LID rats but decreased in the right cortex. Our previous study showed that the disturbed Glu-Gln-GABA cycle occurred in the striatum of PD rats and bFGF treatment might alleviate PD symptoms through regulating these alterations (Zheng et al., 2016), another study reported that there was a significantly decreased striatal level of Glu in LID rats (Wang et al., 2018). Both higher or lower levels of Glu can be noxious, as excessive Glu can stimulate the activation of the NMDA receptor and induce excitatory toxicity (Jazvinšćak Jembrek et al., 2018).

Asp is another excitatory neurotransmitter in the central nervous system (Liu et al., 2013). Notably, the concentrations of Asp increased in all brain regions of rats in the experimental groups compared with the control group. Except for the right striatum and right hippocampus, the Asp level in PD group was significantly higher than that in the Con group and the Asp level in all brain regions had significant differences between Con and LID group. Since Glu, Gln and Asp are critical neurotransmitters, the brain-regional disturbance in neurotransmitters level observed in both PD and LID model could be considered a functional perturbation of Glu-Gln-GABA cycle in the synapse. We wondered if the PD as well as LID was associated with the changes of synaptic plasticity. In recent years, abnormal synaptic plasticity of cortical neurons was found

to be causally involved in PD and LID (Ueno et al., 2017). Our results showed that the expression of SYP, a critical marker for synaptic structure and plasticity (Zhu et al., 2019), significantly reduced in the right cortex in PD and LID rats. We, therefore, hypothesized that synaptic damage and neurotransmitter disturbance was involved in LID in parkinsonism, thus could be a potential target in the treatment or prevention of motor function impairment in PD and LID.

Meanwhile, osmoregulation plays an important role in maintaining cell structure and function. Myo is regarded as a marker for astrocytic and has various physiological functions such as membrane structure and osmoregulation (Isaacs et al., 1994; Edamatsu et al., 2018). In the present study, a significantly increased level of Myo in the midbrain and right hypothalamus of LID rats but no differences in PD rats as compared to normal rats may indicate the changed astrocytic activity underlying LID. Tau, another organic osmolyte in the brain, which was critical in osmoregulation and membrane stabilization (Trachtman et al., 1992). However, relative to Con rats, the concentration of Tau was only significantly decreased in the midbrain of PD rats but not in LID rats, suggesting that osmoregulation may be involved in PD. Thus, the disturbed osmoregulation as well as astrocytes-neurons crosstalk might involve in the occurrence of PD and LID.

The results of this study have detailed a widespread yet brain-regional specific metabolic disturbance in PD and LID rats. The midbrain and cortex exhibited significant metabolic disorders more than other brain regions. Moreover, various neurotransmitters and several intriguing metabolites, including glutamate, glutamine, aspartate, and myo-inositol were identified among the most discriminating metabolites. Our results suggest a possible mechanism: metabolic perturbation of neurotransmitter metabolism, especially in the synaptic Glu-Gln-GABA cycle may represent the pathological basis for the onset of PD and dyskinesia. While additional experiments will be necessary to firmly establish causal relations

between metabolic disturbance and dyskinesia, these findings highlight the glutamate-glutamine cycle and synaptic plasticity in LID.

## BIOSECURITY STATEMENT

All standard biosecurity and institutional safety procedures have been adhered to in all the experiment procedures in this article.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

## ETHICS STATEMENT

The animal study was reviewed and approved by the Institutional Animal Care and Use Committee of Wenzhou Medical College (wydw2018-015).

## AUTHOR CONTRIBUTIONS

HG, YY, and CY contributed to the experimental design. TZ, YX, QH, and CX contributed to animal experiments and behavior testing. TZ, WW, LZ, and HZ contributed to the sample collection, NMR metabolomic analysis, and synaptic plasticity analysis. CY, TZ, and HG contributed to the data analysis, result interpretation and writing. All authors have read, revised and approved the final manuscript.

(2020) Relationship Between Exercise  
and Alzheimer's Disease: A Narrative  
Literature Review.  
Front. Neurosci. 14:131.  
doi: 10.3389/fnins.2020.00131

This narrative review aimed to summarize evidence regarding the responses to exercise among patients with preclinical Alzheimer's disease (AD) and the effectiveness of long-term exercise interventions in improving cognitive function and neuropsychiatric symptoms. We performed a narrative review of existing literature on the effectiveness of long-term exercise interventions in improving cognitive function and neuropsychiatric symptoms in patients with AD. Patients with AD who presented with long-term exercise interventions appeared to have improved blood flow, increased hippocampal volume, and improved neurogenesis. Most prospective studies have proven that physical inactivity is one of the most common preventable risk factors for developing AD and that higher physical activity levels are associated with a reduced risk of AD development. Physical exercise seems to be effective in improving several neuropsychiatric symptoms of AD, notably cognitive function. Compared with medications, exercise has been shown to have fewer side effects and better adherence.

**Keywords:** Alzheimer's disease, neurogenesis, cognitive function, exercise, hippocampal volume

## BACKGROUND

Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by memory loss and multiple cognitive disorders (Reddy and Oliver, 2019). This symptom is the most frequent cause of neurogenesis. Individuals with AD develop progressive mild cognitive impairment (MCI), leading to the development of neuropsychiatric manifestations. Agitation and anxiousness are common complications in individuals diagnosed with AD. Other complications such as bladder and bowel problems, depression, infection, and head trauma or broken bones are the main cause of imbalance and incoordination in these patients (Higuera, 2016).

Alzheimer's disease is associated with common causes of dementia and is estimated to account for 60–80% of these cases (Alzheimer's Association [AA], 2016). Aging can be treated as the greatest risk factor for AD progression. About 81% of AD patients are aged over 75 years as estimated by the Alzheimer's Association [AA], 2016). The diagnosis and treatment of AD involves many challenges. Studies have shown that drug combinations are effective and that there is no efficient treatment for patients diagnosed with preclinical AD or MCI. With respect to the definition of MCI, it is regarded as a syndrome of cognitive decline that is higher than the expectation of the age of individual and level of education

without significantly obstructing with daily living activities. Notably, it develops into AD during 5 years in over half of the MCI patients (Gauthier et al., 2006). Based on the possibility of side effects of drugs, people are very interested in the non-pharmacological treatment of AD (Raggi et al., 2017).

Inconsistent benefits of treatments, comprising cognitive training and cognitive stimulation, have been reported. There is an intension to prevent and treat AD, MCI, and dementia via regular exercise (Laurin et al., 2001; Lindsay et al., 2002; Andel et al., 2008). This article aims to review important studies with this scope and consider the association of exercise and AD in patients.

## OVERVIEW OF ALZHEIMER'S DISEASE

Alzheimer's disease is a chronic neurodegenerative disease in which pathological features include changes in the brain structure and function (Scheltens et al., 2016). The consequences have a significant impact on individual lives and societal costs (World Health Organization [WHO] and Alzheimer's Disease International [ADI], 2012). The emotions derived from the disease, changes in neurocognition, and physical disability are common and also lower the quality of life considerably, e.g., higher dependence on people and reduction of functioning mobility (Glenthøj et al., 2017). Additionally, the prevalence rate of depressive symptoms in AD patients was 10 times higher than that in the normal population (Lee and Lyketsos, 2003; Strober and Arnett, 2009). Approximately 747,000 (15%) Canadians aged over 65 years were affected by a particular form of person cognitive impairment or dementia in 2011 (Alzheimer Society of Canada [ASC], 2011). Around 60–70% of people have AD (World Health Organization [WHO] and Alzheimer's Disease International [ADI], 2012). Commensurate statistics from United States estimate that nearly one in eight among the aged have AD (Alzheimer's Association [AA], 2012). Therefore the annual cost for treatment is as high as \$600 billion (World Health Organization [WHO] and Alzheimer's Disease International [ADI], 2012). The care cost is estimated to grow to around \$20 trillion for American AD patients if the present trend is unchanged for the next 40 years (Alzheimer's Society [AS], 2010). Psychosocial care takers still need to take on the burden of AD-related disease even though the economic cost has been cut back in Canada (Herrmann et al., 2010). The age-standardized death rate (per 100,000 people) of the aged in Ontario remains stable (Statistics Canada, 2011). The results show that women's death rate are higher than men. It seems older people (over 65 years of age) represent number of AD patients' growth was more than other age groups. Early identification and management of AD is a challenging task but a public health priority.

## DIAGNOSIS AND TREATMENT

Diagnosis is mostly clinical and commonly includes the patient's main care doctor. Acquiring good medical, family

medical, and neuropsychiatric history is essential. If necessary, neuropsychological test and serologic tests for biomarkers can bolster the diagnosis. Other causes of dementia are ruled out by routine laboratory test with whole blood cell counts, metabolome comparison, thyroid stimulating hormone, vitamin B-12, folate, and MRI. These are regarded as part of the routine diagnostic examination.

In accordance with the definition of National Institute on Aging in 2011, AD is characterized by three progressive and overlapping stages of deterioration, including preclinical AD, MCI, and Dementia (Sperling et al., 2011). In the early phase of the disease, most of the symptoms may be misinterpreted as ordinary changes in behavior, attention, and forgetfulness (Burns and Illiffe, 2009). The intricacies and gradualness of the symptoms have led to some people classifying the features as "syndromes."

The only way to obtain a definitive diagnosis of AD is through autopsy and an accurate examination of the brain tissue (Caroli and Frisoni, 2009). However, physician diagnosis can reach relatively high accuracy in a clinical setting because serum or cerebrospinal fluid biomarkers have been proven to provide high diagnostic accuracy, accounting for 85–90% for sensitivity and specificity (Jack et al., 2010; Scheltens et al., 2016). Thus the diagnostic accuracy is as high as 90%.

Factors associated with the clinical analysis of AD cases are particular medical history and physical examination to determine the family history of dementia and changes in behavior, mood, and motor performance and to rule out other explanations so that physicians can oversee, treat, and arrange supporting services (Burns and Illiffe, 2009).

## RISK FACTORS

Age is the biggest risk factor for AD. There is a possible minor risk (less than 1%) owing to gene mutation, mutant amyloid precursor proteins, among patients account 40–65% with AD may also accompany APOE-ε4 genetic variant (Mahley et al., 2006; Alzheimer's Association [AA], 2016). Family history can be another risk factor for AD; it can also be influenced by cardiovascular disease, low education level, social factors, and cognitive involvement, as well as traumatic brain injury prior to MCI (Alzheimer's Association [AA], 2016). The evidence also shows that chronic disease risk factors (such as physical inactivity, diabetes, smoking, abdominal obesity, and high cholesterol) (Purnell et al., 2009; Li et al., 2011) may increase the risk of developing AD, whereas social participation and low saturated fat/high fiber vegetable diet can reduce the risk of developing AD (Alzheimer's Association [AA], 2012).

It is unclear whether this relationship is dependent on the dose; it seems that there is reduced risk with higher levels of physical activity (Yaffe et al., 2001). This may be vital in patients with risk factors or early progression MCI. Exercise seems to have potential benefits for people diagnosed with AD. However, the management of AD is still challenging. Drug treatment is limited to date. Three most common classes of drugs include: acetylcholinesterase inhibitors for behavioral symptoms;

N-methyl D-aspartate antagonists to treat cognitive decline and slow progression of AD; and antipsychotics (not recommended) (National Institute of Aging [NIA], 2008). Other complementary treatments such as group-based social procedures (e.g., art and music) and cognitive and emotional orientation treatments (e.g., psychotherapy, validation, recall, etc.) have been used and have varied ineffectiveness (Olazarán et al., 2010; Ballard et al., 2011).

## NEUROPHYSIOLOGY

One of the most vital and majestic organs in an organism is the brain which can be categorized under the CNS. A human brain contains approximately 98% of the body's neural tissue (Martini et al., 2011). It consists of over 100 billion nerves that are connected to one another through long protoplasmic fibers named axons (Hendrickson, 2004). These fibers carry signal pulses to different parts of the brain and body targeting specific recipient cells. The main function of the brain is to conduct, consolidate, and control different organs of the body physiologically. Brain coordinates and controls most of the sensory system, social behavior, muscle movements and synchronized body functions such as heart and respiratory rate, blood pressure, fluid balance, and body temperature. The brain is the cradle of mood, emotion, cognition, memory, motor, and different forms of learning.

Exercise could be a strategy to prevent or postpone the aging brain from decline in cognition (Barnes, 2015). Thus, a great amount of effort and research have undertaken to understand the physiology of aging brain, which is changed or tempered by exercise (Marks et al., 2011; Burzynska et al., 2014; Bullock et al., 2018). Exercise may cause effects on three areas of the brain: vascular physiology, hippocampal volumes, and neurogenesis (Barnes, 2015). With advancing age, blood flow to the brain is negatively influenced and is related to cognition (Barnes, 2015). It is shown that moderate-intensity exercise causes intense augmentation of blood flow to the brain, also the cerebral blood flow increment is found in participants trained by exercise than participants who were seated for a long period (Bailey et al., 2013). A randomized trial with 12-week-long exercise training showed that the cerebral blood flow is higher in the anterior cingulate cortex (Chapman et al., 2013). In AD, hippocampal circuits that are considered as relatively significant for episodic-like memory are affected initially. Higher volume of the hippocampus is related to improved cognition. Over a year of mild-to-moderate exercise seems to protect against shriveling hippocampal volume (Duzel et al., 2016). Hippocampal volume variation was also associated with improved heart health (Duzel et al., 2016). Physical exercise can improve cognitive ability and is associated with a boost in the hippocampal volume as shown by Erickson et al. (2009). Currently, it has been assessed that AD is caused by neuropathological and physiological factors. The current drug treatment for AD is aimed at an advanced stage, where severe morbidity, mortality and the burden on caregivers may increase. For the early stages of AD and general dementia prevention, exercise seems to be a useful way to treat and prevent it (Tabei et al., 2018).

## PHYSICAL ACTIVITY AND ALZHEIMER'S DISEASE

Prospective studies have shown that physical activity can reduce the likelihood of dementia and AD, even at mild to moderate intensity (Yaffe et al., 2001; Erickson et al., 2009; Hamer and Chida, 2009; Smith et al., 2010; Barnes and Yaffe, 2011; Sattler et al., 2011; Buchman et al., 2012; Norton et al., 2014). Exercise could help diminish the occurrence of dementia and AD so that it has been cited as a possible lifestyle intervention. Some previous studies have proof to support this hypothesis. A study measured that 54% of AD risk factors may be avertible (Barnes and Yaffe, 2011). Another study estimated the demographic risk of global AD, which can be attributed to seven potentially adjustable risk factors by using the relative risks of existing meta-analyses (Norton et al., 2014). The lack of physical activity was the highest attributable risk that they found. In a systematic review that collated evidence from 163,000 non-psychotic participants and compared highest physical activity category to the participants with least relative risk of dementia (Hamer and Chida, 2009). They also found that the risk of dementia and AD can be lowered by 28% and 45% with physical activity. A systematic review of randomized controlled trials observing the connection of exercise and cognitive performance between 1966 and 2009 was completed by Smith et al. (2010). They chose research that had ample influence, supervised aerobic exercise programs and control groups. They showed improvement in attention and processing speed in the exercise group, executive function and memory improvement. Inconsistency of the impact on working memory was seen. The duration of exercise or intensity seems to be essential for the benefit. As mentioned earlier, the hippocampus of dementia patients gets decayed. Erickson et al. (2009) observed the relation between exercise and hippocampus because exercise effectively reduces cortical decay in the elderly. They noticed that among 165 non-demented elderly people, active individuals had higher levels of health, larger hippocampus, and better spatial memory by using MRI. The benefits of exercise for diminishing cognitive degeneration and dementia have been demonstrated by population-based prospective studies. A 14-year time course German population study showed a lower risk of MCI and AD in participants with regular physical activity and better performance in the neuropsychological tests (Sattler et al., 2011). Another prospective trial examined the hypothesis that objectively measuring daily activities could forecast the incidence rate in AD and MCI (Buchman et al., 2012). Participants wore wrist activity recorders to observe their overall physical activity instead of relying on questionnaires, which self-reported in this study. It was determined that levels of daily overall activity were associated with incidence of global cognitive decline and AD, at 4 years of follow-up. A significant reduction in AD risk was associated with higher levels of physical activity. Besides, a prospective study of more than 8 years showed that women who walked more had less cognitive decline during the entire study period (Yaffe et al., 2001). A Cochrane review examined how aerobic activity affected mentally healthy older adults. The objective was to assess whether heart health affects the impact

of physical activity on cognition (Forbes et al., 2015). With this intention, they included trials that have demonstrated an increase in cardiovascular health through a test for VO<sub>2</sub>max. Their findings did not show any evidence of the benefits of exercise in cognition and the research they studied had a moderate to high risk of bias (Forbes et al., 2015). It has to be considered that their comments exclude studies where exercise interventions do not add cardiovascular health (i.e., mild aerobic exercise), weightlifting or stretching. Studies that performed a test for VO<sub>2</sub>max or other tests for heart health were included. We found that comments may be useful for a specific individual subgroup, but should be cautious in interpretation. In addition, other systematic reviews and meta-analyses show that exercise has significant improvements and benefits in cognition (Farina et al., 2014).

## EXERCISE AS TREATMENT FOR ALZHEIMER'S DISEASE

Although several studies have shown that exercise has a potential benefit in declined cognition, are there any evidences to prove that exercise is good for people with AD? Some of the previous studies have limitations associated with randomization and surveillance in the group with treatment. There are also relatively few large-scale studies focusing on Alzheimer's patients.

A randomized, controlled trial was designed to tackle these issues by evaluating whether exercise programs could impact the decline in activities of daily living (ADL) in AD patients (Rolland et al., 2007). With an hour of training twice a week in aerobic exercise, strength level, balance skill and flexibility as intervention for 1 year, they found that ADL was slower than the non-active group. However, there was no effect on behavioral disorders, depression or nutritional scores. Another study attempted to compare the effects of drug and exercise on AD and MCI (Ströhle et al., 2015). The study allowed for including exercise or pharmacological intervention as the treatment group. For AD, exercise had a medium to strong pooled effect size, with a small effect on MCI. Treatment with a cholinesterase inhibitor in the meantime had a consequent slight effect on the perception in AD but had no effect on MCI. Note that the drug withdrawal rate is very high, but the exercise group has a much lower rate of discontinuation. In addition, systematic reviews and meta-analyses display improvement in dementia, reduced neuropsychiatric symptoms, and slight decline in ADL (Hamer and Chida, 2009; Smith et al., 2010; Forbes et al., 2015). In a large systematic review, exercise had less side effects and superior compliance than medications (Ströhle et al., 2015). Exercise also has intrinsic benefits for cardiovascular health and personal health. It is difficult to suggest specific exercises for AD patients or for prevention of AD based on the available evidence. These studies including the various types of exercises are established based on the duration of intervention. Nelson et al. (2007) believe the American Sports Medicine Association and the American Heart Association's recommendations can be used to comprehensively treat the elderly. These suggestions are also

more likely to cover most of the support activities needed to identify potential benefits.

A randomized controlled trial examined aerobic exercise programs with moderate to high-intensity on mild AD patients (Hoffmann et al., 2016). Training for 60 min was performed three times a week for 16 weeks, but there was no benefit for cognitive ability; however, the score on neuropsychiatric symptoms significantly improved. This study is indeed related to subjects that follow the training program. A general problem is that most people use intentional treatment models in their studies. During longer intervention studies, you are more likely to see compliance disruptions throughout the process. This makes the duration of intervention support for observation questionable. A 3-month randomized study looked at supervised exercise program three times a week (Chapman et al., 2013). Through the training interval, they found immediate and delayed memory improvements. In the anterior cingulate area, the exercise group also showed a cerebral blood flow while resting. Unfortunately, we may not be able to compare findings of AD patients to adults with normal cognition. Another minor study of eight people with MCI observed an exercise intervention for 9-months and a training during 2, 3-months (Sacco et al., 2016). Their cognitive performance improved, but their influence weakened after disrupting the training. A Cochrane review investigated the effects of exercise on Alzheimer's patients (Forbes et al., 2015). Their meta-analysis showed no clear evidence that exercise is beneficial for cognitive function. However, they did get the ability to perform ADL from the exercises. It should be noted that the results and studies found by the reviewers comprised diverse data and lack of quality owing to insufficient evidence. They suggest more qualified trials to assess various dementias of different types with severity, which will help to improve the quality of evidence for reviews (Forbes et al., 2015). Finally, a few systematic reviews and accompanying analyzed results showed a favorable effect on AD patients receiving exercise programs based on six randomized controlled trials (Farina et al., 2014). Farina, Rusted, and Tabet show a downturn in a declining rate of cognition and a positive impact on global cognitive function (Farina et al., 2014).

## LIMITATIONS

The study was conducted under narrative review approach. There are several limitations of this research. First, hypothesis was set as board overview of a topic-related research area. Second, search method depends on non-predefined protocol based which may involve subjective selection bias. Third, inclusion criteria of studies for review also rely on researchers' experiences. Finally, search media usually via PubMed or Medline. In the meantime, extracted studies with non-protocol based may partially grade objectively by anecdotal resources for their quality.

## CONCLUSION

To present the core information of this review, we constructed a **Supplementary Table S1** has brief summary extracted

from aforementioned references (except citations from specific associations and monograph). Systematic reviews and meta-analyses indicate the benefits of physical activity based on large-scale prospective trials. Unfortunately, many of these comments and studies have been plagued by methodological problems and noted the heterogeneity of the population.

In the next few decades, AD will be a huge challenge for the country in the field of medicine. Moreover, there are still much to learn despite a lot of rigorous and large-scale research. More high quality randomized trials are needed to really determine if AD can be prevented and treated by exercise.

## AUTHOR CONTRIBUTIONS

QM and I-ST proposed the research idea, wrote the background and conclusion, and contributed to the literature review. M-SL supported the literature review, helped to revise the

manuscript and provided clinical suggestions. I-ST prepared the manuscript for submission. All authors read and approved the final manuscript.

## FUNDING

Huaqiao University's Academic Project Supported by the Fundamental Research Funds for the Central Universities (19SKGC-QT06) for this study.

Identifying patients with mild cognitive impairment (MCI) who are at high risk of progressing to Alzheimer's disease (AD) is crucial for early treatment of AD. However, it is difficult to predict the cognitive states of patients. This study developed an extreme learning machine (ELM)-based grading method to efficiently fuse multimodal data and predict MCI-to-AD conversion. First, features were extracted from magnetic resonance (MR) images, and useful features were selected using a feature selection method. Second, multiple modalities of MCI subjects, including MRI, positron emission tomography, cerebrospinal fluid biomarkers, and gene data, were individually graded using the ELM method. Finally, these grading scores calculated from different modalities were fed into a classifier to discriminate subjects with progressive MCI from those with stable MCI. The proposed approach has been validated on the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort, and an accuracy of 84.7% was achieved for an AD prediction within 3 years. Experiments on predicting AD conversion from MCI within different periods showed similar results with the 3-year prediction. The experimental results demonstrate that the proposed approach benefits from the efficient fusion of four modalities, resulting in an accurate prediction of MCI-to-AD conversion.

**Keywords:** Alzheimer's disease, extreme learning machine, mild cognitive impairment, multimodal, prediction

## INTRODUCTION

Alzheimer's disease (AD) is the most common cognitive impairment disease, which gradually impacts the activities of a patient's daily life. The number of AD patients was estimated to be approximately 30 million in 2015 (Vos et al., 2016), which has placed a huge socioeconomic burden on those taking care of AD patients. The pathology changes of AD begin several years before the

first clinical symptoms, and mild cognitive impairment (MCI) is thought to be the prodromal stage of AD (Markesbery and Lovell, 2010). Approximately 10–17% of those with MCI progress to AD over the course of a few years, yet some MCI patients remain stable after several years (Hamel et al., 2015). It is crucial to identify people who are at high risk of progressing from MCI to AD because it can help physicians treat these patients sooner and apply suitable therapies to slow down the progression or even improve a patient's condition. Numerous studies have used machine learning techniques for computer-aided diagnosis of AD or prediction of AD conversion. The diagnosis of AD is relatively easier than the prediction of AD because there are apparent differences between AD and a normal control (NC), and the accuracy of diagnosis has reached to above 96% (Lei et al., 2016; Kim and Lee, 2018). However, the prediction of AD, more specifically, discriminating progressive MCI (pMCI) from stable MCI (sMCI), is more challenging because the differences between these two groups are slight.

Different modalities of medical data have been used to detect the pathology associated with AD. Structural magnetic resonance imaging (sMRI) is one of the most widely used modality due to its high resolution and non-invasive characteristics (Querbes et al., 2009; Oliveira et al., 2010; Coupé et al., 2012; Eskildsen et al., 2013). AD patients are always accompanied by cerebral atrophy or ventricular expansion that is caused by the death of neurons in the affected regions. The cerebral atrophy patterns associated with AD can be revealed by MRI, and MRI is a good detection technique for the atrophy of AD. Moradi et al. (2015) calculated an MRI-based biomarker for the prediction of MCI-to-AD conversion. Tong et al. (2017a) applied an elastic net regression to grade MRI features and to predict MCI-to-AD conversion. Lin et al. (2018) used a convolutional neural network-based framework to extract high-level AD-related features from MRI for the prediction of AD. These methods only focused on MRI data and could only predict a 3-year AD conversion with an accuracy no greater than 80%. Fluorodeoxyglucose positron emission tomography (FDG-PET) is another useful neuroimaging modality for the detection of AD. Studies (Mosconi et al., 2009; Jack Jr., Knopman et al., 2010; Landau et al., 2011) have shown that AD and MCI patients have reduced glucose metabolism in certain cerebral regions, which occur prior to the changes in brain structure. The brain's metabolic activity can be quantitatively measured by FDG-PET, which makes FDG-PET a potential tool for the early detection of AD (Gray et al., 2013; Cheng et al., 2015; Iaccarino et al., 2017). In a recent study (Lu et al., 2018), FDG-PET images were used in a multiscale deep neural network to classify AD/NC and pMCI/sMCI, where accuracies of 93.58 and 82.51% were achieved, respectively. In addition to MRI and FDG-PET, biological biomarkers can also contribute to the detection of AD. The abnormal concentrations of proteins in cerebrospinal fluid (CSF), such as total tau (T-tau), hyperphosphorylated tau (P-tau), and the 42 amino acid isoforms of amyloid  $\beta$  (A $\beta$ 42), are some of the earliest signs of AD that occur many years before the onset of clinical symptoms (Niemantsverdriet et al., 2017). Therefore, these biomarkers can provide valuable information for the early detection of AD. Genetics are also an important

indicator of the risk of AD. Individuals with the apolipoprotein E (APOE)  $\epsilon$ 4 gene have a much higher risk of developing AD than those without APOE  $\epsilon$ 4 (Vounou et al., 2012; Lambert et al., 2013). Taking APOE  $\epsilon$ 4 into account with imaging or biological biomarkers can improve the accuracy of AD prediction.

Different modalities of biomarkers reflect the AD-related pathological changes in different aspects, thus there may be complementary information among several modalities. Combining multimodal biomarkers would provide more information and improve the accuracy of AD prediction. A simple way to fuse different modalities is to directly concatenate multimodal features and feed them into a classifier (Kohannim et al., 2010; Walhovd et al., 2010; Westman et al., 2012). However, this is not the optimal approach, and it can lead to bias of the modality with a larger number of features. A better way is to map these multimodal features into a kernel space before concatenation (Hinrichs et al., 2011; Zhang et al., 2011; Young et al., 2013), but these methods are sensitive to the weight assigned to each modality. In recent years, deep learning architecture has been employed to extract multimodal feature representations. Liu et al. (2015) used stacked auto-encoders and a zero-mask strategy to fuse MRI and PET data. Suk et al. (2014) proposed a joint feature representation of MRI and PET with a multimodal deep Boltzmann machine. Liu et al. (2018) constructed multiple deep three-dimensional (3D) convolutional neural networks to transform MRI and PET images into compact high-level features. These deep learning-based methods achieved promising results in the classification of AD/NC, but the accuracy of classifying pMCI/sMCI was just 74.58% (Suk et al., 2014). To exploit the complementarity across multimodal data, Tong et al. (2017b) employed a non-linear graph fusion that achieved better results in the diagnosis of AD and a three-way classification of AD/MCI/NC than the approaches based on a linear combination, but the classification of pMCI from sMCI was not validated. Although all of these multimodal data-based methods achieved promising results in the diagnosis of AD, the performance of AD prediction needs to be further improved for clinical use with the help of an efficient fusion of multimodal biomarkers.

Since the efficient multimodality fusion can improve the performance of an artificial intelligence system (Hu et al., 2018), in this work, we present a novel extreme learning machine (ELM)-based (Huang et al., 2012) grading method to combine four modalities (MRI, FDG-PET, CSF, and APOE  $\epsilon$ 4) that predict MCI-to-AD conversion. Specifically, each modality feature, from the MCI subjects, was individually graded by an ELM that trained with the corresponding modality features of AD and NC, and the grading score represented the similarity of MCI-to-AD or NC. Then, the scores of all modalities were concatenated and fed to an ELM classifier for classification of pMCI/sMCI. The results of the proposed method were evaluated by 100 runs of 10-fold cross-validation with data from the ADNI cohort. The contributions of this paper are as follows:

- (i) Useful information about AD/NC was included by using the AD/NC features when training the grading ELMs, which improved the process of discriminating pMCI from sMCI.

- (ii) These grading ELMs were trained with discrete labels of AD/NC and modified to output grading values, instead of discrete labels, to represent the similarity of MCI to AD or NC.
- (iii) Each modality was graded into one single score, avoiding bias of the modality with a greater number of features.
- (iv) The proposed approach achieved promising results in the prediction of MCI-to-AD conversion.

## MATERIALS

The multimodal data used in this study included 313 MRI features, 20 FDG-PET features, three CSF biomarkers, and one gene feature. The MRI features, consisting of volume, surface area, and cortical thickness of the cerebral regions, were obtained through analysis with the FreeSurfer software using cross-sectional processing (Fischl and Dale, 2000; Fischl et al., 2004). There was 345 features obtained from the FreeSurfer analysis; however, because 32 features were absent from most subjects, only 313 MRI features were selected. For FDG-PET scans, five regions, frequently cited in FDG-PET studies of AD, were adopted, including left angular, right angular, bilateral posterior cingulate, left inferior temporal, and right inferior temporal (Landau et al., 2010; Landau et al., 2011). The mean, minimum, maximum, and standard deviation values of the intensity in each region were taken as the FDG-PET features. The levels of the biomarkers A $\beta$ 42, T-tau, and P-tau in CSF were used as the CSF features. The gene feature was a single categorical variable indicating the presence of APOE  $\epsilon$ 4 in subjects. All the multimodal data were downloaded from the ADNI website. Specifically, the MRI, CSF, and gene data were provided by the Tadpole Challenge Data files, and the FDG-PET data were provided by the UC Berkeley FDG Analysis file.

To date, there have been over 1,500 participants, ages 55 to 90 years, recruited by ADNI, and most of them were visited and tested multiple times in the following years for long-term study. In this study, we only take baseline data to predict the future state (progress to AD or remain MCI) for MCI subjects. Because not all subjects underwent all possible examinations, we excluded subjects without all modalities data available at the baseline visit, which presented 200 NC subjects, 102 AD subjects, 110 pMCI subjects who converted to AD within 3 years, and 205 sMCI subjects who did not convert to AD. Demographic and clinical information of these subjects are listed in **Table 1**,

including gender, age, education history, and Mini Mental State Examination (MMSE) score.

## METHODS

The overall framework of the proposed approach is shown in **Figure 1**, and we also summarize the process of our proposed approach as pseudo-code in **Algorithm 1**. There are three major steps in this framework: (i) MRI features are first preprocessed by feature selection with the least absolute shrinkage and selection operator (LASSO) algorithm; (ii) each modality (CSF and gene are combined as biological modality) of MCI is graded by ELM. These ELMs are trained with corresponding modality of features and labels from AD/NC groups. A grading score is calculated for each modality, which represents the similarity of MCI-to-AD or NC; (iii) these scores are combined to form the new representative features of MCI and fed into an ELM classifier to discriminate pMCI from sMCI. Ten-fold cross-validation is utilized to assess the performance of the proposed approach. Before these steps, all features of AD/NC are first normalized to have zero mean and unit variance. The features of MCI are also normalized with the mean and deviation of the AD/NC features. In the following sections, we will present the details of these steps.

### Feature Selection With Least Absolute Shrinkage and Selection Operator

Different from other modalities, the MRI features are the morphological characters of all cerebral regions. However, some of them may be aging-related and not AD-related, which can interfere with the classification, and thus need to be excluded. In this study, we adopted LASSO to select only useful MRI features. LASSO is an  $L_{2,1}$  norm sparse regression model (Kukreja et al., 2006) and has the following formula:

$$\min_{\alpha} 0.5\|y - D\alpha\|_2^2 + \lambda\|\alpha\|_1. \quad (1)$$

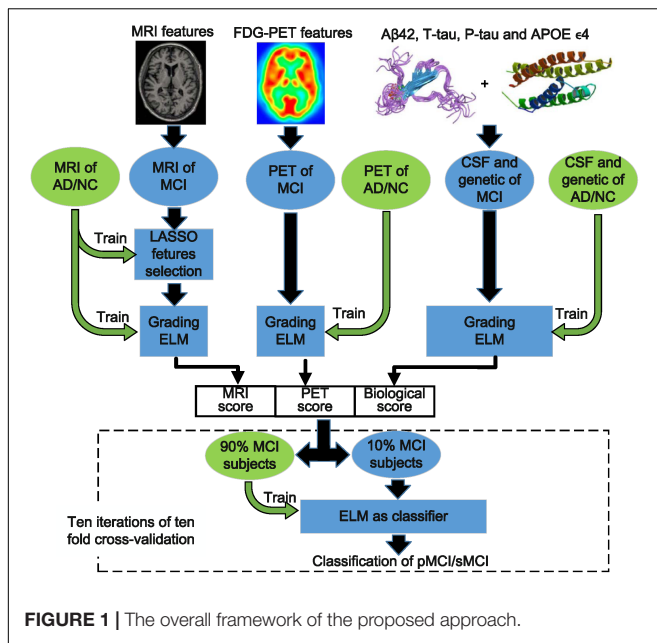

In formula (1),  $y \in \mathbf{R}^{1 \times N}$  is the vector of  $N$  labels, and  $D \in \mathbf{R}^{N \times M}$  is a feature matrix that consists of  $N$  training samples with  $M$  features in each sample. The variable  $\lambda$  is the penalty coefficient that was set to 0.015 in this study, and  $\alpha \in \mathbf{R}^{1 \times M}$  is the target sparse coefficients. When this model is solved, only some coefficients in  $\alpha$  would be non-zero, where the larger absolute value of these coefficients indicates higher usefulness of the corresponding features. Therefore, the results of  $\alpha$  can be used to select discriminative features. Unlike previous studies

**TABLE 1** | The demographic information of subjects.

Mean $\pm$ SD	NC	sMCI	pMCI	AD
Count (F/M)	200 (93/107)	205 (90/115)	110 (47/63)	102 (35/67)
Age	73.9 $\pm$ 6.0	71.8 $\pm$ 7.1	73.9 $\pm$ 7.2	75.7 $\pm$ 8.0
Education	16.4 $\pm$ 2.7	16.1 $\pm$ 2.7	16.2 $\pm$ 2.7	15.4 $\pm$ 3.0
MMSE	29.0 $\pm$ 1.2	28.1 $\pm$ 1.7	27.1 $\pm$ 1.7	23.2 $\pm$ 2.0

In cells of the second row, the first number is total number with numbers of female (F) and male (M) in brackets. AD, Alzheimer's disease; MMSE, Mini Mental State Examination; NC, normal control; pMCI, progressive mild cognitive impairment; SD, standard deviation; sMCI, stable mild cognitive impairment.

**ALGORITHM 1 |** The pseudo-code of the proposed method.

**Input:**  $M_{AD/NC}$ ,  $P_{AD/NC}$ ,  $B_{AD/NC}$ ,  $M_{MCI}$ ,  $P_{MCI}$ ,  $B_{MCI}$

- $\alpha = \text{LASSO}(\text{train} = M_{AD/NC}).\text{coefficients};$
- $M_{AD/NC} = M_{AD/NC}[:, \alpha! = 0]$ ,  $M_{MCI} = M_{MCI}[:, \alpha! = 0]$ ;
- $\text{score}_{MRI} = \text{ELM}(\text{train} = M_{AD/NC}).\text{outputScore}(M_{MCI});$   
 $\text{score}_{PET} = \text{ELM}(\text{train} = P_{AD/NC}).\text{outputScore}(P_{MCI});$   
 $\text{score}_{Bio} = \text{ELM}(\text{train} = B_{AD/NC}).\text{outputScore}(B_{MCI});$
- $\text{scores} = [\text{score}_{MRI}, \text{score}_{PET}, \text{score}_{Bio}];$  ##  $\text{scores} \in \mathbb{R}^{N \times 3}$

**Classification and Validation:**

- for  $n$  from 1 to 100:
- $\text{scores} = \text{scores}[\text{random\_permute}, :];$
- Ten folds cross-validation:**
- separate scores into ten folds along first dimension;
- for  $i$  from 1 to 10:
- $\text{testSet} = \text{scores}[\text{foldth} = i, :];$
- $\text{trainSet} = \text{scores}[\text{others}, :];$
- $\text{record predict} = \text{ELM}(\text{train} = \text{trainSet}).\text{classify}(\text{testSet});$
- end for
- end for
- statistics of 100 runs

(Lee et al., 2016; Lin et al., 2018), which trained the LASSO model with pMCI/sMCI features for the pMCI/sMCI classification task, we thought the features of AD/NC were more representative and used them to train LASSO model. Then, the features with non-zero coefficients in  $\alpha$  were selected.

## Extreme Learning Machine

Extreme learning machine is a one-step learning algorithm that is faster and has a higher performance than the support vector machine (Huang et al., 2012; Zeng et al., 2017). There are two types of basic ELM; the first is a feed-forward neural network with only a single layer of randomly generated hidden nodes (Huang et al., 2006). The second type is an ELM with kernels

(Huang et al., 2012), which avoids the random generation of an input weight matrix. ELM with kernels yields more stable results and has a higher performance than the feed-forward neural network. In our previous work (Lin et al., 2018), the ELM with kernels showed more efficiency than support vector machine and random forest in the prediction of AD. Therefore, we adopted ELM with a Gaussian kernel in this study. The process of ELM with a Gaussian kernel can be described as follows:

Suppose we have  $N$  training samples  $[x_1, x_2, \dots, x_N]$  and  $N$  labels. The variable  $x_n$  represents a vector with  $M$  features of one sample, and  $Y \in \mathbb{R}^{N \times 2}$  is a ground truth label matrix with  $N$  rows. In each row, the element corresponding to the true label is set to 1, and the other is set to -1. When a new sample,  $x$ , is obtained, the label of  $x$  can be predicted as

$$f(x) = \begin{bmatrix} K(x, x_1) \\ K(x, x_2) \\ \vdots \\ K(x, x_N) \end{bmatrix} \left( \Omega + \frac{I}{C} \right)^{-1} Y, \quad (2)$$

where  $K(x, x_N)$  is the Gaussian kernel described as

$$K(u, v) = \exp\left(\frac{-\|u - v\|^2}{\gamma}\right), \quad (3)$$

and  $\Omega$  is an  $N \times N$  kernel matrix that is related to the training samples, which is calculated in the training phase as

$$\Omega = \begin{bmatrix} K(x_1, x_1) & K(x_1, x_N) \\ K(x_2, x_1) & K(x_2, x_N) \\ \vdots & \vdots \\ K(x_N, x_1) & K(x_N, x_N) \end{bmatrix}. \quad (4)$$

The variable  $C$  in formula (2) is a regularization coefficient and is set to 1. The variable  $\gamma$  in formula (3) is a parameter of the Gaussian kernel, which is set to 10 times  $M$  number of features in this study.

The output of formula (2) is a vector with two elements:  $[s_1, s_2]$ . When ELM is used as the classifier, the output is the result of comparing the values of  $s_1$  and  $s_2$ . In this study, we used the ELM to grade MCI samples, and the output of ELM was modified as  $s = s_1 - s_2$ . When the ELM was trained with AD/NC and tested on MCI, the output score  $s$  can represent the similarity of MCI-to-AD or NC.

## Classification and Performance Analysis

Ten-fold cross-validation was implemented to assess the performance of the proposed approach. All MCI subjects were separated into 10-folds randomly. In each validation iteration, one different fold was selected as testing data and the other nine folds were used as training data. This process was repeated for 10 iterations. The classification results of 10 iterations were compared to the true labels, and the accuracy, sensitivity, specificity, and area under receiver operating characteristic (ROC) curve (AUC) were calculated. To avoid sampling bias, the 10-fold cross-validation was run 100 times with randomly

permuted samples, and the mean and standard deviation of the accuracy, sensitivity, specificity, and AUC were given.

## EXPERIMENTS AND RESULTS

### Results Using Multimodality Data

To evaluate the improvement of the proposed approach, we compared it with the method that directly concatenates multimodal data. The results of the comparison are shown in **Figure 2**. From these results, we found that the method that directly concatenates the four modalities had a high accuracy and specificity of 80.1 and 91.1%, respectively, but the sensitivity was quite low. For a non-biased performance evaluation, we calculated the balanced accuracy, which is the

average of sensitivity and specificity, and obtained 75.3%, which is not optimal. The proposed approach had better results in terms of accuracy and sensitivity, with an accuracy of 84.7% and a sensitivity of 72.7%. This is approximately 13% higher than the direct concatenation method. The proposed approach also has a promising balanced accuracy of 81.9%, which is 6.6% higher than the other method. Beside these scores, we also obtained an improved AUC of 88.8% for our proposed method. This comparison indicates that the proposed approach is more efficient at predicting the MCI-to-AD conversion than the method using directly concatenated multimodal data.

### Contributions of Different Modalities

To reveal the contributions of the different modalities in the proposed method, experiments were conducted with only one modality and one modality absent. The results are listed in **Table 2**. Because the APOE  $\epsilon 4$  data failed to classify pMCI/sMCI individually (with balanced accuracy of 55.2%), we used CSF + APOE  $\epsilon 4$  to demonstrate the effect of APOE  $\epsilon 4$ .

From these results, we can see that when only one modality was used, the performance of the CSF ranked third in terms of accuracy and AUC, but it had the best sensitivity. The APOE  $\epsilon 4$  feature can slightly improve the results using CSF. FDG-PET achieved the best results, but the best accuracy and balanced accuracy were only 76.7 and 71.7%, respectively. When all modalities were used, the accuracy and balanced accuracy was greatly improved to 84.7 and 81.9%, respectively, and there was also a significant improvement in AUC. **Figure 3** shows the improvement in the ROC curves of the proposed approach, when all modalities were used compared with only one modality used. In the situation with one modality absent, it shows that the performance declined without CSF, especially a significant decline of sensitivity, which led to the decline of balanced accuracy. The MRI and FDG-PET had a similar impact on the performance of the proposed method, while the APOE  $\epsilon 4$  had minimal influence on the performance. Even when all modalities were used, if the LASSO was disabled, the performance suffered from a 1.2 and 1.8% drop in the accuracy and balanced accuracy, respectively, which illustrates the contribution of LASSO.

**TABLE 2 |** The contributions of different modalities.

Modalities	ACC	SEN	SPE	BACC	AUC
MRI	74.5 ± 0.4%	54.8 ± 0.9%	85.0 ± 0.3%	69.9 ± 0.5%	79.2 ± 0.2%
FDG-PET	76.7 ± 0.4%	55.1 ± 0.8%	88.2 ± 0.5%	71.7 ± 0.4%	80.9 ± 0.2%
CSF	73.0 ± 0.5%	62.5 ± 1.0%	78.7 ± 0.5%	70.6 ± 0.6%	79.0 ± 0.3%
CSF + APOE $\epsilon 4$	73.9 ± 0.4%	63.2 ± 0.7%	79.7 ± 0.6%	71.4 ± 0.4%	78.8 ± 0.3%
- MRI	81.3 ± 0.5%	67.0 ± 1.0%	89.0 ± 0.5%	78.0 ± 0.6%	86.8 ± 0.2%
- FDG-PET	81.0 ± 0.5%	67.2 ± 0.8%	88.4 ± 0.5%	77.8 ± 0.5%	86.7 ± 0.2%
- CSF	79.6 ± 0.6%	63.5 ± 1.2%	88.3 ± 0.5%	75.9 ± 0.7%	85.8 ± 0.2%
- APOE $\epsilon 4$	83.2 ± 0.5%	69.8 ± 1.0%	90.4 ± 0.5%	80.1 ± 0.6%	88.7 ± 0.2%
- LASSO	83.5 ± 0.6%	69.0 ± 1.2%	91.2 ± 0.6%	80.1 ± 0.7%	88.8 ± 0.2%
All	84.7 ± 0.4%	72.7 ± 0.8%	91.2 ± 0.4%	81.9 ± 0.5%	88.8 ± 0.2%

"- modality" means the absence of the modality in experiments. In each cell, the two numbers represent the mean and standard deviation derived from 100 runs of validation. ACC, accuracy; APOE, apolipoprotein E; AUC, area under receiver operating characteristic curve; BACC, balanced accuracy; CSF, cerebrospinal fluid; LASSO, least absolute shrinkage and selection operator; SEN, sensitivity; SPE, specificity.

## Prediction Within Different Periods

The 3-year cutoff period for predicting MCI-to-AD conversion is not a unique criterion. We also conducted experiments to predict the states of MCI patients with different periods from 1 to 5 years. With the criterion changed, different numbers of pMCI/sMCI for different conversion times were obtained: 46/343 (1 year), 89/268 (2 years), 110/205 (3 years), 119/146 (4 years), 117/62 (5 years). The results of predicting MCI-to-AD conversion at different time periods are shown in **Figure 4**. From **Figure 4A**, we can see that the accuracies are all above 83% for 1–5 years prediction. However, from **Figure 4B**, we found the specificity

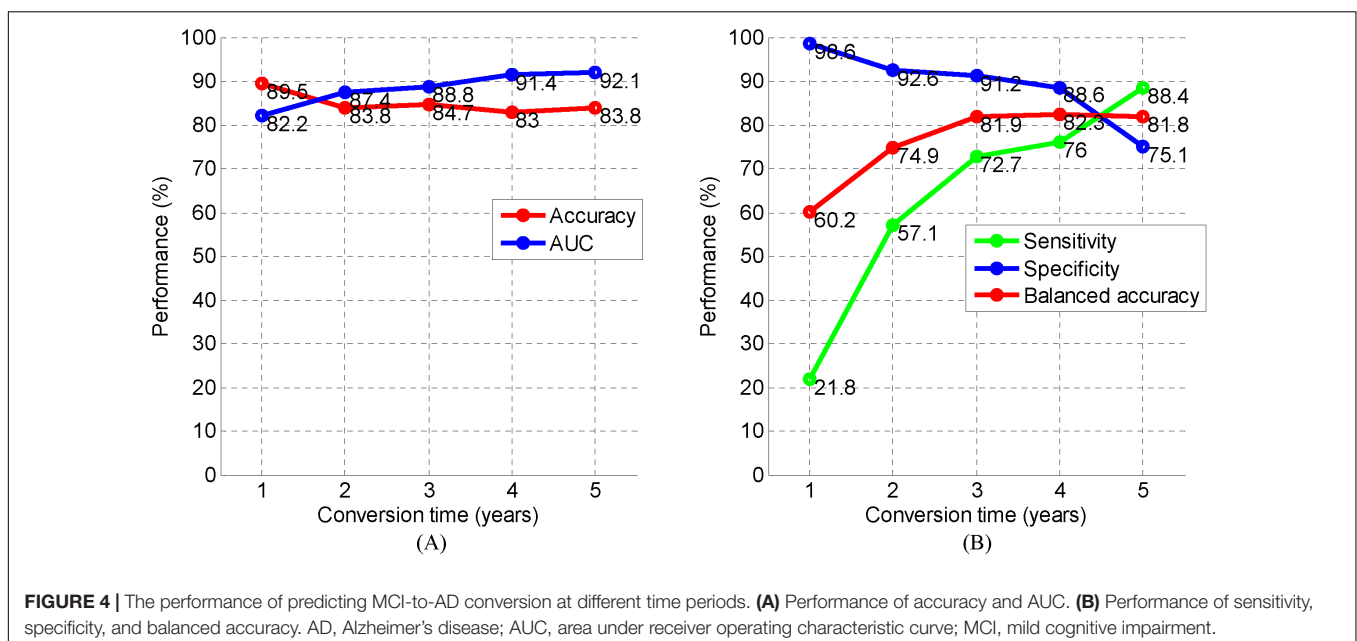

was high and the sensitivity was low at the point of 1 year, owing to the disparity of the number of individuals with pMCI versus sMCI (46/343), and the balanced accuracy was only 60.2%. At the point of 2 years, the bias is still large: 89/268 pMCI/sMCI. As a result, the balanced accuracy was only 74.9%. At the 3–5-year mark, the bias reduced and the balanced accuracies stabilized at approximately 82%. At the points of 3–5 years, we achieved an accuracy, balanced accuracy, and AUC of 83, 81.8, and 88.8%, respectively. These results show a promising performance of the proposed approach for predicting MCI-to-AD conversion within different periods.

## Experiments on Other Conditions

We also conducted the experiments on different conditions, including:

- An Support Vector Machine (SVM) version, in which SVM was the classifier instead of ELM.
- In some studies, neuropsychological test scores (MMSE, clinical dementia rating-sum of boxes, Alzheimer's disease assessment scale-cognitive subtest, Rey's auditory verbal learning test, functional activities questionnaire) were included to boost the performance of prediction. Therefore, these neuropsychological test scores were also included and concatenated with grading scores.
- In previous studies (Moradi et al., 2015; Tong et al., 2017a), the definition of sMCI was stricter, and the subjects who converted to AD beyond 3 years or the diagnosis changed from MCI to NC were removed from the sMCI group. Therefore, we also excluded 64 subjects with the same criterion, and then obtained 141 sMCI and 110 pMCI.

The results are listed in **Table 3**, from which it can be seen that the ELM classifier has a better performance than the SVM classifier. When neuropsychological test scores were included in

**TABLE 3 |** The experiments on different conditions.

Classifier	Modalities	pMCI/sMCI	ACC	AUC
SVM	MRI, PET, CSF, APOE	110/205	83.6%	–
ELM	MRI, PET, CSF, APOE	110/205	84.7%	88.8%
ELM	MRI, PET, CSF, APOE, neuropsychological scores	110/205	85.1%	92.6%
ELM	MRI, PET, CSF, APOE, neuropsychological scores	110/141 (ambiguous subjects excluded)	87.1%	94.7%

ACC, accuracy; APOE, apolipoprotein E; AUC, area under receiver operating characteristic curve; CSF, cerebrospinal fluid; ELM, extreme learning machine; pMCI, progressive mild cognitive impairment; sMCI, stable mild cognitive impairment; SVM, support vector machine.

the proposed method, there was not a significant improvement in accuracy, but the AUC greatly improved. When the ambiguous subjects were excluded from the sMCI group, the performance was further improved. To the best of our knowledge, the accuracy of 87.1% and AUC of 94.7%, achieved in this experiment, are the best for predicting AD.

## DISCUSSION

In this study, we propose a novel approach for predicting MCI-to-AD conversion with multimodal data. To effectively fuse different modalities and avoid the bias of a number of features in each modality; an ELM-based grading method was employed to calculate a grading score for each modality. The scores of multiple modalities were combined and fed into the ELM classifier to discriminate the pMCI from sMCI. With the help of AD/NC information included in the grading procedure, the scores effectively represented the states of the MCI subjects and were used to predict the AD conversion individually. When the scores from all modalities were combined, the accuracy of prediction was boosted to 84.7%. The results of the experiments conducted on the ADNI cohort demonstrate that: (i) the proposed method with multimodality scores has a much higher accuracy than with a single modality score, such that the proposed method has at least a 10% higher balanced accuracy than when a single modality is used. This means that the complementary information among the multimodal data can be represented by these scores. (ii) Direct concatenation of multimodal data is not the best way of exploiting the complementary information, and the proposed method showed a more efficient fusion of multimodal data and achieved a much better performance. (iii) The proposed method can predict MCI-to-AD conversion of different periods with a high accuracy.

As more modalities bring more complementary information, the performance of the prediction should improve. As shown in **Table 3**, when the neuropsychological test scores were included in our approach, the AUC improved, but the accuracy only had a 0.4% improvement. The assumption is that there might be an up-boundary for discriminating pMCI from sMCI, from the fact that the diagnosis in ADNI is not 100% reliable (Ranginwala et al., 2008). Therefore, when we defined the sMCI more strictly and excluded ambiguous samples, the accuracy was further boosted to 87.1% as shown in **Table 3**. It is also observed that the specificity was much higher than sensitivity in **Table 2**, and we assume the reason for this might be a bias in the number of pMCI against the number of sMCI. This can be explained in **Figure 4B** that shows

that as the bias in the number of pMCI versus sMCI decreased, a similar specificity and sensitivity were obtained.

Although the proposed approach achieved a promising result in predicting AD conversion, it requires four modalities, which is difficult to obtain in clinical practice. However, in the research of longitudinal regression for modeling the trajectory of AD progression, it is crucial to estimate the cognitive states of patients. In our future work, we will consider the use of the ELM-based grading method proposed in this study to improve the accuracy of longitudinal regression for AD trajectory modeling.

In the proposed approach, the feature selection was only applied to MRI features since the PET features were from five AD-related regions and the three CSF biomarkers and APOE  $\epsilon 4$  gene contained useful information about AD. Because the MRI features from the FreeSurfer analysis were morphology features of whole brain, inevitably it had to include some useless features. As a result, LASSO was employed to do the feature selection on MRI features, and it improved the results of prediction. To explore which MRI features were selected, we have listed the top 10 features in **Table 4**. We can observe that the volumes and thicknesses of the hippocampus, amygdala, temporal lobe, and entorhinal cortex play an important role in the detection of AD, which is consistent with previous studies (Van Hoesen et al., 1991; Convit et al., 2000; Mu and Gage, 2011; Poulin et al., 2011).

## CONCLUSION

In this study, we have developed an ELM-based grading method to fuse multimodal data for the prediction of MCI-to-AD

**TABLE 4 |** The top 10 AD-related MRI features from LASSO feature selection.

Num.	MRI features
1	Volume of left hippocampus
2	Volume of left amygdala
3	Volume of left inferior lateral ventricle
4	Surface area of left isthmus cingulate
5	Volume of right hippocampus
6	Volume of left inferior temporal
7	Cortical thickness average of left middle temporal
8	Cortical thickness standard deviation of right transverse temporal
9	Cortical thickness standard deviation of right lateral orbitofrontal
10	Cortical thickness average of right entorhinal

AD, Alzheimer's disease; LASSO, least absolute shrinkage and selection operator.

conversion within 3 years. With the input of four modalities: MRI, FDG-PET, CSF, and gene presence, we achieved a promising result with an accuracy of 84.7% and AUC of 88.8%. When compared with method that directly concatenates multiple modalities, the proposed approach outperformed the other in terms of accuracy and AUC. The experiments demonstrated that this approach can also predict AD conversion of other periods with a similar performance of the 3-year prediction.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

## ETHICS STATEMENT

As per ADNI protocols, all procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. The ADNI data collection was carried out after obtaining written informed consent from the participants. More details can be found at [adni.loni.usc.edu](http://adni.loni.usc.edu).

## AUTHOR CONTRIBUTIONS

WL and TT conceived the study, designed the experiments, analyzed the data, and wrote the manuscript. QG provided the preprocessed data. JY and ZC carried out experiments. CF and WC helped to analyze the data and experiments result. MD and TT revised the manuscript.

## FUNDING

This work was supported in part by National Natural Science Foundation of China under Grant 61901120 and Grant 61802065,

in part by the Key Projects of Technological Department in Fujian Province under Grant 321192016Y0069201615, in part by the Science and Technology Program of Fujian Province of China under Grant 2019YZ016006, in part by the Natural Science Foundation of Fujian Province of China under Grant 2018J01565, in part by the Foundation of Educational and Scientific Research Projects for Young and Middle-aged Teachers of Fujian Province under Grant JAT170406, in part by the Scientific Research Climbing Project of Xiamen University of Technology under Grant XPDKT19006, and in part by the High-level Talent Project of Xiamen University of Technology under Grant YKJ17021R.

## ACKNOWLEDGMENTS

The ADNI data collection and sharing for this project were funded by the Alzheimer's Disease Neuroimaging Initiative (ADNI; Principal Investigator: Michael Weiner; NIH grant U01 AG024904). ADNI is funded by the National Institute on Aging, the National Institute of Biomedical Imaging and Bioengineering (NIBIB), and through generous contributions from the following: Pfizer Inc., Wyeth Research, Bristol-Myers Squibb, Eli Lilly and Company, GlaxoSmithKline, Merck & Co., Inc., AstraZeneca AB, Novartis Pharmaceuticals Corporation, Alzheimer's Association, Eisai Global Clinical Development, Elan Corporation plc, Forest Laboratories, and the Institute for the Study of Aging, with participation from the U.S. Food and Drug Administration. Industry partnerships are coordinated through the Foundation for the National Institutes of Health. The grantee organization is the Northern California Institute for Research and Education, and the study is coordinated by the Alzheimer's Disease Cooperative Study at the University of California, San Diego. ADNI data are disseminated by the Laboratory of Neuroimaging at the University of California, Los Angeles.

Functional and Structural Brain  
Alterations in Encephalitis With LGI1  
Antibodies. *Front. Neurosci.* 14:304.  
doi: 10.3389/fnins.2020.00304

**Objective:** The purpose of this study was to examine the neural substrates and mechanisms that generate memory deficits, seizures and neuropsychiatric abnormalities in encephalitis with LGI1 antibodies using a data-driven, multimodal magnetic resonance imaging (MRI) approach.

**Methods:** Functional MRI data were acquired from 14 anti-LGI1 encephalitis patients and 14 age and gender matched normal controls. Independent component analysis with hierarchical partner matching (HPM-ICA) was used to assess the whole-brain intrinsic functional connectivity. Granger causality (GC) was applied to investigate the effective connectivity among the brain regions that identified by HPM-ICA. Diffusion tensor imaging (DTI) was utilized to investigate white matter microstructural changes of the patients.

**Results:** Participants with LGI1 antibodies encephalitis presented reduced functional connectivity in the brain areas associated with memory, cognition and motion circuits, while increased functional connectivity in putamen and caudate in comparison to the normal controls. Moreover, the effective connectivity in patients was decreased from the frontal cortex to supplementary motor area. Finally, patients had significant reductions in fractional anisotropy (FA) for the corpus callosum, internal capsule, corona radiata and superior longitudinal fasciculus, accompanied by increases in mean diffusivity (MD) for these regions as compared to controls.

**Conclusion:** Our findings suggest that the neural disorder and behavioral deficits of anti-LGI1 encephalitis may be associated with extensive changes in brain connectivity and microstructure. These pathological alterations affect the basal ganglia and limbic system besides the temporal and frontal lobe.

**Keywords:** anti-LGI1 encephalitis, multimodal MRI, functional connectivity, effective connectivity, white matter microstructure

## INTRODUCTION

Encephalitis with leucine-rich, glioma-inactivated 1 (LGI1) antibodies is a disease characterized by progressive memory loss, confusion, sleep disturbances, and problems with behaviors and spatial orientation. The most common clinical symptoms include memory dysfunction, multifocal seizures, faciobrachial dystonic seizures (FBDS) and hyponatremia (Irani et al., 2010; van Sonderen et al., 2016; Beimer and Selwa, 2017; Wang et al., 2017). The LGI1 is a protein that binds together two epilepsy-related proteins called ADAM22 (a disintegrin and metalloproteinase 22) and ADAM23 (Kegel et al., 2013). Encephalitis with LGI1 antibodies occurs when antibodies mistakenly attack LGI1 (Gao et al., 2016; van Sonderen et al., 2016).

Prior neuroimaging studies have reported structural and functional neural differences in various brain areas between anti-LGI1 encephalitis patients and normal controls (NC). Several positron emission tomography (PET) studies have reported alterations of basal ganglia hyperintensities in LGI1-autoantibody faciobrachial dystonic seizures (FBDS) (Flanagan et al., 2015; d'Orsi et al., 2018). In addition, structural magnetic resonance imaging (MRI) studies have revealed decreased volumes of the hippocampus, pallidum, nucleus accumbens, brainstem and cerebellum in patients with anti-LGI1 encephalitis (Finke et al., 2017; Miller et al., 2017; Szots et al., 2017). Hippocampal atrophy with further reduced mediodorsal thalamic and posteromedial cortical volumes were reported in the limbic encephalitis associated with antibodies to components of the voltage-gated potassium channel complex (VGKCC-Ab-LE), where LGI1 was the prominent autoantibody (Loane et al., 2019). Another recent study showed that hippocampal dentate gyrus atrophy predicted pattern separation impairment in patients with LGI1 encephalitis (Hanert et al., 2019). Besides, diffusion tensor imaging (DTI) has been extensively applied to unveil white matter abnormalities in diverse neurological diseases (Gatto et al., 2018; Gatto and Weissmann, 2019). The microstructural integrity impairments of the hippocampus (Finke et al., 2017), corona radiata, capsula interna and corpus callosum (Szots et al., 2017) were found in patients with anti-LGI1 encephalitis in the DTI studies. The magnetic resonance spectroscopy (MRS) revealed lower glutamine/glutamate white matter (WM) levels compared with controls (Szots et al., 2017).

Disruptions of large-scale functional networks including default mode network (DMN), sensorimotor, salience and higher visual networks in patients with anti-LGI1 encephalitis have been revealed in the resting-state fMRI study (Heine et al., 2018). Another VGKCC-Ab-LE study in which LGI1 was the main autoantibody demonstrated that patients had reduced posteromedial cortico-hippocampal and interhippocampal functional connectivities which were correlated with memory scores (Loane et al., 2019). A task-based fMRI study in autoimmune encephalitis with FBDS have reported that higher peak FBDS frequency was significantly related to lower hippocampal activity during scene-encoding task (Nantes et al., 2018).

However, the neural mechanisms underlying memory deficits, seizures and neuropsychiatric abnormalities in anti-LGI1

encephalitis remain unclear. Therefore, the aim of this study was to examine the whole-brain functional and structural alterations as well as their correlations with clinical disease severity in encephalitis with LGI1 antibodies using a data-driven, multimodal MRI approach. We applied the independent component analysis with hierarchical partner matching (HPM-ICA) to assess the brain functional connectivity networks. The causal influence between the independent components was estimated by utilizing granger causality method. Diffusion tensor imaging was used to investigate white matter microstructural changes of the patients. The hypothesis was that we would detect brain connectivity and microstructure differences in anti-LGI1 encephalitis within the cortical-subcortical neural systems that support memory, cognition, and motion dysregulation for anti-LGI1 encephalitis.

## MATERIALS AND METHODS

### Participants

Fourteen participants with anti-LGI1 encephalitis (11 males, 3 females, mean age  $55.9 \pm 10.6$  years) were recruited from the psychological outpatient clinic at the Qilu Hospital of Shandong University (Table 1). Anti-LGI1 encephalitis was diagnosed by LGI1 antibodies positive in all patients who had serum LGI1 antibodies. The (+) scoring was found in one patient, and

**TABLE 1 |** Demographic and clinical characteristics of anti-LGI1 encephalitis patients.

Age, mean (SD)	55.9 (10.6) years
Sex	11 male, 3 female
Modified Rankin Scale score <sup>a</sup> , mean (SD)	2.2 (0.8)
Time from symptom onset to diagnosis, mean (SD)	3.4 (2.3) months
Mini-Mental State Examination (MMSE), mean (SD)	22.1(5.9)
Montreal Cognitive Assessment (MoCA), mean (SD)	18.3(5.5)
<b>Symptom</b>	
Memory impairment	10/14 (71%)
Seizure	11/14 (79%)
Faciobrachial dystonic seizures	4/14 (29%)
Mental and behavioral abnormalities	4/14 (29%)
<b>Cerebrospinal fluid</b>	
Glucose (mmol/L), mean (SD)	4.6 (1.2)
Chlorine (mmol/L), mean (SD)	121 (5.6)
Protein <sup>b</sup> (g/L), mean (SD)	0.38 (0.17)
Lactic acid <sup>c</sup> (mmol/L), mean (SD)	2.2 (0.3)
<b>Antibodies to LGI1</b>	
Serum (positive)	14/14 (100%)
Cerebrospinal fluid (positive)	10/14 (71%)

<sup>a</sup>The criteria of the modified Rankin Scale (mRS) score can be described as: 0 – No symptoms at all. 1 – No significant disability despite symptoms; able to carry out all usual duties and activities. 2 – Slight disability; unable to carry out all previous activities, but able to look after own affairs without assistance. 3 – Moderate disability; requiring some help, but able to walk without assistance. 4 – Moderately severe disability; unable to walk and attend to bodily needs without assistance. 5 – Severe disability; bedridden, incontinent and requiring constant nursing care and attention. <sup>b</sup>CSF Protein normal values: <0.45 g/L. <sup>c</sup>CSF lactic acid normal values: 1.2–2.1 mmol/L.

(++) scoring was found in thirteen patients. Ten patients were CSF LGI1 antibody positive that showed (+) scoring. Thirteen patients underwent CSF examination with twelve CSF samples showing a normal white cell count. Four patients had increased protein concentrations (Four patients: 0.75, 0.46, 0.53 and 0.5 g/L [normal: <0.45 g/L]). Six patients had increased lactic acid concentrations (Six patients: 2.7, 2.5, 2.3, 2.5, 2.5, and 2.3 mmol/L [normal: 1.2–2.1 mmol/L]). Ten patients had memory impairment. Eleven patients experienced seizure and four patients had mental and behavioral changes. The FBDS occurred in four patients. All anti-LGI1 encephalitis participants had been diagnosed by a licensed neurology pathologist before enrollment. We evaluated symptom severity on the day of MRI scan using the assessment of the modified Rankin Scale (mRS) for all patients. The mental and cognitive functions of patients were assessed by Mini-Mental State Examination (MMSE) and Montreal Cognitive Assessment (MoCA).

Fourteen group-matched by age and sex normal controls (9 males, 5 females, mean age  $55.5 \pm 9.3$  years) were recruited by public advertisement to take part in the study. All participants were right-handed, native Chinese speakers. The safety screening form and informed consent form were approved by the Institutional Review Board of Qilu Hospital of Shandong University. The written informed consents were obtained from all participants.

## Image Acquisition

Imaging was performed on a Siemens Verio 3.0 Tesla MRI scanner (Siemens, Erlangen, Germany) with a 32-channel head coil at the Qilu Hospital of Shandong University. Participants were instructed to rest with their eyes closed but not to fall asleep during scanning. Foam cushions were used to reduce head movement. We acquired the resting-state functional MRI data using a single-shot gradient-echo echo-planar imaging (EPI) sequence with the following parameters: repetition time (TR) = 2000 ms, echo time (TE) = 30 ms, flip angle =  $90^\circ$ , field of view (FOV) =  $24 \text{ cm} \times 24 \text{ cm}$ , matrix size =  $64 \times 64$ , voxel size =  $3.4 \times 3.4 \times 4.0 \text{ mm}$ , slice thickness = 3 mm. Thirty-six axial slices were acquired aligned the AC-PC plane. The acquisition time was about eight minutes, resulting in a total of 240 volumes. The DTI scanning parameters were as follows: 65 diffusion directions in the axial plane, TR = 6400 ms, TE = 98 ms, flip angle =  $90^\circ$ , FOV =  $24 \text{ cm} \times 24 \text{ cm}$ , matrix size =  $128 \times 128$ , voxel size =  $2 \times 2 \times 2 \text{ mm}^3$ ,  $b$ -value =  $1000 \text{ s/mm}^2$ , slice thickness = 3 mm, no slice gap.

## The Functional MRI Image Analysis

The resting-state fMRI image analysis consisted of five procedures: preprocessing of functional imaging data, spatial independent component analysis (ICA) of the preprocessed data, identification of reproducible ICA components, statistical comparison of the processed ICA components, granger causality analysis of the ICA components.

The fMRI images were preprocessed using SPM12 (Wellcome Department of Imaging Neuroscience, London, United Kingdom) that was run under MATLAB. The slice timing correction was performed to correct phase shifts between

slices caused by interleaved scans. Then motion correction was conducted to correct for head movements. After that, all images were normalized to the Montreal Neurological Institute (MNI) coordinate system and smoothed by an isotropic Gaussian kernel of 8 mm full-width at half-maximum.

The spatial independent component analysis with hierarchical partner matching (HPM-ICA) (Wang et al., 2011; Qiao et al., 2015, 2017) was performed on the preprocessed data to explore the functional connectivity networks. In detail, spatial ICA was firstly used to generate  $N$  components for each participant in which the number of sets of independent components (ICs)  $N$  was determined by information criteria. The minimum description length and Akaike's information criterion were combined to estimate the lower and upper bounds of the numbers of ICs, defining an interval for the number  $N$  of components. Secondly, the hierarchical partner matching was performed to identify independent components that were reproducible in their spatial configuration across all individuals.

Statistical analysis was implemented to detect random effects of group difference in functional connectivity between anti-LGI1 encephalitis patients and normal controls. The  $z$ -score maps of the identified reproducible ICs were entered into a second-level factorial analysis, covarying for age and sex. The uncorrected  $p$ -value of 0.001 with cluster extent threshold of 30 voxels (determined by Monte Carlo simulation) was used for the correction of multiple comparisons. The Pearson's correlation analysis was also performed in patients to investigate the correlation between the severity (mRS score) and functional connectivity.

Granger causality was carried out to analyze causal influences across the ICs identified by HPM-ICA method. The granger causality indices (GCIs) were computed using the time courses of the identified ICs (Wang et al., 2011; Qiao et al., 2018). The two-sample  $t$ -tests were finally used to detect group difference in GCIs between patients and normal controls in which age and sex were applied as covariates.

## Diffusion Tensor Imaging Analysis

The DTI images were analyzed using FMRIB Software Library (FSL) software<sup>1</sup>. We first performed eddy-current correction on DTI data for each participant to adjust the distortions and motion artifacts. Then we used the brain extraction tool (BET) (Smith, 2002) to extract brain tissue from the eddy-current-corrected B0 image and generate brain mask. The FMRIB Diffusion Toolbox (FDT) was subsequently used to reconstruct the diffusion tensor and calculate the fractional anisotropy (FA) and mean diffusivity (MD) map for each participant.

The voxel-wise statistical analysis of the DTI images was performed using tract-based spatial statistics (TBSS) (Smith et al., 2006). First, FA maps of all subjects were aligned to the standard MNI152 space through a non-linear registration. Second, the mean FA image was created and skeletonised. A threshold of 0.2 was used to exclude non-skeleton voxels and generate the mean skeleton. The aligned FA and MD map of each subject were then projected onto the skeleton. Finally, permutation-based

<sup>1</sup>www.fmrib.ox.ac.uk/fsl

non-parametric inference with 5,000 permutations was adopted to identify the differences in the FA and MD images between patients and controls. Age and sex were entered as covariates in the statistical analysis. The threshold-free cluster enhancement (TFCE) was used as multiple comparison correction (Smith and Nichols, 2009; Winkler et al., 2016). A family wise error corrected  $P < 0.05$  was considered statistically significant.

## RESULTS

### Reproducible Independent Components

We identified nine clusters of ICs that were significantly reliable and reproducible in their spatial patterns across anti-LGI1 encephalitis patients and normal controls groups by HPM-ICA method. The general linear model in SPM was applied to conduct a one-sample  $t$ -test on each of the clusters to generate nine independent component maps that represented statistically significant functional connectivity. The nine ICs of patients and controls were then compared in a second-level analysis. Compared with controls, patients showed significantly reduced connectivity in hippocampus, inferior frontal gyrus (IFG), amygdala, superior temporal gyrus (STG), anterior cingulate cortex (ACC) and posterior cingulate cortex (PCC), but increased connectivity in caudate, putamen and supplementary motor area (SMA) (Table 2 and Figure 1). The higher disease severity (mRS score) correlated with the weaker functional connectivity in the left hippocampus in patients ( $r = 0.76$ ,  $p < 0.01$ ).

### Granger Causality Interactions

The granger causality index was used to assess the effective connectivity between the regions associated with memory, cognition and motion dysregulation brain networks. The patients had decreased effective connections from the IFG to PCC

[( $0.15 \pm 0.02$  versus  $0.07 \pm 0.01$ ;  $p = 0.01$ ) (mean  $\pm$  std)], from the IFG to SMA ( $0.12 \pm 0.03$  versus  $0.07 \pm 0.02$ ;  $p = 0.01$ ), while increased effective connectivity from the SMA to caudate ( $0.16 \pm 0.03$  versus  $0.36 \pm 0.09$ ;  $p = 0.007$ ).

### White Matter Microstructure Integrity Alterations

The voxelwise statistical group comparison between patients and controls showed significantly lower FA in patients for the genu, body, and splenium of corpus callosum, anterior limb, retrolenticular part of internal capsule, external capsule, corona radiata, posterior thalamic radiation, sagittal stratum, fornix/stria terminalis, and superior longitudinal fasciculus (Figure 2 and Table 3), accompanied by increases in MD for these brain regions (Figure 3 and Table 4), as compared to controls. There was a negative association between mRS scores and FA values ( $r = 0.83$ ,  $p < 0.001$ ) and a positive association with MD ( $r = 0.87$ ,  $p < 0.001$ ) in the anterior corona radiate.

## DISCUSSION

In this study, we found that patients with LGI1 antibodies encephalitis presented reduced functional connectivities in the hippocampus, IFG, STG, ACC, PCC and amygdala, while increased functional connectivities in putamen, caudate and SMA. Furthermore, the effective connectivity in patients was decreased from the frontal cortex to supplementary motor area. Meanwhile, patients had significant decreased FA and increased MD for the corpus callosum, internal capsule and external capsule, corona radiata, posterior thalamic radiation, sagittal stratum and superior longitudinal fasciculus as compared to controls. The results indicated that abnormal brain connectivity and microstructure in brain areas associated with memory, cognition and motion dysregulation circuits were related to the generic risk of anti-LGI1 encephalitis, which makes it a potential endophenotype for anti-LGI1 encephalitis.

The most commonly brain alteration in anti-LGI1 encephalitis was hippocampal atrophy in the previous MRI studies (Finke et al., 2017; Miller et al., 2017; Szots et al., 2017). Correspondingly, we identified the decreased functional connectivity in hippocampus and its correlation with the disease severity in this study. Moreover, changed functional connectivities were shown in widespread brain regions related to frontal cortex, temporal cortex, motor cortex, basal ganglia and limbic system. These findings were consistent with the previous neuroimaging studies. A resting state fMRI study found disrupted large-scale functional networks including DMNs, sensorimotor, salience and higher visual networks (Heine et al., 2018). The involvement of ACC and frontal lobe in non-paraneoplastic limbic encephalitis has been reported in a recent case study (Ibi et al., 2019). Another PET study showed the hypermetabolism in the anterior cingulate cortex in an anti-NMDAR encephalitis patient (Chanson et al., 2012). The motor cortex has been demonstrated as one of the major signs of LGI1-antibody encephalitis with striatum involvement in parallel (Navarro et al., 2016). In addition, the DTI analysis revealed impaired microstructural integrity in more

extensive brain areas compared with the previous surveys (Finke et al., 2017; Szots et al., 2017).

The hippocampus plays important roles in the consolidation of information from short-term memory to long-term memory, and in spatial memory that enables navigation (Eichenbaum, 2017; Lisman et al., 2017; Voss et al., 2017), which is one of the major signs of LGI1-antibody encephalitis (Navarro et al., 2016). The hippocampal atrophy and impaired hippocampal microstructural integrity have been reported in encephalitis with

LGI1 antibodies in the previous studies (Finke et al., 2017; Szots et al., 2017). In this study, we identified that patients with anti-LGI1 encephalitis exhibit decreased functional connectivity in hippocampus compared with normal controls, confirming that the alteration of the hippocampus may be related to the development of memory disorders. Furthermore, the correlation of the reduced connectivity in hippocampus with disease severity suggests that the hippocampal damage plays an important role in the symptomatology of anti-LGI1 encephalitis.

We found significantly decreased intrinsic functional connectivity in patients compared to controls in the inferior frontal gyrus and superior temporal gyrus. As one of the major components of executive control functions, the IFG is critical for inhibiting inappropriate motor responses in the framework of top-down control of behavior (Miyake et al., 2000; Swick et al., 2008; Hampshire et al., 2010; Hallam et al., 2018). Evidence has shown that interictal epileptic events were preferentially generated by the temporal or frontal lobes during sleep or drowsiness (Navarro et al., 2016). Therefore, the unsuccessful implementation of inhibitory control over motor responses of the frontal cortex may result in the motor abnormalities such as multifocal seizures and FBDS. In addition, the superior temporal gyrus was identified to support auditory short-term memory capacity and speech comprehension ability (Bigler et al., 2007; Leff et al., 2009) as well as social cognition (Guo et al., 2017; Mier et al., 2017). Thus, the functional connectivity reduction in STG may lead to abnormal memory capacity and cognitive impairments in anti-LGI1 encephalitis patients.

We found decreased connectivity in PCC which is the central core of the default mode network (DMN). Increased DMN connectivity has been revealed as a compensatory mechanism for

memory impairment induced by hippocampal damage (Heine et al., 2018). The ventral PCC is involved in internally directed cognition such as memory retrieval and planning, while the dorsal PCC has a specific role in modulating the metastability of networks involved in internally directed attention (Leech and Sharp, 2014). The decreased connectivity in PCC may be associated with a reduction in metastability, resulting in an inability to flexibly change between different cognitive states and uncontrolling of attentional focus in patients. In addition, we found reduced functional connectivity in ACC in anti-LGI1 encephalitis patients compared with controls. The ACC is a part of the limbic system and involved in rational cognitive functions, such as reward anticipation, decision-making and impulse control (Agam et al., 2010; Tolomeo et al., 2016). Therefore, the results of our study indicate that the dysregulation of the functional connectivity in ACC might be associated with impaired cognitive control in anti-LGI1 encephalitis.

The anti-LGI1 encephalitis patients exhibited increased connectivity in motor-related brain areas including putamen, caudate and SMA. The striatum which consists of the caudate and the putamen is crucial in the planning and modulation of movement pathways as well as some cognitive

processes involving executive function (Zink et al., 2004). The abnormal functional connectivity of striatum may result in the dysfunction of motor generation or control. The decreased effective connectivity from the frontal cortex to supplementary motor area in patients further suggests that the uncontrolled movement in patients may be caused by the disruption of the motor circuits.

Meanwhile, TBSS analysis revealed widespread structural white matter damage in anti-LGI1 encephalitis as assessed using DTI. The corpus callosum (CC) is the largest fiber bundle which transfers motor, sensory, and cognitive information between the brain hemispheres (Bloom and Hynd, 2005; Roland et al., 2017). The genu of CC connects the left and right frontal lobes of the brain. The body and splenium of CC connect the hemispheres of the temporal lobes and the hemispheres of the occipital lobes. We found that anti-LGI1 encephalitis patients had decreased white matter integrity in the genu, body, and splenium of corpus callosum than controls, leading to the lack of movement coordination, low muscle tone, distorted head or facial features, spasms, and seizures. In addition, the internal capsule is a pathway connecting nerves that control the sensation and motor function (Smania et al., 2003). We found the patients exhibited reduced FA in the bilateral anterior limb and right retrolenticular part of internal capsule, which may cause the uncontrolled motor function or the sensation loss in the arm, leg, neck or face of the patients. Moreover, the corona radiata consists of afferent and efferent fibers that connect the cerebral cortex and the brain stem. The decreased white matter integrity of the anterior, superior and posterior of corona radiata in the anti-LGI1 encephalitis patients may affect the sensory input sent from the body to the brain and the messages that are sent from the brain to the body, resulting in the motor and sensory dysfunction of the patients. Furthermore, the superior longitudinal fasciculus is the largest association fiber, which connects the gray matter in frontal, parietal and temporal lobes. It is an important component of the working memory brain network. In this study, the decreased FA in the superior longitudinal fasciculus indicated that the integrity of frontal-parietal network connection was destroyed, which may be the main reason for the significant decline of memory in anti-LGI1 encephalitis patients.

Several limitations should be addressed. First, the sample size in this study was not large, which may decrease the statistical power of our analysis. The future work should be done on more cases to replicate our findings. Second, the patients in the study were all at the acute disease stage, a longitudinal design should be used to address the clinical symptoms and neural

alterations with a longer follow-up period such as 3–5 years (Szots et al., 2014). Third, the DTI data processing method using in this study is a mono-exponential approach which has intrinsic limitations to accurately capture intricate WM tracts, particularly around crossing fiber regions, as well as in superficial and deep GM structures. Therefore, other non-Gaussian approaches would potentially be applied on the future clinical investigations such as diffusion kurtosis (Gatto et al., 2019a) and continuous random-walk models (Gatto et al., 2019b) which have been validated in neurological diseases. Finally, it will be important to confirm our results using other techniques, such as EEG-fMRI, which can provide simultaneous cortical and subcortical recording of brain activity with high spatiotemporal resolution.

doi: 10.3389/fnagi.2020.00065

**Introduction:** Freezing phenomenon is a striking feature of Parkinson's disease. However, it has never been studied in people with dementia with Lewy bodies (DLB). We designed a freezing of speech single questionnaire (FOSSQ) and investigated the frequency and association of freezing of speech (FOS) in patients with DLB and other types of dementia.

**Methods:** This is a retrospective analysis of data from the project of history-based artificial intelligent computerized dementia diagnostic system. We compared the frequencies of FOS among non-demented (ND) participants, patients with Alzheimer's disease (AD), vascular dementia (VaD), and DLB. Further, we explored the association factors of FOS in all the participants.

**Results:** We enrolled 666 individuals with the following disease distribution: 190, ND; 230, AD; 183, VaD; and 63, DLB. Compared to individuals with ND (2.1%), patients with AD (6.1%), or VaD (18.0%), DLB (54.0%) showed a significantly higher frequency of positive FOS (all  $p < 0.001$ ). The association factors of FOS were older age, more severe dementia, more severe motor dysfunction, fluctuating cognition, visual hallucinations, parkinsonism, rapid eye movement sleep behavior disorder, attention, mental manipulation, and language.

**Conclusion:** Our study showed that the informant-based FOSSQ may be a practical screening tool for discriminating DLB from individuals with ND or other forms of dementia. The FOSSQ can be applied in clinical practice as well as on the artificial intelligent platform.

**Keywords:** freezing of speech, fluctuating cognition, dementia with Lewy bodies, Alzheimer's disease, vascular dementia

## INTRODUCTION

Freezing phenomenon is a striking feature of Parkinson's disease (PD). Freezing of gait (FOG) is a form of akinesia and is one of the most disabling symptoms of PD (Giladi et al., 2001). Previous studies on FOG in PD have reported a prevalence of 7.1–46% (Giladi et al., 2001; Macht et al., 2007) according to different criteria. However, there have only been a few studies on the freezing of speech (FOS) phenomenon (Ackermann et al., 1993; Giladi et al., 1997; Louis et al., 2001; Park et al., 2014; Vercruysse et al., 2014) in PD. Further, freezing phenomenon has rarely been mentioned or studied in neurological disorders other than PD, with some mentioning the phenomenon of FOS sharing a similar neural mechanism with FOG (Park et al., 2014; Vercruysse et al., 2014). The underlying mechanism of the freezing phenomenon is probably related to dysfunction of the fronto-striatal circuits (Vercruysse et al., 2014). To our knowledge, there have been no studies on FOS in dementia with Lewy bodies (DLB) or other degenerative types of dementia. DLB is one of the Lewy body diseases (LBD) and it shares a similar pathological manifestation with PD, especially PD with dementia (PDD) (Kosaka et al., 1984; Jellinger, 2018). Therefore, patients with DLB should demonstrate similar freezing phenomenon as PD/PDD. It remains unclear whether FOS is a deficit of language or other cognitive functions. However, language dysfunction is indeed one of the common cognitive features of a diagnosis of dementia due to Alzheimer's disease (AD) or other forms of dementia (McKeith et al., 2005; McKhann et al., 2011; Hardy et al., 2016). Similarly, the association factors of FOS have not yet been well studied.

To study FOS, we designed a simple informant-based FOS single questionnaire (FOSSQ) that was embedded in the History-based Artificial Intelligent Clinical Dementia Diagnostic System (HAICDDS) (Lin et al., 2018; Chiu et al., 2019). We aimed to investigate the frequency and association of FOS in DLB and other types of dementia. We proposed that since the FOS phenomenon is a striking feature of PD, it could be an important feature of DLB because both language (Lin et al., 2018) and motor deficits (McKeith et al., 2005) are common clinical presentations of DLB. Based on the findings that the underlying mechanism of the freezing phenomenon is probably related to dysfunction of the fronto-striatal circuits (Vercruysse et al., 2014), we proposed that FOS could be a deficit involving language and motor dysfunction as well as dysfunction of other cognitive functions such as attention and executive dysfunction. Similarly, as a striking clinical phenomenon, we also proposed that FOS may involve fluctuation of attention and cognition, and thus performed fluctuation scale comparisons.

## MATERIALS AND METHODS

This is a sub-study of the project of HAICDDS, which is currently used as a registration platform in the Show Chwan Healthcare System (Lin et al., 2018; Chiu et al., 2019). Participants who visited either hospital of the healthcare system with suspected cognitive or motor dysfunction were registered

with their demographical, clinical, cognitive, neuropsychiatric, motor, laboratory, and neuroimaging data in the database. The HAICDDS questionnaire is part of the database for recording of clinical history. It is composed of 100 questions designed after a consensus meeting of 12 neurologists, one geriatric psychiatrist, three nuclear medicine doctors, and one neuroradiologist. The fundamental structure of the questionnaire is similar to that of history-taking used by physicians for acquiring detailed clinical information. Before commencing the project, thirty patients with their informants were assessed by neuropsychologists from three centers and the reproducibility was studied using the interrater reliability analysis. Cronbach's alpha coefficient was calculated to estimate the reliability of the entire novel screening questionnaire. The original writing of FOSSQ was in Chinese as follows: 跟人講話時常常思緒突然中斷, 腦袋好像一片空白, 難以互動嗎 (The tentative translation to English is: "When speaking, does he/she pause frequently, seem blank, and have trouble communicating?"). In this sub-study, we analyzed and compared the FOSSQ results among non-demented (ND) participants as well as participants with AD, vascular dementia (VaD), and DLB. Further, we studied the association factors of FOS among the participants.

### Diagnosis of AD, VaD, or DLB

A diagnosis of AD was made according to the criteria for dementia due to AD developed by the National Institute on Aging-Alzheimer's Association workgroups on diagnostic guidelines for AD (McKhann et al., 2011). A diagnosis of VaD was made according to the criteria for probable VaD or possible VaD in the 2011 AHA/ASA criteria for vascular cognitive impairment (VCI) (Gorelick et al., 2011). A diagnosis of DLB was made according to the revised consensus criteria for probable DLB developed by the fourth report of the DLB consortium (McKeith et al., 2017).

### Diagnosis of ND, or Different Stages of Dementia

ND participant was diagnosed with a global CDR (Morris, 1993) score of 0 or 0.5 without significantly impaired activities of daily living, which was defined by an Instrumental Activities of Daily Living (IADL) score greater than 6 (Mao et al., 2018). A diagnosis of dementia was made according to the criteria for dementia developed by the NIA-AA (McKhann et al., 2011). Specifically, people with dementia had impairments in two cognitive domains or more as well as declined daily functions (at least one of the domains of community affairs, home hobbies, and personal care with a CDR score  $\geq 0.5$  and an IADL score  $\leq 6$ ) (Mao et al., 2018). Dementia severity was defined by the global CDR scale score; specifically, participants with a global CDR score of 0.5, 1, 2, and 3 were defined as having very mild, mild, moderate, and severe dementia, respectively (Morris, 1993).

### Procedure of the Study

This is a retrospective analysis of data from the HAICDDS, which is currently applied in three centers in Taiwan (two in central Taiwan and one in southern Taiwan). Daily function was

assessed using the Instrumental Activities of Daily Living (IADL) Scale (Lawton and Brody, 1969). Cognitive function was assessed using the Cognitive Abilities Screening Instrument (CASI) (Lin et al., 2002) and the Montreal Cognitive Assessment (MoCA) (Chen et al., 2016). Neuropsychiatric symptoms were assessed using the Neuropsychiatric Inventory (NPI) (Cummings, 1988). Language function was assessed using the language subscales in the CASI and HAICDDS (HAICDDS-Language) (Lin et al., 2018). Language domain in CASI screens cognitive performance on reading, writing, naming, and comprehension whereas, language questions in HAICDDS acquire information on speech fluency, comprehension, naming, volume, and tone based on clinical history (Lin et al., 2018). Trained neuropsychologists administered the cognitive tests and NPI to all the patients.

## Statistics

The Chinese version of SPSS 22.0 for Windows (IBM, SPSS Inc., Chicago) was used for statistical analyses. Between-group comparisons of demographic data, neuropsychological tests, CDR sum of boxes (CDR-SB), IADL score, MoCA score, CASI score, NPI total score (NPI-sum), motor subscale of the Unified Parkinson's Disease Rating Scale (UPDRS-M), and DLB features were analyzed using independent t-test or one-way ANOVA with either Bonferroni or Dunnett T3 *post hoc* analysis according to the homogeneity of variance. Between-group comparisons of demographic and background characteristics with positive FOSSQ (FOSSQ+) and negative FOSSQ (FOSSQ-) were adjusted for age and disease severity. Comparisons of each cognitive domain in the CASI between FOSSQ+ and FOSSQ- groups were adjusted for age, gender, and disease severity. Comparison of frequency of symptom fluctuation in the Mayo Fluctuation Composite Score (MFCS) and language symptoms in the HAICDDS-Language between FOSSQ+ and FOSSQ- groups were adjusted for age and disease severity.

## Ethical Consideration

The participants were selected from a registry-based database of the Show Chwan Health System. The study design was retrospective, and the data were anonymously analyzed. The Committee for Medical Research Ethics of Show Chwan Memorial Hospital reviewed the project and the Data Inspectorate approved the study.

## RESULTS

We enrolled 666 individuals with the following disease distribution: 190, ND; 230, AD; 183, VaD; and 63, DLB. The frequency of FOSSQ+ in patients with CDR scores of 0, 0.5, 1, 2, and 3 were 3.8, 3.0, 15.2, 26.1, and 43.5%, respectively. Compared to patients with ND (2.1%), AD (6.1%), or VaD (18.0%), those with DLB (54.0%) showed a significantly higher frequency of FOSSQ+ (all  $p < 0.001$ ). Comparison of demographic and background characteristics among patients with ND, AD, VaD, and DLB revealed significant differences in all the parameters ( $p < 0.001$ ), except for informant age or education (Table 1).

Comparison of demographic and background characteristics between the FOSSQ+ and FOSSQ- groups before adjustment revealed that the FOSSQ+ group had a significantly older age and more severe dementia stages. Further, there were significant differences in all other parameters ( $p < 0.001$ ) except for gender, education, and history of cerebrovascular accident (Table 2). After adjustment for age and disease severity, FOSSQ+ had more males and higher DLB features including UPDRS-M, cognitive fluctuations, visual hallucinations, parkinsonism, and REM sleep behavior disorder (Table 2).

Comparison of each cognitive domain in the CASI between the FOSSQ+ and FOSSQ- groups before adjustment revealed that the FOSSQ+ group had significantly lower scores in all domains ( $p < 0.001$ ). After adjustment for age and disease severity, the FOSSQ+ group had significantly lower scores only in the attention and language domains (Table 3).

Comparison of frequency of symptom fluctuation in the MFCS and language symptoms in the HAICDDS-Language between FOSSQ+ and FOSSQ- before and after adjustment for age and disease severity showed that FOSSQ+ had a significantly higher frequency in all domains in the MFCS and HAICDDS-Language except for language impairment, which occurred much earlier than the other symptoms (HAICDDS-L7) (Table 4). Given our recent finding that HAICDDS-L8 has the highest power for discrimination of DLB when compared to other types of dementia (Lin et al., 2018), we further combined FOSSQ with HAICDDS-L8 and found that the positive rate for each question were DLB (61.9%), VaD (29.0%), AD (7.8%), and ND (2.6%).

## DISCUSSION

As a sub-study of the project HAICDDS, we analyzed data from a relatively large population (666 individuals) and obtained important results. First, we successfully demonstrated that even a single question could provide good discrimination among dementia stages and subtypes. The frequencies of FOSSQ+ in patients with CDR scores of 0, 0.5, 1, 2, and 3 were 3.8, 3.0, 15.2, 26.1, and 43.5%, respectively, indicating that the frequency of FOS significantly increased with increase in dementia severity. Regarding discrimination of dementia subtypes, the FOS phenomenon was found more often in patients with DLB (54.0%) compared to those with either AD (6.1%) or VaD (18.0%). The frequency of FOSSQ+ was lower among females, which is consistent with previous findings on freezing phenomenon in Parkinson's disease (Park et al., 2014).

Second, the frequency of FOS was not only highest in patients with DLB but was also more significantly associated with DLB features ( $p < 0.001$ ), including cognitive fluctuations (OR = 10.22), visual hallucinations (OR = 4.18), parkinsonism (OR = 4.68), and REM sleep behavior disorder (OR = 2.84). Motor dysfunction according to the UPDRS-M is more severe in the FOSSQ+ group (OR = 1.02;  $p = 0.002$ ). Therefore, it is reasonable to consider FOS as part of the characteristic features in the diagnosis of DLB than that of ND or other types of dementia. The dopamine transporter imaging is not significantly different after adjustment, however. We proposed that non-DLB

**TABLE 1** | Comparison of demographic data among ND, AD, VaD, and DLB groups.

MFCS, Mayo Fluctuation Composite Score; HAICDDS-Language; Language subscale in the History-based Artificial Intelligent Clinical Dementia Diagnostic System; FOSSQ, Freezing of Speech Single Questionnaire; CDR, Clinical Dementia Rating scale; N, number of cases; NA, not applicable; NS, not significant; OR, odds ratio; L1, Does his/her speaking become noticeably less fluent? L2, Can't he/she understand words or sentences of others? L3, Is it difficult to express a sentence completely? L4, Does he/she repeat the same words or repeat the words of others? L5, Does he/she speak very little? L6, Does he/she have trouble finding words or names? L7, Does language impairment occur early and much earlier than other symptoms? L8, Does his/her speech reduce pitch range (monotone) and reduced volume (hypophonia)? Any, at least one scale of the language questionnaire was positive.

participants who performed dopamine transporter imaging were comorbid with motor dysfunction and were highly suspected to have parkinsonism. Hence, a relatively high percentage of DaTabN was found among these patients (47.1 and 20% in VaD and AD). Our next piece of research to address this issue and to clarify the association of FOS and dopamine transporter uptake in the striatal area is underway.

Third, after adjustment for age and dementia severity, the FOSSQ + demonstrated a strong relationship with dysfunctions

in attention, mental manipulation, and language domains in the CASI. This indicated that FOS might be a combination of these types of cognitive dysfunction, which is consistent with our hypothesis. Some researchers may argue that using the cognitive screening tool CASI, attention domain screens only registration and repetition and language domain screening cognitive performance on reading, writing, naming, and comprehension. Whether attention and language subscales in CASI represent the actual functions of attention and language might be controversial

based only on a cognitive screening tool. Further detailed and specific neuropsychological tests to clarify the association of FOS with cognitive functions will be necessary.

Fourth, it is consistent with our recent findings of language dysfunction being more severe in patients with DLB than those with other dementia using the HAICDDS-Language questionnaire (Lin et al., 2018). In the study, we found that the discriminative ability of the HAICDDS-Language, especially the HAICDDS-L8 (“Does his/her speech reduce pitch range and reduced volume?”) among patients with DLB/PDD and AD was robust (OR = 9.16; 95% CI: 6.33–13.25) (Lin et al., 2018). Therefore, in the current study, we combined the FOSSQ with HAICDDS-L8 and found an increase of positive rate in DLB (61.9%) which is much higher than those in VaD (29.0%), AD (7.8%), or ND (2.6%).

Finally, in the HAICDDS project, we have continuously provided evidence that the combination of multiple standardized and structured questions is more powerful and can be optimized using artificial intelligence with machine learning techniques. This was the original idea behind the design of the HAICDDS questionnaire.

This study has several limitations. First, we used a single questionnaire for detecting FOS in patients with DLB and other forms of dementia; therefore, further studies using more tools are required to confirm the findings. Second, we used the original Taiwanese version of the questionnaire, which, although we translated to English, would call for a more precise and colloquial translation. Third, our study was conducted in only three centers in Taiwan. Therefore, the findings on the prevalence and association factors of FOS are not generalizable to all patients with DLB or other types of dementia.

## CONCLUSION

In conclusion, our study showed that the informant-based single questionnaire FOSSQ can be a practical screening tool for the discrimination of DLB from ND or other types of dementia. The FOSSQ can be applied in clinical practice as well as in the dementia registration platform. Further machine learning techniques using artificial intelligence could improve the accuracy and efficiency of the questionnaire.

Nanotechnology utilizes engineered materials and devices which function with biological systems at the molecular level and could transform the management of neurodegenerative diseases (NDs) by provoking, reacting to, and intermingling with target sites to stimulate physiological responses while minimizing side effects. Blood-brain barrier (BBB) protects the brain from harmful agents, and transporting drugs across the BBB is a major challenge for diagnosis, targeting, and treatment of NDs. The BBB provides severe limitations for diagnosis and treatment of Alzheimer's disease (AD), Parkinson's disease (PD), and various other neurological diseases. Conventional drug delivery systems generally fail to cross the BBB, thus are inefficient in treatment. Although gradual development through research is ensuring the progress of nanotheranostic approaches from animal to human modeling, aspects of translational applicability and safety are a key concern. This demands a deep understanding of the interaction of body systems with nanomaterials. There are various plant-based nanobioactive compounds which are reported to have applicability in the diagnosis and treatment of these NDs. This review article provides an overview of applications of nanotheranostics in AD and PD. The review also discusses nano-enabled drug delivery systems and their current and potential applications for the treatment of various NDs.

## INTRODUCTION

Technological developments across various fields have proven to be beneficial for the advancements of medical research. These developments have assisted in developing various novel and efficient techniques, machines, and methods which can cure different challenging conditions and disorders of the human body. In addition to these technological advancements, an increase in research in the

field has also led to the development of various techniques which can help in combating different disorders (Bronzino, 2014). One such recent development is nanotheranostics, which has been defined by Lammers et al. (2010) as an approach which integrates target-specific diagnostics as well as therapeutics for complete recovery from the disease. These integrated practices are dependent on the use of different nanotechnology platforms, which are specifically designed for being able to target a given physical condition or disorder and hence can be used for both diagnostics and therapeutics purposes. One of the most common applications of this therapy or practice is in the treatment of neurodegenerative disorders, which are caused by different hereditary or sporadic conditions and mostly result in various dysfunctions of the nervous system of patients (Sharma, 2014). This review provides an overview of applications of nanotheranostics in neurodegenerative diseases (NDs) and recent advancements in nano-enabled drug delivery systems.

## DISCUSSION AND ANALYSIS

### Neurodegeneration

Neurodegeneration, as explained by Williams (2002), is the basis of all neurodegenerative disorders like Parkinson's disease (PD), Huntington's disease, and Alzheimer's disease (AD) and is primarily used to describe any condition which tends to affect the normal functioning of neurons in the brain. Williams (2002) explained that neurodegeneration combines two words, "neuro" and "degeneration," and hence refers to the degeneration of neurons, which in turn affects memory and other cognitive abilities of the patients. There are several researches which focused on the analyses of these neurological disorders. While several people assume it to be incurable, latest findings have revealed that the use of new techniques and approaches like nanotheranostics can render better outcomes. In addition to genetic mutations, other factors which have been found to result in neurodegeneration among patients include the buildup of different toxic proteins in the brain and the formation of neurotoxic molecules that can be caused by the loss of mitochondrial functions (Ingelsson, 2016). Further discussions explain the symptoms and molecular mechanisms associated with some of the neurodegenerative disorders which will help to understand the effectiveness of various nanotheranostic approaches.

### Common Neurodegenerative Disorders

#### Alzheimer's Disease

Alzheimer's Disease is one of the most commonly observed neurodegenerative disorders across the world. According to Glenner and Wong (1984), it is one of the major causes of dementia among older patients, which further leads to the death of huge masses of people in developed countries across the globe. According to the data presented by Vos et al. (2015), more than 25 million people in the world are suffering from AD at present, among which the most prevalent countries being China, Western Europe, and Latin and North America. The total incidences of AD in the world are expected to rise to almost 42.3 million

by the end of 2020 (Das et al., 2012). The key implication of the disorder which is witnessed in patients suffering from this disease is neurodegeneration, which may be initiated by protein deposition or synaptic injury and then results in neuronal loss, which tends to cause memory loss, cognitive disabilities, and behavioral changes in the patients (Garand et al., 2000).

Although there have been several studies that explain the molecular mechanisms associated with the disease, Sastre et al. (2006) argue that it continues to be unclear as to which of the mechanisms are most suitable and relevant in describing the occurrence of AD in people. One of the most commonly discussed molecular mechanisms used to explain the disorder is the hyperactivation of cyclin-dependent kinase-5 (CDK5), which is a signaling protein. As explained by Masters et al. (2006), CDK5 is one of the most important proteins which is responsible for neuronal development and usually gets activated by the generation of p35 or p39, which ultimately results in the formation of a specific complex, which tends to become a very important element of the overall neuroplasticity as observed in the pathogenesis of the disorder (Masters et al., 2006).

The molecular mechanism occurring during the interaction of CDK5 with p25 leads to over activation of CDK5 and also results into tau hyperphosphorylation, and these two occurrences collaboratively lead to the formation of neurofibrillary tangles (NFTs), which results in neural disorder (Dong et al., 2009). The cleavage of the activators has been found to occur because of the abnormal processing of amyloid precursor protein (APP) due to genetic disorders, which results in the changes in overall calcium signaling. The model suggests that the p25 activator is associated with the memory of people and hence over generation of the same in patients' brains results in memory loss (Giese, 2014).

However, the recent discussions presented by Lloret et al. (2015) confirmed that there is actually a decline and not increase in the quantity of p25 in AD. While there have been several debates regarding the same, Lloret et al. (2015) explained that the reduction in overall quantity of p25 leads to higher levels of amyloid-induced synaptic toxicity, which eventually results in a reduction in calcium signaling, thus causing degeneration of the neurons. In addition to this, there is yet another model that describes the occurrence and molecular phenomenon and mechanism associated with the disease which is related to abnormal accumulation of amyloid- $\beta$  (A $\beta$ ) and plaques containing the same, which finally results in toxic oligomers and neuronal disorders (Rajmohan and Reddy, 2017). Thus, these molecular changes and reactions have been found to be the main causes of AD and will further help in understanding the application of nanotheranostics for treating the same.

#### Parkinson's Disease

The second most common neurodegenerative disorder is PD, which is a disorder of the central nervous system (CNS), thus leading to various problems in motor abilities and system of the patients. As explained by De Lau and Breteler (2006), the disorder leads to malfunctioning or even death of the different vital neurons in the brain, especially those present in the substantia nigra region. The death of these neurons leads to a decrease in the production of dopamine (DA), which is a key chemical and

is used for instructing brain to carry out and control different activities and movements. Thus, a reduction in DA leads to impaired movement and affects other body functions (Mazzoni et al., 2012). Some of the key signs or symptoms of PD include stiffness of limbs, slow movement, tremor in hands and other joints, and difficulty in balance and coordination of different body parts and movements (Jankovic, 2008). Although the exact cause of PD has not been established yet, studies have explained the molecular mechanisms underlying the same that help in explaining the occurrence of the disease.

One of the key molecular mechanisms that is found to be associated with the onset of PD is the development of filamentous structures of the major protein constituent of the brain, i.e., alpha-synuclein ( $\alpha$ -synuclein), which results into the development of toxic materials (Burré et al., 2010). As explained by Stefanis (2012), the protein  $\alpha$ -synuclein plays an extremely pivotal and significant role in the recycling and compartmentalization of neurotransmitters in the brain and also exhibits a key propensity to get aggregated because of its internal constituents. The enhanced aggregation of the protein is then found to lead to elevated toxicity, which can result in neuron dysfunction in the patients. Another perspective or mechanism *via* which this protein tends to lead to PD is when the protein gets aggregated in the form of Lewy bodies inside the brain, it leads to the development of  $\alpha$ -synucleinopathies (Kim et al., 2014). The molecular mechanism of cell–cell transmission is known to activate and push the accumulation of the protein, thus resulting in the reduction of DA production, causing an increase in the onset of the disorder (Mothes et al., 2010).

These mechanisms as described above have explained the causes behind the two most commonly observed neurodegenerative disorders. Further discussions thus evaluate and explain the recent advancements in the field of translational nanotheranostics for treating these disorders. The study presents the findings obtained from the approach used in different forms of modeling to deduce its applicability and limitations.

## NANTHERANOSTICS AND ITS DEVELOPMENT IN THE CONTEXT OF NEURODEGENERATION

Nanotheranostics, as described by Zhang et al. (2018), includes the injection of the nanotheranostic agent *via* different drug particles, and after reaching the target area of the body, the shell of the medicine tends to disintegrate, resulting in the release of the agents. This helps in aiming at the molecules or neurons that are causing or leading to the disorder. According to Tripathy et al. (2018), the fact that the treatment is being given so much attention in the medical field is because it is an extremely aggressive treatment and targets directly the affected area in patients' bodies. Moreover, it can be tailored according to the disease and needs of every individual, which leads to an enhancement in the overall practical applications of the approach, hence resulting in the provision of personalized treatment and medicine options (Assaraf et al., 2014). It has been argued that the therapy or treatment has become possible

only because of the recent developments that have taken place in the field of chemistry and technologies as the chemical developments have led to the development of a phenomenon, wherein electromagnetic waves can be easily converted into processes that are medically relevant at the nanoscale because of the use of different metal nanoparticles (NPs) (Han et al., 2017). This chemical phenomenon is thus combined with the laser technologies that can help in penetration of the agents to a deeper level in tissues of human bodies, thus making the process simpler and much more effective. While these developments seem to make the application of nanotheranostic process extremely effective (Melancon et al., 2012), it is arguable whether the results that have been obtained until now are completely based on *in vitro* studies and the *in vivo* applicability still remains a challenge. The therapy has been tested in different situations and developed *via* animal, cell, and human modeling. Various tests have been conducted, and their outcomes are described below to explain the recent developments that have taken place in the field (McCarroll et al., 2014; Clift et al., 2015; Kievit et al., 2017; Zavaleta et al., 2018).

## Possible Methods to Overcome the Blood–Brain Barrier

There are a number of pharmacologically active substances that have the potential to treat CNS disorders, but due to the blood–brain barrier (BBB), they are not able to access their targets (Cipolla, 2009). Naturally, there are two transport methods (a) active and (b) passive by which molecules are absorbed by the BBB (Tsuji, 2005). Passive transport is a passive diffusion which follows two non-energetic transportation pathways known as paracellular and transcellular diffusion. Hydrophilic compounds are diffused between endothelial cells *via* paracellular diffusion, and small lipophilic molecules are diffused through endothelial cells *via* transcellular diffusion. Here, one thing is noted that lipid solubility plays a critical role in passive transport into the BBB, this method can be used for the chemical transformation of water-soluble molecules into lipid-soluble molecules that can cross the BBB. The drug molecules can be designed by the addition of lipid or functional moiety to them (Lu et al., 2014). Steroids and diphenhydramine are the examples of these types of drugs that can cross the BBB (Au-Yeung et al., 2006; De Gregori et al., 2012). Antibodies and erythropoietin are the examples of paracellular pathways that influence the molecules entering to some extent into the brain. These are usually the case of molecules that have long half-lives, small distribution volumes, and strong effects on the CNS (Banks, 2004). Passive diffusion of liposoluble molecules occurs *via* the transcellular transport (Abbott, 2005; Vos et al., 2015). The active transport requires energy for transport of therapeutic molecules to reach the CNS *via* crossing the BBB through biological gradients, i.e., as opioid analgesics, cardiac glycosides, and calcium channel blockers (Sanchez-Covarrubias et al., 2014). Passage of amino acids across the BBB is mediated by specialized transporters, i.e., glucose transporter (GLUT-1), that assist glucose to cross the brain (Du et al., 2014). Several amino acids, i.e., methionine, valine, histidine, and tyrosine, are required for crossing the BBB to gain access to

the CNS *via* the transporter. L-DOPA or levodopa, an anti-PD drug, is the classical example of drug that enters the CNS by this mechanism which operates with large amino acid transporter 1 (LAT-1) (del Amo et al., 2008). Glucose, vitamins, and some peptides follow the same mechanism to cross the BBB to gain access to the CNS at a faster rate than expected (Banks, 2016). Transport through the BBB also occurs by efflux mechanisms. P-glycoprotein (Pgp) mechanism is the example efflux unwanted complexes, such as anticancer drugs and antibiotics (Begley, 2004; Huwyler et al., 2008). NP interactions with the blood coagulation can be engineered to carry anticoagulant drugs initiating factors to treat PD and AD. Coagulation system with nanomaterials and anticoagulant properties of NPs on the blood coagulation system represent significant concerns in the field of nanomedicine using physicochemical properties (e.g., size, charge, and hydrophobicity) that regulate their undesirable properties on the blood coagulation system to understand unwanted side effects that are used for industrial and medical applications because of their small size, toxicity, risk assessment, and management which warrant attention to clotting, reactions triggering inflammatory, immune responses, and hemolysis.

## Animal Modeling

Animal modeling has been one of the key approaches used by researchers to evaluate the impacts and implications of nanotheranostics, and the results of the same have been extremely positive. The modeling was started with small animals like mice and is now being scaled up to the human levels (Kievit and Zhang, 2011). One of the key carriers, whose impacta have been studied and evaluated on animals, is gold nanoparticles (AuNPs). AuNPs have been found to exhibit characteristics that make them extremely suitable for the purpose of nanotheranostics, and they can also be used in various shapes, thus providing higher flexibility to the clinicians (De Lau et al., 2006). The research carried out by Mieszawska et al. (2013) made use of the peptide-functionalized AuNPs to evaluate its impact on the gastric-releasing peptide (GRP) receptor. The AuNPs were conjugated along with an RGD-peptide and injected into small animals, i.e., mice, to evaluate the impacts of the elements on the animal. The application and injection of the NPs in the mice indicated higher tumor accumulation, thus providing a successful approach for treating tumors as well as NDs like AD (Ramanathan et al., 2018).

A similar study carried out by Muthu et al. (2014) included the testing on 24 mice, wherein AuNPs were injected in local tumors contained in those animals (Muthu et al., 2014). The mice were also divided into four different groups to be able to compare the results effectively; the groups contained agent-only group, laser-only group, control group, and lastly agent and laser group. The results of the study revealed that the use of gold coating on the medicine proved to be extremely beneficial in treating the animals and led to the destruction of tumor cells without having any impact on the animal (Muthu et al., 2014). Further explaining the fact that the practice or approach has been found to be effective for tumor ablation makes it effective for even treating diseases like PD wherein the proteins tend to accumulate and cause motor dysfunction, and thus the practice of nanotheranostics can be used to address those areas and

destroy the over-accumulation of particles for better outcomes and results. Lee et al. (2015) have discussed that the developments that have taken place in nanotheranostics in South Korea and explained the way the application and modeling of the approach on animals like mice have given key insights into the benefits of the technique. One of the key nanotheranostic techniques that have been tested on mice is the synchrotron radiation x-ray computerized topography (SR-CT) approach, which is a high-speed imaging process (Lee et al., 2015). The approach was used on mice along with a colloidal hybrid silica NP, which resulted in an *in vivo* broad circulation and distribution of the same in the animal, thus leading to treatment of neuron-related defects. While these discussions reveal and confirm the effectiveness of nanotheranostics in treating neurodegenerative disorders in animals, Conde et al. (2015) argue that whether the same can be scaled up to humans or not is something that has not been verified yet.

## Cell Modeling

Another approach or practice that has been adopted in addition to the animal modeling approach is that of cell modeling, wherein different models are developed based on cell culture and characteristics of the human body to evaluate the impacts of the applied treatment. Researchers have made use of the cellular models of brains of different animals like mice to evaluate the impacts of nanotheranostics technique or approach on the factors causing the onset of neurodegenerative disorders (Chen et al., 2017; Kievit et al., 2017; Ulapane et al., 2017). Zhang et al. (2015) developed and made use of the cell-based models of different disorders like AD and PD and evaluated the impacts of NPs on macrophages on the cells contained in the model. The cell modeling based on the use of theranostics in microphage assisted in highlighting that the technique helps in ablation of macrophages, which tends to inhibit and reduce the overall inflammation in cells, thus resulting into treatment of the neurodegenerative disorder. However, the cell modeling-based results as presented by Zhao et al. (2017) highlight that the use of nanotheranostics has been found to be effective only at the preliminary stage on different cell structures of diseases and have not been very effective in the long run (Dilnawaz et al., 2012).

Cell modeling has been found to be majorly used for highlighting the benefits and application of the nanotheranostics technique in the diagnosis of neurodegenerative disorders. Mohan and Rapoport (2010) carried out multiple experiments, in which different nanotheranostic agents were developed and used for different diagnostic practices and approaches such as computed tomography and cellular imaging (Chowdhury et al., 2018). The results presented by Mohan and Rapoport (2010) highlighted that the inclusion of nanotheranostic agents and processes have led to the development of new practices, such as magnetic resonance spectroscopy, which help in better diagnosis of neurodegenerative disorders like AD and PD due to the enhanced ability of identifying the activation of CDK5 protein or identifying the areas of excessive accumulation of proteins causing PD. Niu et al. (2017) developed a silicon model of the cells of PD patients wherein the DA transporter cells were modeled. The use of nanotheranostic approach using NPs on the model was

found to be aggressive and invasive and led to the stimulation of these transporter cells, thus resulting in the creation of higher DA which, as discussed earlier, has been found to be responsible for facilitating motor activities in humans.

These results obtained from human and cell modeling have given satisfactory results and outcomes but whether the approach can be used for clinical applications for treating neurodegenerative disorders is still doubtful. Recent developments have hence made use of a few human models to test the same, which are being described below.

## Human Modeling

García et al. (2017) carried out an evidence-based study of using nanotheranostics for personalized medicine in treating neurodegenerative disorders. The study made use of metallothioneins (MTs) as a drug discovery biomarker which was injected in patients suffering from neurodegenerative disorders. This nanotheranostic approach proved that the use of such biomarkers helps in targeting specific cells in human bodies, thus resulting in eradication of different malignancies and neural dysfunctions that usually results in disorders like AD and PD (García et al., 2017; Kumar et al., 2017; Kaushik et al., 2018b, 2019a,c; Pan et al., 2019). However, the study carried out by Ruozzi et al. (2014) which focused on injecting AuNPs in voluntary AD patients revealed that the approach was effective and beneficial for early diagnosis of the neurodegenerative disorders, but was not yet completely able to treat the same.

Similar human modeling and test were carried out by Maysinger et al. (2015), and they studied the characteristics and problem areas of multiple human beings and identified different biomarkers on the basis of their conditions such that the unique characteristics of each of the NPs could be targeted at treating specific conditions. The study confirmed that while the use of these NPs is effective for diagnostics of neurodegenerative disorders, they still cannot be validated as an effective approach for treating them. Similar discussions as presented in a paper (Wang et al., 2017) confirm that the technique holds great promises for being used as a non-invasive technique for treating NDs like AD by targeting the specific problem areas and spots. Dual-functional NPs targeting amyloid plaques in the brains of AD mice have also been reported (Zhang et al., 2014; Kaushik et al., 2019b). However, these studies do not confirm the effectiveness of the method, and there are various limitations of the same that have been identified by experts. Some of the key limitations of the technique are hence being described in this review.

## Access of Nanoparticles to the Central Nervous System

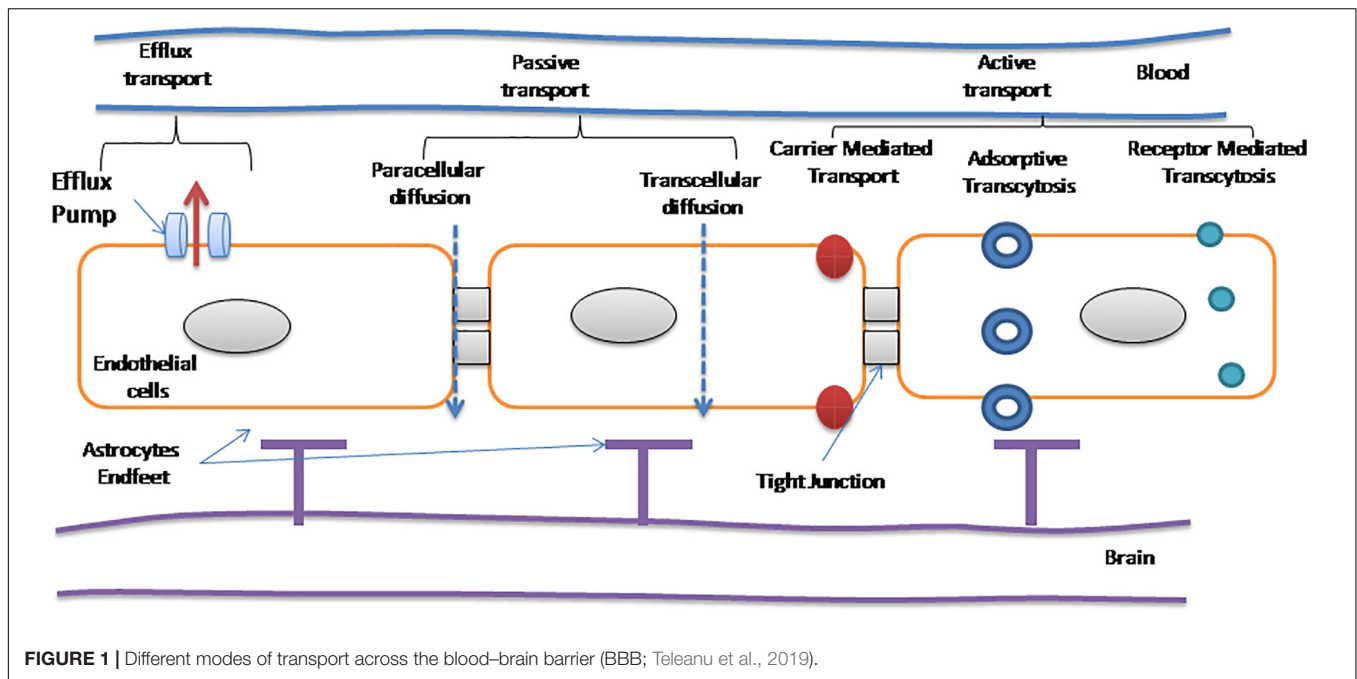

With the advent of nanotechnology, new perspective to treat NDs has been opened for diagnostics as well as therapeutics purposes. Due to multifunctional and versatile structures of NPs, they can be utilized for brain drug delivery. But prior to their application, the major considerations are the surface chemistry, hydrophobicity, shape, size and charge, etc. An ideal NP should be biocompatible, has reduced toxicity, and has the ability to bind

and transport drugs or therapeutics. It should not be degraded readily *in vivo* to control therapeutics release for prolonged time periods and can navigate *via* the BBB. All these features lead to those NPs which can penetrate the BBB with high efficacy (Goldsmith et al., 2014). Deliver NP conveniently and effectively has controlled to a deep examination of site-specific drug delivery, toward the convenient non-invasive delivery to specific sites of the delivered dose, to gain access to specific concentrate of therapeutic dose at the specific sites of pharmacological action. Currently, drugs/NPs gain access to the CNS *via* non-invasive methods, i.e., intranasal delivery that are based on drug modification to enhance the permeability of the BBB (Illum, 2003; Kaushik et al., 2018a) and invasive methods that impart direct intraventricular or intracerebral injection/implantation, infusion (Pardridge, 2016). Temporary disruption is also useful to some extent to cross the BBB (McDannold et al., 2012). The BBB disruption is broadly used to enhance drug delivery efficiency to the brain. For example, to treat certain CNS cancers, mannitol is used for osmotic opening to disrupt the BBB (Kroll and Neuwelt, 1998) and temporary pores are made open by using ultrasound in the BBB (Dasgupta et al., 2016). Recently, it has been evident that in the case of AD and multiple sclerosis, pathological BBB disruption occurs which leads to permeability for small therapeutic molecules (<1,000 Da) (Cheng et al., 2010). NPs have their intrinsic physical and chemical properties which decide the route of transport and mechanisms to cross the BBB (Chowdhury et al., 2018). When NPs are functionalized with an appropriate ligand, they can cross the BBB and are capable to distribute drugs in the diseased brain (Tosi et al., 2008; Kaushik and Wei, 2019). In **Figure 1**, several transport mechanisms of NPs have been illustrated and discussed. They can enhance the permeabilization of the BBB by opening tight junctions and letting drugs or drug-conjugated NPs infiltrate into the CNS (Choi et al., 2010); may follow transcytosis mechanism to pass through endothelial cells (Choi et al., 2010); and can be transported by endocytosis into endothelial cells (Kong et al., 2012). Neuropharmaceuticals research is the new emerging niche that is evolving gradually by understanding the receptor-mediated transcytosis and the adsorptive-mediated transcytosis mechanisms and by studying all the intrinsic physicochemical properties of NPs. This could lead to therapeutics that can cross the BBB more efficiently and can provide a patient-oriented therapy (Smith and Gumbleton, 2006).

## NANOPARTICLE APPLICATIONS IN NEURODEGENERATIVE DISEASES

### Nanocomposite

Most of the AD treatments have focused on A $\beta$ -targeted therapy. Chen et al. (2018) brought into picture that tau pathway is closely related to the development of AD (Kaushik et al., 2018b) (Uddin et al., 2018). They constructed a methylene blue-loaded multifunctional nanocomposite (CeNC/IONC/MSN-T807), which possessed a high binding affinity to hyperphosphorylated tau. The surface-decorated CeNC mitigated mitochondrial oxidative stress and suppressed tau hyper

phosphorylation, whereas the loaded MB inhibited hyper phosphorylated tau aggregation. As a result, in comparison with the effectiveness of CeNC/IONC/MSN-T807 or MB alone, when both are combined to form a multifunctional nanocomposite, a synergistic therapeutic effect was achieved.

Siddique et al. (2016) studied the effect of alginate nanocomposite (BANC) on PD model flies. A significant decrease in lipid peroxidation and glutathione-S-transferase activity and an increase in glutathione content were observed in PD flies when exposed to BANC. Nevertheless, there was no gross morphological change in the brains of PD flies. The results suggested that BANC is effective in reducing the PD symptoms in these transgenic flies (Siddique et al., 2016).

Oxidative stress disorders have a wide influence on pulmonary, neurodegenerative, and autoimmune diseases and on many more disorders. Selenium (Se) is capable of suppressing oxidative stress disorder, but there is a very thin line between the toxicity and beneficial effects of Se, which makes it difficult and challenging to be used in therapy. Deng et al. (2017) developed porous Se:SiO<sub>2</sub> nanocomposites which ensured controlled release of Se particles, having favorable biocompatibility and could effectively reduce reactive oxygen species (ROS) damage.

## Metal Nanoparticles

Nerve growth factor (NGF) is one of the most essential factors for neuronal growth. Nevertheless, its application in neurogeneration is limited due to slow diffusion and short half-life. Moreover, the main obstruction is that the NGF cannot be easily transported through the BBB because of its selective permeability of the BBB. Although there are many magnetic NPs that have been used as an effective nano-carrier for NGF, uncoated magnetic NPs face problems due to their instability

in neuronal environment, aggregation, and cellular toxicity. To address these issues, Yuan et al. (2018) proposed that coating them with a thin and impenetrable shell with materials such as polymer, alloy, metals, etc. can solve the problem to some extent. NGF functionalized Au coated SPIO core NPs [Diameter (D): 20.8 nm] was synthesized by them. They selected gold (Au) stating it to be the best candidate due to its outstanding biocompatibility, high stabilities, and tunable surface function. This gold coating not only protects the iron oxide but also provides tunable surface functionalization with several ligands, such as proteins, aptamers, and peptides, due to which precise and controlled release of neuroregeneration can be achieved toward specific sites.

It has been reported that microRNA 141 (miR141) could silence the expression of lncRNA HOTAIR by binding to specific sites on lncRNA HOTAIR. Liu et al. (2018) mediated the high expression of microRNA141 in human amniotic epithelial stem cells by using super paramagnetic iron oxide NPs (SPIONs). They also reported that SPION-mediated overexpression of miR141 is able to promote the expression of brain-derived neurotrophic factor (BDNF), DAT, and 5TH in human amniotic epithelial stem cells (HuAESC)-derived dopaminergic neuron-like cells (iDNLCs). Their study confirmed that the efficiency of HuAESC differentiation into dopaminergic neuron-like cells could be highly improved by miR141 mediated by SPIONs.

Amyloid fibrils are closely associated with various NDs. The hindrance to the diagnosis and development of therapeutic strategies is the identification of fibrils at low concentrations (Kumar et al., 2018). Employed gold nanorods to detect the formation of amyloid fibrils based on  $\alpha$ -synuclein. They observed no apparent interaction of gold nanorods with monomeric proteins. However, effective adsorption onto fibril structures

via non-covalent interactions was reported. The strong dipolar coupling in helical Au nanorod promoted the intense chiral response as a result allowed them to detect amyloid fibrils as low as nanomolar concentrations.

Selective detection and quantification of DA is an important key to monitor NDs. However, the limit of detection for DA is in the lower nanometer range. It is significant to push the detection limit to few picomolar or lower. Cao et al. (2018) utilized DA DNA aptamer (DAAPT)-AuNP conjugate to enhance the surface plasmon resonance (SPR) signal (Xue et al., 2018). As a result, this enabled the detection and quantification of DA in the femtomolar to picomolar range. They reported that this is the lowest detection limit achieved for sensing of DA through SPR (Yuan et al., 2018).

## Quantum Dots

With emerging technology, it is indicated that the pathogenesis of PD is strongly related to the accumulation of  $\alpha$ -synuclein aggregates. Anti-aggregation agent is yet to be achieved for this disease (Dong et al., 2009). Kim H. et al. (2018) showed that graphene quantum dots (GQDs) interact with  $\alpha$ -synuclein to exhibit anti-amyloid activity. They reported that GQDs have notable potency not only in inhibiting fibrillization of  $\alpha$ -synuclein, but they can also disaggregate mature fibrils with time. They also reported remarkable property of GQDs such as rescued neuronal death and synaptic loss. Moreover, GQDs were found out to help reduce Lewy body (LB)/Lewy neurite (LN) formation, ameliorate mitochondrial dysfunctions, and prevent neuron-to-neuron transmission of  $\alpha$ -synuclein pathology induced by  $\alpha$ -synuclein preformed fibrils (PFFs) in neurons. They proposed that GQD could function as an anti-aggregation agent, which provides a promising novel therapeutic target for the treatment of PD. The toxicity of QDs in the milieu and biological systems become a key point for the NP, and the potential toxicity of QDs on immunotoxicity of QDs is still unclear. Brain disorders' major hurdle is BBB, many drugs are being proposed for brain disorders, which however fail because of their inability to cross the BBB. Hence, as the molecular structure of the BBB is better elucidated, several approaches are being evaluated, such as adsorptive-mediated transcytosis, inhibition of active efflux pumps, receptor-mediated transport, cell-mediated endocytosis, and delivery from microspheres, biodegradable wafers, and colloidal drug-carrier systems (e.g., liposomes, NPs, nanogels, dendrimers, micelles, nanoemulsions, polymersomes, exosomes, and QDs).

## Labeling and Biomarkers

Subtle alterations in synaptic connections and perturbed neuronal network functionality are the main characteristics to determine neurodevelopmental and neurodegenerative disorders. The presence of dendritic spines, micron-sized protrusions of the dendritic shaft that compartmentalize single synapses to fine-tune synaptic strength, is the hallmark of neuronal connectivity. However, it is hard to quantify spine density and morphology in mature neuronal networks due to the lack of targeted labeling strategies (Xiong et al., 2018) and optimize a method to deliver cell-impermeable compounds into selected cells based on spatially resolved

nanoparticle-enhanced photoporation (SNAP) to resolve the above-stated problem (Xiong et al., 2018). They showed that efficient labeling of selected individual neurons and their spines in dense cultured networks can be achieved by SNAP without affecting short-term viability. SNAP holds promise for high-content screening campaigns of neuronal connectivity in the context of neurodevelopmental and neurodegenerative disorders.

## Biosensor

Multifactorial pathways affect AD, which is associated with the loss of nerve cells in the brain. This as a result leads to changes in related biomolecular levels as AD progresses. Therefore, for accuracy regarding AD, diagnosis is supposed to be done with combined detection of several lesions. Amyloid beta 1–40, 1–42, and  $\tau$  (tau) protein can be used as main diagnostic target markers. Kim D. et al. (2018) reported highly selective biosensor for detection of AD core biomarkers using distinct localized SPR (LSPR) depending on AuNP shapes, which is called shape-code biosensor. This plasmonic sensor does not need any other method for separation of samples and identification of markers. It consists of only AuNPs and antibody. In addition to this, they reported that this is the first highly sensitive shape-code biosensor to detect AD biomarkers (Indrasekara et al., 2014).

## LIMITATIONS

One of the key limitations or challenges of making use of the nanotheranostic technique for treating neurodegenerative disorders, as identified by Indrasekara et al. (2014) is that every patient has a different genome and neural functioning and characteristics, and hence no single approach can be used to treat all of them. The practitioners not only are required to be able to diagnose the causes of these neurodegenerative disorders in every individual separately but also need to identify the suitable treatment for them, which is a challenging task and does not help in identifying one method or treatment technique that is suitable for all (De Lau et al., 2006).

Another challenge or limitation that has been identified by Kim et al. (2013) and suggests that the technique tends to become ineffective because the absorption time of the NPs used in the technique is very low and hence if the injection is not done adequately, these NPs might get absorbed in the blood or by other body parts instead of the area at where it was targeted. It has been found that the neurodegenerative disorders like AD and PD are caused by the neurodysfunction or accumulation of proteins and hence if the drug is not injected adequately, it will not be absorbed or used for treating the desired area (Kim et al., 2013). In fact, it has been argued that, in practice, only a small proportion or part of the drug gets transmitted and transferred to the affected areas and hence the treatment has not yet been established to be completely effective (Rahman et al., 2015).

Another limitation as identified is that the treatment cannot be monitored effectively and efficiently, which imposes a big challenge for the practitioners because they are not able to monitor the progress and impacts of the treatment that they are

giving to the patients. This thus makes the treatment method and technique ineffective. The treatment is also extremely expensive currently. Diou et al. (2012) discuss that most of the research done in the field has failed massively, which has led to an increase in the overall costs of research, thus also leading to higher costs of delivery of the same in the market. These limitations are thus needed to be overcome in order to enhance the applicability of the technique (Hans and Lowman, 2002; Diou et al., 2012; Ilinskaya and Dobrovolskaia, 2013; Luo et al., 2015; Liu et al., 2017; Radhakrishnan and Kamalasanan, 2018; Khan et al., 2019).

## CONCLUSION

The molecular changes and reactions have been found to be the key causes of NDs. The research in this field predominantly focuses on genetic mutations, building up of toxic proteins, and formation of neurotoxic molecules. The discussions presented in this study reveal that the nanotheranostics approach has a huge potential in the field of medicine for treating different neurodegenerative disorders. Animal, cell, and human modeling using nanotheranostics approaches for the treatment of neurodegenerative disorders has revolutionized the field. Nanocomposite, metal NPs, and QDs are well reported to treat these neurodegenerative disorders. Limitations that are associated with these NPs are needed to

be overcome. Although the studies that have been carried out for the field until now have not provided any significant results to be scaled up to humans, their impacts on the reduction of molecular activities causing neurodegenerative disorders have been significant and hence the approach has a strong potential for developing significant outcomes in the long run.

## AUTHOR CONTRIBUTIONS

All authors conceptualized the ideas, conducted the literature search, prepared the figure, drafted the manuscript, and read and approved the final manuscript.

## FUNDING

This work was supported by the Key Research Area Grant 2016YFA0501703 of the Ministry of Science and Technology of China, the National Natural Science Foundation of China (Contract nos. 61832019 and 61503244), the State Key Lab of Microbial Metabolism, and the Joint Research Funds for Medical and Engineering and Scientific Research at Shanghai Jiao Tong University (YG2017ZD14).

Tseng K-K, Li J, Tang Y-J, Yang C-W, Lin F-Y and Zhao Z (2020) Clustering Analysis of Aging Diseases and Chronic Habits With Multivariate Time Series Electrocardiogram and Medical Records. *Front. Aging Neurosci.* 12:95. doi: 10.3389/fnagi.2020.00095

**Background:** With recent technology, multivariate time-series electrocardiogram (ECG) analysis has played an important role in diagnosing cardiovascular diseases. However, discovering the association of wide range aging disease and chronic habit with ECG analysis still has room to be explored. This article mainly analyzes the possible relationship between common aging diseases or chorionic habits of medical record and ECG, such as diabetes, obesity, and hypertension, or the habit of smoking.

**Methods:** In the research, we first conducted different ECG features, such as those of reduced binary pattern, waveform, and wavelet and then performed a k-means clustering analysis on the correlation between ECGs and the aforementioned diseases and habits, from which it is expected to find a firm association between them and the best characteristics that can be used for future research.

**Results:** In summary, we discovered a weak and strong evidence between ECG and medical records. For strong evidence, most patients with diabetes are always assigned into a specified group no matter the number of classes in the k-means clustering, which means we can find their association between them. For weak evidence, smokers, obesity, and hypertension have less unique ECG feature vector, enabling clustering them into specific groups, so the ECGs might be used to identify smokers, obesity, and hypertension. It is also interesting that we found obesity and hypertension, which are thought to be related to cardiovascular system. However, they are not highly correlated in our clustering analysis, which might indirectly tell us that the impact of obesity and hypertension to our body is various. In addition, the clustering effect of waveform feature is better than the other two methods.

**Keywords:** electrocardiogram, disease analysis, habit analysis, feature extraction, k-means clustering

## INTRODUCTION

In modern clinical medicine, electrocardiogram (ECG) technology is a common diagnostic technique for cardiovascular diseases. Electrocardiogram signal is multivariate time-series data to represent the time of electrical change of the voltage variation, which is detected on the skin. Electrocardiogram technology started in 1903, and so it has existed for more than a century. In this

century, rapidly developing ECG technology has made a great contribution to health, and it has become an indispensable routine examination technology in clinics.

Electrocardiography plays an important role in the diagnosis of heart diseases, such as heart rate variability, myocardial ischemia, and myocardial infarction. However, pathological ECG has complex causes and variations. There are significant differences among the ECGs of patients with the same kind of pathology, even among ECGs of the same patient. To make an accurate judgment, physicians usually need to have a rich knowledge and clinical experience. If the physicians have been engaged in identifying a large number of graphics, fatigue could easily cause them to make a mistake. Thus, there is a strong demand for automatic ECG diagnosis, which has been intensively concerned and studied for a period of time.

For automatic ECG diagnosis, there has been much discussion among many scholars, from the suppression of noise to the identification of feature points, detection of the characteristic parameters, waveform category judgment, and even to the final diagnosis approach. Even though some automatic ECG analysis programs have been put into clinical applications from the laboratory, many research results have not been widely accepted by clinicians because ECGs are inaccurate and not uniform, changing from time to time. Moreover, automatic ECG analysis is still confined to heart disease, such as arrhythmia and myocardial infarction. However, for other diseases, such as obesity, hypertension, and diabetes, or habits, such as smoking, there is little related research. In the latest survey, there is only a simple study where heart rate and diabetes are investigated (Niu et al., 2018).

However, we suspect ECG can provide more information on aging diseases and chronic habits. This article is dedicated to finding the relationships between ECGs and common diseases and habits using k-means clustering (Alsabti et al., 1997; Qin et al., 2018) based on ECG features [reduced binary pattern (RBP) (Tseng et al., 2015), waveform (Tseng et al., 2018), and wavelet (Saechia et al., 2005; Chan et al., 2008; Chiu et al., 2009)], expecting that we can extract accurate feature information from ECG signals for further research of automatic diagnosis.

In this article, some related studies are introduced in *Related Studies*, and *Methods With Feature Extraction* presents the used feature extraction methods. In *Methods With K-Means Clustering*, we introduce the k-means clustering method for this research; *Experimental Results* and *Discussion* follow.

## RELATED STUDIES

### ECG Signal and Noise

Since the ECG signal (Figure 1) is relatively weak, it is vulnerable to environmental disturbances. In order to enhance the active ingredients in the ECG signal, suppress noise and interference, and improve the accuracy of waveform detection, not only is it necessary to have high requirements for the anti-interference ability of the ECG recorder hardware, but it is also necessary to have effective ECG signal filtering preprocessing.

FIGURE 1 | Components of ECG signal.

Electrocardiogram signal acquisition can be divided into two types: one uses multiple (three or more) ECG leads to record the body surface ECG, so obtaining more comprehensive information about heart activity over a certain period of time and focusing on understanding whether heart electrical activity is abnormal, the nature and degree of any abnormality, and the extent of the lesion area; the other uses one or two ECG leads to record and analyze the ECG continuously for a prolonged period (up to hours or even days), so focusing on understanding the rhythm of the heart's electrical activity over a long period, whether the individual heart rate is normal, and the time, type, and frequency of arrhythmia occurring. Electrocardiogram disease diagnosis commonly uses the standard 12-lead ECG acquisition method. The ECG should be collected in a relatively quiet environment, with the person relaxed and calm. In general, the basic requirements (Miao et al., 2015) for ECG acquisition include high gain, high common mode rejection ratio, high input impedance, low noise, low drift, high security, and so on.

During the ECG recording, the signal may be corrupted by low-frequency or high-frequency noise, which alters the waveform of the ECG trace from its original structure. To eliminate this noise, the most common types of noise should be considered (Blanco-Velasco et al., 2008; Li et al., 2016) as follows:

**Extraneous noise:** Extraneous noise in the ECG trace may be caused by a variety of noise sources including perspiration, respiration, body movements, and poor electrode contact.

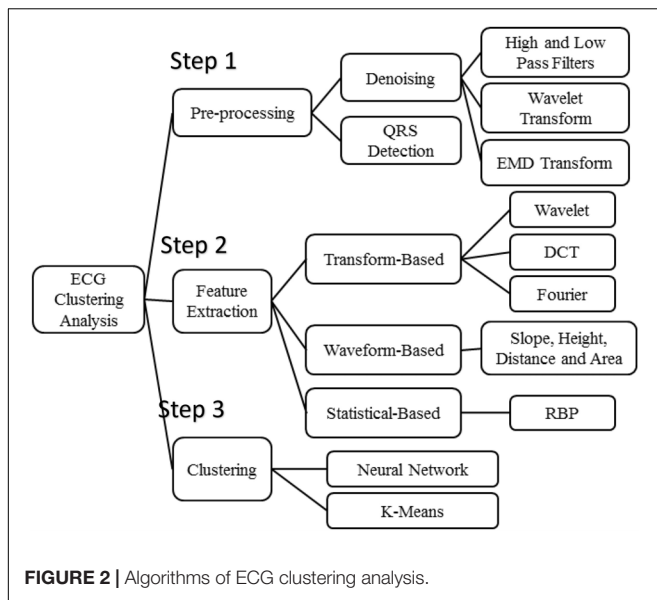

**Electrode motion artifacts:** These are manifested as large-amplitude waveforms primarily caused by stretching that alters the impedance of the skin around the electrode.

**Power line interference:** This is high-frequency noise caused by interference from nearby devices, resulting from improper grounding of the ECG equipment.

**Electromyography noise (EMG noise):** EMG noise is caused by the electrical activity of skeletal muscles during periods of contraction or owing to a sudden body movement. Although the frequency component of EMG overlaps considerably with that of the QRS complex, it also extends into higher frequencies.

**Baseline wander:** Baseline wander is caused by body tiny movements and poor electrode contact, 0.05 to 2.00 Hz.

There are several commonly used filtering methods (Figure 2), such as the traditional finite impulse response (FIR) filter method (Gholam-Hosseini et al., 1998; Lu et al., 2009; Li et al.,

2016), wavelet transform method (Agante and Marques de Sa, 1999; Alfaouri and Daqrouq, 2008), and empirical mode decomposition (EMD) method (Pan et al., 2007; Blanco-Velasco et al., 2008). In recent years, wavelet analysis has been introduced into the ECG filtering process and is widely used. Wavelet transform has good time-frequency localization characteristics, achieving conversion of the signal from time domain to frequency domain. Through multiscale analysis, we can obtain different local characteristics of signals in different scales, which is applicable in analyzing and processing such biomedical signals as ECGs with strong randomness, lower signal-to-noise ratio, non-linear and non-stationary nature, and more singular points.

## Algorithms of ECG Clustering Analysis

**Figure 2** presents the three steps of algorithms used in the ECG clustering analysis. According to experimental flow, it consists of three parts sequentially: step 1: preprocessing, step 2: feature extraction, and step 3: clustering. Denoising methods and QRS detection are the main schemes employed in signal preprocessing. The high- and low-pass filters, wavelet transform, and EMD transform are commonly used for ECG denoising.

Most ECG-based disease analyses rely on features that are derived from the ECG signals. According to our survey, the features are usually extracted according to three various models, that is, transform-based, waveform-based, and statistical-based as is shown in **Figure 2**.

First, transform-based algorithms consist of wavelet transforms (Saechia et al., 2005; Chan et al., 2008; Chiu et al., 2009) and frequency domain transforms, including Fourier transform or discrete cosine transform (Sorwar et al., 2001). Because the wavelet transform contains information in the time and frequency domains, it is more popular than the frequency domain transform.

Waveform-based algorithms extract different time-domain characteristics (distance, height, and area) from fiducial points inside the ECG waveform. These waveform descriptors will

be used to match or classify ECG signals in the disease analysis process. These algorithms usually have good accuracy in recognizing regular ECG signals but show the opposite results for irregular data.

An ECG signal can be described as a non-stationary time series that presents some irregularities in the waveform. Unlike the waveform-based algorithms, the transform-based algorithms analyze the non-stationary information based on the signal's presentation in the frequency domain. Not only is this process slow, but it is also difficult to extract good features for the purpose of classification.

Statistical-based algorithms usually depend on statistical evaluations (count, mean, and variance). They are usually less time-consuming but definitely need a well-designed statistical model to ensure high-quality accuracy. A method based on rank-order statistics was presented to analyze the human heartbeat (Tseng et al., 2015).

For clustering analysis, k-means and neural network are two commonly used clustering methods, but for the sake of simplicity and processing speed, k-means is more applicable in this experiment. Moreover, experiments showed that k-means clustering achieves a positive performance in exploring the relationship between ECGs and the aforementioned diseases and habits.

## PREPROCESSING

During the ECG recording, the signal may be corrupted by low- or high-frequency noise, which alters the waveform of the ECG trace from its original structure. As mentioned above, the raw data in the Physikalisch-Technische Bundesanstalt (PTB) Diagnostic ECG Database are severely affected by noise, whereas the quality of signal in the ECG database from the local hospital is significantly better than in the PTB database, which influences the preprocessing methods, and QRS detection has impact on feature extraction and even the final clustering of ECG features. Therefore, we may need to investigate different features for different ECG databases in order to find the best features for each diagnostic system.

## ECG Denoising

Extraneous noise in the ECG trace may be caused by a variety of noise sources including perspiration, respiration, body movements, and poor electrode contact. Electrode motion artifacts manifest as large-amplitude waveforms primarily caused by stretching, which alters the impedance of the skin around the electrode. Power line interference is high-frequency noise caused by interference from nearby devices resulting from improper grounding of the ECG equipment. Electromyography noise is caused by the electrical activity of skeletal muscles during periods of contraction or resulting from a sudden body movement. Although the frequency component of EMG overlaps considerably with that of the QRS complex, it also extends into higher frequencies. Commonly used filtering methods include the traditional FIR filter method, wavelet transform method, and the EEMD (ensemble EMD) method.

## QRS Detection

For the waveform feature extraction, a more accurate ECG segmentation is needed, so QRS detection and ECG cutting are needed first. QRS detection is based on the matched filter. In order to improve the accuracy of QRS detection under the conditions of Gaussian noise and variable QRS amplitude, the first-order derivative is used for zero threshold detection. In addition, the two non-linear circuits cut off low-amplitude noise and all spikes that occur within a certain time after QRS detection.

## METHODS WITH FEATURE EXTRACTION

### RBP Feature Extraction

The idea of RBP algorithm (Tseng et al., 2015) for ECG disease is related to Yang et al. (2003) and Kumar et al. (2005) works, but we expand it to a different field of application.

All ECG signals are non-stationary. Consider an ECG signal as  $x = \{x_1, x_2, x_3, \dots, x_N\}$ , where the real-valued  $x_i$  corresponds to the  $i^{\text{th}}$  input datum. Each pair of consecutive input signals is compared, and the data are categorized into one of the two cases: a decrease or increase in  $x_i$ . A preliminary reduced function then maps these two cases to 0 or 1, respectively, according to the rule:

$$y_i = \begin{cases} 0, & x_{i+1} \leq x_i \\ 1, & x_{i+1} > x_i \end{cases} \quad (1)$$

This procedure converts the ECG signal of length  $N$  to a binary sequence  $Y = \{y_1, y_2, \dots, y_{N-1}\}$  of length  $N - 1$ . Every  $m$  bit in  $Y$  is grouped to construct a reduced binary sequence of length  $m$ , referred to as an  $m$ -bit word, and then all such words are collected to form an RBP  $B = \{b_1, b_2, \dots, b_{N-m}\}$  where  $b_k = \{y_k, y_{k+1}, \dots, y_{k+m-1}\}$ . We then convert each  $m$ -bit word  $b_k$  to its decimal expansion  $w_k$ . The relative occurrence frequency of  $w_k$  is considered as the features of ECG signals, which we use as the input of clustering method. **Figure 3** presents the process of RBP feature extraction.

### Wavelet Feature Extraction

The procedures of the wavelet-based algorithm (Chiu et al., 2009) include the following: each R-R cardiac cycle is obtained through R-R detection; the first 169 and the last 85 points in each R-R cycle are assembled to form a 256-point segment; every four segments are grouped, and an  $n$ -level discrete wavelet transform (DWT) is performed to obtain the corresponding wavelet coefficients. Four of the computed wavelet coefficients are gathered as a wavelet vector. Here we use the coefficients vector of DWT as the ECG feature. An example with  $n = 9$  is illustrated in **Figure 4**.

### Waveform Feature Extraction

In a waveform-based feature study (Tseng et al., 2018), a total of 24 features are extracted from five classes: position (P, Q, R, S, T), amplitude (PQ, RQ, TQ, RT, PS, RP, TS, RS, PT, QS), duration (QS, PR, QR, ST, QT), slope (RS, ST and QR), and area (area of the QRS triangle). These features form a feature vector  $S$ . Before extracting the features mentioned above, we need to first

accurately locate R, P, Q, T, and S points, which is a key issue for waveform feature extraction. **Figure 5** displays the extraction procedure of waveform feature.

## METHODS WITH K-MEANS CLUSTERING

K-means clustering (Alsabti et al., 1997; Qin et al., 2018) is a rather simple but well-known algorithm for grouping objects. Each object can be represented by a feature vector. First, it extracts ECG features with RBP, waveform, and wavelet and then randomly chooses  $k$  samples in that vector space, which serve as the initial centers of the clusters. Afterward, all objects are each assigned to their closest center. Usually, the distance measure is chosen by the user and determined by the learning task. In this experiment, we chose the Euclidean distance as follows:

$$D = (X_i - X_j)^T (X_i - X_j) = \sum_{k=1}^n (x_{ik} - x_{jk})^2 \quad (2)$$

where  $X_i$  and  $X_j$  are samples, and  $x_{ik}$  and  $x_{jk}$  are the  $k^{\text{th}}$  attribute of  $X_i$  and  $X_j$ .

Then, for each class, a new center is computed by averaging the feature vectors of all objects belonging to this class. The process of assigning objects and recomputing the centers is repeated until the process converges. The algorithm can be proven to converge after a finite number of iterations. Usually, to determine whether the process converges, we take the square error criterion as follows:

$$E = \sum_{i=1}^k \sum_{p \in C_i} |p - m_i|^2 \quad (3)$$

where  $E$  is the sum of the square errors of all samples in the database,  $p$  denotes a sample in the database, and  $m_i$  denotes the means of clustering group  $C_i$ .

## EXPERIMENTAL RESULTS

### Dataset

We conducted a comprehensive experiment on a public ECG dataset, the PTB Diagnostic ECG Database (Bousseljot et al., 1995). The database contains 549 records from 290 subjects (aged 17–87 years, mean 57.2 years; 209 men, mean age 55.5; and 81 women, mean age 61.6; ages were not recorded for 1 female and 14 male subjects, the data of patients 124, 132, 134, and 161 were missed in the PTB database). Each subject is represented by one to five records. Each record includes 15 simultaneously measured signals: the conventional 12 leads (i, ii, iii, avr, avl, avf, v1, v2, v3, v4, v5, v6) together with the three Frank lead ECGs (vx, vy, vz). Each signal is digitized at 1,000 samples per second, with 16-bit resolution over a range of  $\pm 16.384$  mV. By special request to the contributors of the database, recordings may be available at sampling rates of up to 10 kHz.

FIGURE 3 | Process of RBP feature extraction.

FIGURE 4 | Process of wavelet feature extraction.

Within the header (.hea) file of most of these ECG records is a detailed clinical summary, including age, gender, diagnosis, and, where applicable, data on medical history, medication and interventions, coronary artery pathology, ventriculography, echocardiography, and hemodynamics. The clinical summary is not available for 22 subjects. The diagnostic classes of the remaining 268 subjects are summarized in **Table 1**.

## Metrics

In the  $k$  clustering algorithm, two metrics are used to evaluate the relationship between ECGs and diseases or habits.

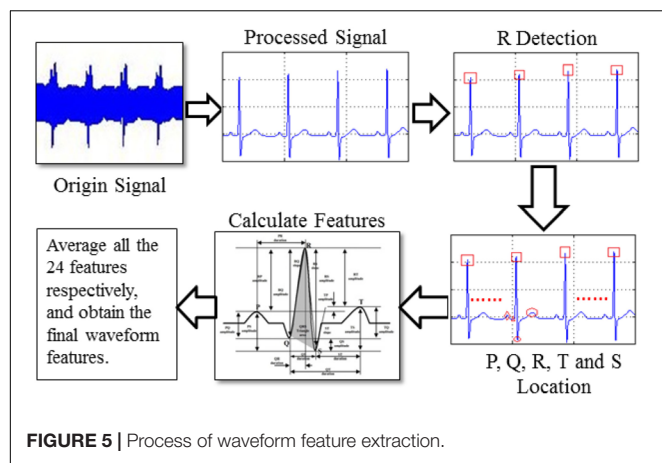

## Ratio

This is a commonly used measurement criterion in the clustering analysis. In order to measure the extent of relationship between ECGs and specified disease or habit, the ratio of the number of subjects with disease or habit to the number of subjects in a group is a good criterion. If the ratio in a group is greater than 50%, there should be a significant correlation between ECGs and disease or habit.

## Concentricity

Sometimes, because of various disturbances, such as shortage of data, it is difficult to achieve a ratio greater than 50%, which

cannot indicate there is no correlation between disease and ECGs, so we need a new criterion to measure the performance of clustering. If all or most of samples with the same disease or habit are assigned into the same group, this disease or habit may be identified based on the ECG feature of this group. This is called concentricity.

## Experiment Software

This research mainly focuses on the ECG signal processing; there are many ECG analysis software developed by MATLAB (Natick, MA, United States). Thus, this research uses MATLAB tools as programming language, especially in signal processing, pattern recognition, mathematical modeling, and other aspects. MATLAB also includes matrix arithmetic operation, relational operation, logical operation, conditional operation, and assignment operation, and these matrix operation methods can be copied into array operation. MATLAB does not need to define dimension in matrix operation and has rich matrix function library for various matrix operations.

**TABLE 1 |** Demographic of PTB database.

Diagnostic class	All patients
Age range	17–87
Man mean age	57.2
Man	209
Woman mean age	55.5
Women	81
Myocardial infarction	148
Cardiomyopathy/heart failure	18
Bundle-branch block	15
Dysrhythmia	14
Healthy controls	52
Arterial hypertension	63
Diabetes mellitus	29
Obesity	20
Smoker	73
Not available	22

## Result Based on RBP Feature

In the experiment, we would cluster the PTB database based on RBP features and chose  $k = 24$ , and 8 ( $k$  being the number of class), which is helpful in observing the variance of clustering performance with increasing  $k$ .

In the clustering with the RBP feature as shown in Table 2 with  $k = 4$  and 8, typically the ratios in the different classes are relatively less than 50%, which indicates that the samples scatter into different classes with  $k$  increasing, and the differences among these classes are not obvious. While  $k = 2$ , the obvious characteristic is that although the number of two groups is approximate, most samples (72.41%) with diabetes are assigned into the second class. Moreover, even though the number of classes in the k-means clustering increases from 2 to 4, even to 8, and the dispersivity of the samples expands, there is always a group in each clustering, for example, group 1 with  $k = 4$  and group 4 with  $k = 8$ , in which the number of samples with diabetes is significantly larger than that in other groups in the same clustering. It demonstrates that diabetes mellitus may be closely related with RBP features of group 2 with  $k = 2$ , group 1 with  $k = 4$  and group 4 with  $k = 8$ .

For other three research targets, there are no highlighted groups in Table 2 in which samples with same disease or habit present the distribution of aggregation, indicating that we cannot detect the relationships between ECGs and obesity, smoking, and hypertension through RBP feature.

## Result Based on Waveform Feature

Similar to the clustering with RBP feature, we would utilize k-means clustering to cluster the PTB database based on waveform feature. Table 3 displays the results of clustering when the number of groups  $k$  is 2, 4, and 8.

With  $k = 4$  and 8, most of samples with diabetes are assigned into a specified group, for example, 22 samples in group 4 of  $k = 4$  and 22 samples in group 6 of  $k = 8$ ; thus, although the number of groups increases from 4 to 8, this group (group 4 with  $k = 4$  and group 6 with  $k = 8$ ) still retains the distribution and composition of various diseases and habits. Moreover, 75.85% of samples with diabetes are allocated in the group with half of all samples, whereas it is a natural and proportional distribution for other three research aspects that only approximately half of their samples are respectively, assigned in this group with half of all samples in the PTB database. It is indicated that diabetes is closely associated with waveform feature extracted from ECGs of the sixth group with  $k = 8$ .

It is observed that there are four classes with  $k = 4$  (corresponding to  $k = 8$ ) with rather higher ratios of smokers, that is, 52.38% in the first group, 77.78% in the fourth group, 66.67% in the seventh group, and 61.45% in the last group. However, there are only three samples in the seventh group, and two of them are also, respectively, patients with obesity or hypertension, which indicates that this group is not practicable and useful because of sparse samples. Perhaps, the sparse samples in the fourth, seventh, and last groups, although with higher ratio of smokers, cannot support the existence of relationship between ECGs and smoking. If we combine these groups with

**TABLE 2 |** Clustering statistics based on RBP feature,  $k = 2, 4$ , and 8.

$k$	Category	Number	Obesity	Smoker	Hypertension	Diabetes

	Group 6	149	11	35	34	22
	Group 7	3	2	2	2	0
	Group 8	13	1	8	2	0

the first group with 21 samples to compose a new group, the problem of sparse samples will be solved, and it is sufficient to determine the relationship between waveform feature of ECGs and smoking, which paves the way of further research about smoking classification.

## Result Based on Wavelet Feature

In the wavelet feature extraction, four segments are grouped, and an  $n$ -level DWT is performed to obtain the corresponding wavelet coefficients. **Table 4** presents the clustering results with different number of groups  $k$ .

Compared with RBP feature and waveform feature, clustering upon wavelet feature cannot achieve a positive performance both in the ratio criterion and concentricity criterion. With the number of groups increasing in the  $k$ -means clustering, the samples with specified disease or habit scatter in these groups randomly without any concentricity. Moreover, when the number of groups  $k$  is 8, the ratios in the groups with enough samples are almost less than 50%. So we cannot find useful information to support the relationship between ECGs and the

aforementioned diseases or habits in the  $k$ -means clustering with wavelet feature.

## DISCUSSION

In this section, we discuss some issues that may be interest to readers. There are the issues of  $k$  parameter, feature extraction, ECG dataset, and evidence.

### Issues of $k$ Parameter

#### Why Were Multiple Feature Extraction Algorithms Used?

Each feature extraction algorithm has different characteristics; for example, in **Figure 6**, wavelet has a good clustering performance at  $k = 2$ , but waveform performs better than the other two algorithms at  $k = 4$  and  $k = 8$ .

#### Why Was the Elbow Method Not Used?

We are exploring the effects of different  $k$  parameters and different feature extraction, so we did not use the elbow method. The reason that we use different  $k$  values as  $k = 2, 4$ , and 8 for comparative study, in addition to see the result under different  $k$ , if a disease can show a better clustering effect under different  $k$  parameters, it means that it has a higher degree of stability. In the future, if we want design the classification system, we should use the elbow method.

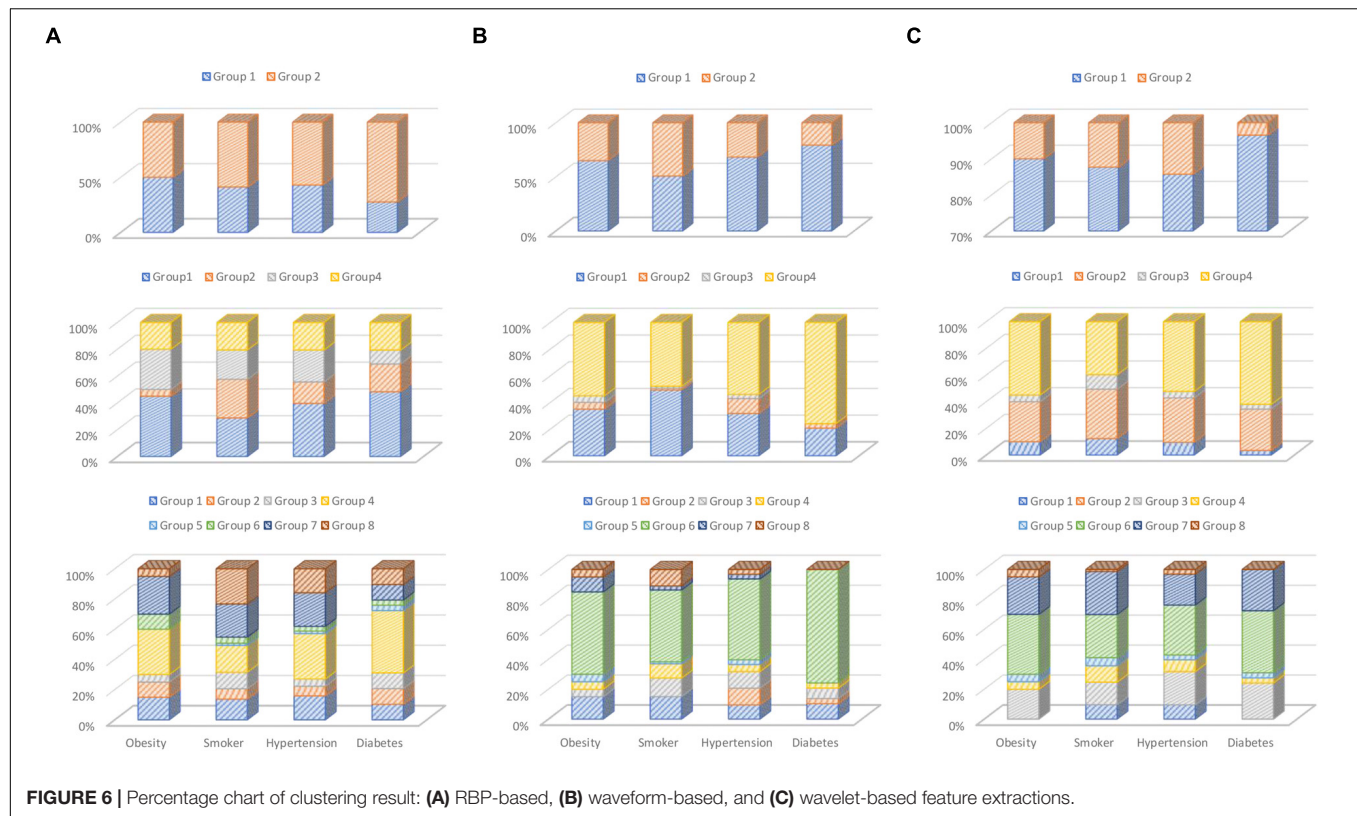

### Issues of Feature Extraction

#### Why Choose These Three Feature Extraction Algorithms for Comparison?

Each feature extraction algorithm has different characteristics; for example, in **Figure 6**, wavelet has a good clustering performance at  $k = 2$ , RBP performance after  $k = 2$ , better than waveform. But waveform performs better than the other two algorithms at  $k = 4$  and 8. In addition, the three feature extraction methods we selected are also representative. The RBP feature is statistical

**TABLE 4 |** Clustering statistics based on wavelet feature,  $k = 2, 4$ , and 8.

$k$	Category	Number	Obesity	Smoker	Hypertension	Diabetes
2	Group 1	257	18	64	54	28
	Group 2	33	2	9	9	1
4	Group1	23	2	9	6	1
	Group2	96	6	27	21	9
	Group3	15	1	8	3	1
	Group4	156	11	29	33	18
8	Group 1	18	0	7	6	0
	Group 2	2	0	0	0	0
	Group 3	58	4	11	14	7
	Group 4	19	1	8	5	1
	Group 5	8	1	4	2	1
	Group 6	105	8	21	21	12
	Group 7	73	5	21	13	8
	Group 8	7	1	1	2	0

method; waveform feature is morphological method, and wavelet is transformation method.

### Why Not Perform Fusion Clustering on the Three Methods of Feature Extraction?

According to our previous clustering and classification experiments, if multiple feature extractions are used together, the performance is often worse, because different features may interfere with each other. Moreover, this study mainly focuses on the clustering correlation study between ECG and disease; using different features for comparative analysis is more desired in this article. In the future, when we develop the classification and diagnosis system, we will seek more sophisticated feature extraction method; the feature fusion issue will be studied as well.

### Issues of ECG Dataset

#### Why Did We Select Only Aging Chronic Diseases for Clustering Analysis?

We have performed only clustering analysis on arterial hypertension, diabetes mellitus, obesity, and smoker. Because other common heart diseases such as myocardial infarction, cardiomyopathy, bundle-branch block, and dysrhythmia have been proven to be observed by ECG, we do not have motivation to conduct further clustering studies. And the purpose of this article is also to explore the future possibility of automatic ECG diagnosis for chronic diseases.

### Is the Number of Samples Sufficient?

Both clustering and classification problems use the same preprocessing and feature processing method. If stable clustering results can be obtained, the sample base should be sufficient as in classification and clustering problems. In addition, we have conducted the experiment on a public ECG dataset, the PTB Diagnostic ECG Database. This database has been used for many researches; thus, the clustering results should be credible.

### Issues of Evidence

#### Overall Observation Evidence

As shown in **Figure 6**, we divided different  $k$  parameters into  $k = 2, 4$ , and  $8$  groups and compared them. At the same time, three different characteristics were compared with the same  $k$ -parameter experiments. In addition, in **Figure 6**, if a group occupies a larger proportion, it indicates that the clustering effect is better. Based on this, our observations are summarized as follows: (Niu et al., 2018) diabetes has strong association with ECG feature; it can almost get better clustering results in different feature extractions and  $k$  parameters, and other chronic diseases have better clustering performance in experiments with different feature extractions and  $k$  parameters (Miao et al., 2015). The smokers, obesity, and hypertension have weak association in ECG features; they have less unique ECG feature vector enabling clustering them into specific groups, although they have some correlation in their ECG features (Blanco-Velasco et al., 2008). Waveform

feature extractions have better clustering performance than RBP and wavelet.

### Other Reference for Association Evidence

Previous clinical case studies have explored the relationship between ECG and other chronic diseases. These are mostly the analysis results from physicians' observation. They found that diabetic patients may have some ECG abnormalities, such as fibrotic changes in the left ventricle (Stern and Sclarowsky, 2009), painless myocardial ischemia (Dweck et al., 2009), and a prolonged QRS duration (Rollins et al., 1992). In addition, as for the other three diseases, we have also found some related studies to prove that they are related to ECG. For example, Renuka Devi et al. (2013) discuss the relationship between heart rate and smoking. The article by Ang and Lang (2008) mentions that left ventricular hypertrophy is related to ECG. The article by Rautaharju et al. (1994) mentions obesity is associated with a wide variety of electrocardiographic abnormalities. Their clinical research and our cluster analysis should prove each other. However, our research results summarize that diabetes has more obvious clustering characteristics than other chronic diseases and should be more suitable for the application of automated ECG diagnosis.

## CONCLUSION AND FUTURE WORK

In this article, three different models of feature extraction, RBP-based, wavelet-based, and waveform-based, are investigated and utilized to analyze the possible relationship between ECGs and diseases and habits, such as the aging diseases of diabetes, obesity, and hypertension and the chronic habit of smoking in the k-means clustering. Based on previous experiments and research, our conclusions are summarized as follows:

- (1) Waveform feature has better clustering effect in the ECG analysis of the four diseases, and it will be stable under different  $k$  parameters. Experiments show that waveform feature is more applicable to the clustering analysis of the correlation in contrast to RBP and wavelet features.
- (2) Diabetes has the most obvious clustering effect. The three feature extractions and different  $k$  parameters are relatively stable. In the  $k$ -means clustering based on RBP, waveform, and wavelet features, most patients with diabetes mellitus are always assigned into a specified group no matter the number of groups; that is, samples with diabetes mellitus have an excellent concentricity upon these characteristics extracted from ECGs.
- (3) The other three diseases may have less influencing factors, and the clustering characteristics are not significantly stable, which can be further studied in the future. However, the remaining groups with higher ratio of smokers, obesity, and hypertension, the relationship between them and ECGs paves the way of further research about their clustering and classification. The results of smoking, hypertension, and obesity are not positive, and

they scatter in every group in the  $k$ -means clustering. So, we cannot find strong relationships between ECG and them and cannot choose a better feature to implement the classification and diagnosis of hypertension and obesity based on ECGs.

Regarding future research, we should have the following detailed issues to explore:

- (1) The PTB Diagnostic ECG Dataset may not be specialized for discovering the relationship between hypertension, obesity, and diabetes mellitus. Some categories have fewer samples; for example, the number of samples with obesity is 20, which may not perform well for clustering analysis.
- (2) The same person may be suffering from a variety of diseases, particularly myocardial infarction, cardiomyopathy, bundle-branch block, and so on, severely affecting the waveform of ECG.
- (3) These feature extractions may not include all the useful information for these diseases and habits. Therefore, lack of useful characteristics may bring about clustering performance.
- (4) The diseases and habits might have various factors from our body; it is not easy to classify from ECG.

Although our research has explained some question of ECG clustering, there are still some detailed issues that need to be further explored as above. In the future, we will explore these issues and also make further contributions to the future ECG diagnostic system.

## DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. This data can be found here: Oeff M., Koch H., Bousseljot R., Kreiseler D. 2012. The PTB diagnostic ECG database. National Metrology Institute of Germany, <http://www.physionet.org/physiobank/database/ptbdb>.

## AUTHOR CONTRIBUTIONS

K-KT and JL performed the statistical analysis and participated in design, and drafted the manuscript. Y-JT and C-WY carried out the related studies and participated in collecting data. F-YL and ZZ helped to improve the final manuscript.

**Introduction:** Studies have shown that excess formaldehyde accumulation in the brain accelerates cognitive decline in people with Alzheimer's disease (AD). Recently, reports from our research team revealed that red light treatment (RLT) improved memory in AD mice by activating formaldehyde dehydrogenase (FDH) and thus reducing formaldehyde levels. Here, we developed a medical RLT device to investigate the safety and efficacy of this device in older adults with mild to moderate AD.

**Methods:** This will be a randomized controlled trial (RCT) that will include 60 participants who will be recruited and randomly divided into an RLT group and a control group. The RLT group will receive RLT intervention 5 days a week for 30 min each time for 24 weeks while the control group will continue their routine treatments without RLT. All participants will undergo neuropsychological and functional assessments including the Mini-Mental State Examination, the AD assessment scale-cognitive subscale (ADAS-cog), the Geriatric Depression Scale (GDS), the Neuropsychiatric Inventory (NPI) and the Barthel Index at baseline, 12 weeks and 24 weeks. All participants will undergo functional magnetic resonance imaging (fMRI) scanning and blood/urine biomarkers tests at baseline and 24 weeks. The primary outcome will be the ADAS-cog score while the secondary outcomes will be the GDS and NPI scores. Adverse events will be recorded and treated when necessary. Both an intention-to-treat analysis and a per-protocol analysis will be performed to evaluate the safety and efficacy of RLT.

**Discussion:** This protocol outlines the objectives of the study and explained the RLT device developed by the research team. The study is designed as an RCT to evaluate the safety and effects of the RLT device on older adults with mild to moderate AD. This study will provide evidence for the clinical use of RLT on treatment for AD.

## INTRODUCTION

As the most common cause of dementia in the elderly, Alzheimer's disease (AD) is becoming increasingly prevalent as the population ages. The Alzheimer's Association has now estimated and reported that the number of people with AD in the world will be more than 130 million by 2050 (Alzheimer's Association, 2019). The neuropathology of AD is characterized by the accumulation of  $\beta$ -amyloid ( $A\beta$ )-related amyloid plaques and phosphorylated tau (p-tau)-related neurofibrillary tangles outside and inside neurons, respectively. These changes are widely believed pathogenic to the onset of AD (Serrano-Pozo et al., 2011; Alzheimer's Association, 2019). As a persistent, disabling, and costly disease, AD unavoidably puts a huge burden on the family and society (Jia et al., 2018). Unfortunately, over the past decades new medications targeting  $A\beta$  production, aggregation and clearance, and tau hyperphosphorylation, such as antibodies, vaccines, and small molecule medicines, have not resulted in desirable clinical efficacy (Lane et al., 2018).

Recently, as a non-pharmacological therapy, low levels of laser light have been found to disaggregate  $A\beta$  (Son et al., 2018); hence phototherapy targeting  $A\beta$  is being increasingly investigated as an alternative therapy for AD (Salehpour et al., 2018). Previous studies showed that endogenous formaldehyde (FA) concentrations were gradually accumulated in animals and humans during the aging process and that FA was abnormally elevated in AD patients (Tulpule and Dringen, 2013). Indeed, excess FA injection led to memory decline in healthy animal models (Tong et al., 2013, 2017; Wang et al., 2019). Notably, excess FA also directly induces  $A\beta$  aggregation (Chen et al., 2006, 2007; Rizak et al., 2014; Yang et al., 2014; Liu et al., 2018), tau protein phosphorylation and aggregation (Lu et al., 2013; Yang et al., 2014; He et al., 2017; Liu et al., 2018), and oxidative stress (Songur et al., 2008; MacAllister et al., 2011). These findings strongly suggest that disaggregation of  $A\beta$  by scavenging FA may contribute to the treatment of AD. Our recent studies found that red light at 630 nm improved cognitive function by activating formaldehyde dehydrogenase (FDH) and thus degrading FA and increasing catalase activity to reduce oxidative stress in senescence-accelerated mouse-prone 8 (SAMP8) mice (Zhang et al., 2019). Red light at 630 nm also reversed memory deterioration by de-aggregating  $A\beta$  and enhancing FA metabolism in amyloid precursor protein/presenilin-1 (APP/PS1) transgenic AD mice (Yue et al., 2019).

Based on the above experimental evidence in animal models, our research team developed a therapeutic device for people with AD by using light-emitting diodes (LED) with a 630-nm red light in 2015. The penetration of the LED red light at 630 nm has been previously tested and we found that 630 nm red light had a strong penetration rate into the human brain cortex (approximately 48%) and liver (approximately 68%; Yue et al., 2019). This device is made of three main parts, including a power control board, an LED helmet for transcranial irradiation of the head, and an LED belly band for transabdominal illumination of the liver (Figure 3), and works by reducing the body's FA levels by

activating FDH in the brain and liver. In this study, a 24-week randomized controlled trial (RCT) was designed to investigate the safety and efficacy of this therapeutic red light treatment (RLT) device on older adults with mild to moderate AD. This protocol is reported according to the Standard Protocol Items: Recommendations for Intervention Trials (SPIRIT) guidelines (Chan et al., 2013).

## Objectives

The primary objectives are to test the safety and effects of the RLT on cognitive function, behavior/mood, and activities of daily living in older adults with mild to moderate AD.

The secondary objectives are: (1) to explore the changes in brain function by using functional magnetic resonance imaging (fMRI); and (2) to examine the changes in the levels or activities of blood/urine biomarkers, such as FA,  $A\beta$ , total tau, p-tau, and FDH.

## METHODS

### Settings

This device was developed and this study was designed at the Beijing Institute of Brain Disorders, Capital Medical University, China. The recruitment, assessment, intervention, and follow-ups of participants will be conducted at the Center for Cognitive Disorders of Beijing Geriatric Hospital (BGH), China. The Case Report Forms will be filled and kept in BGH.

### Study Design

This is an RCT study with two parallel arms (1:1 allocation ratio): an intervention group receiving an RLT program and a control group receiving routine therapy without RLT treatment (Figures 1, 2).

### Recruitment of Participants

Participants will be recruited from the clinic, inpatient ward, or long-term care facilities near BGH. Residents who meet the inclusion criteria will be recruited.

### Inclusion Criteria

The inclusion criteria will be as follows: (1) 60 years old or older; (2) with a diagnosis of probable AD based on the National Institute of Neurological and Communicative Disorders and Stroke and the AD and Related Disorders Association (NINCDS-ADRDA) criteria (McKhann et al., 1984); and (3) with a clinical dementia rating score  $\leq 2$ . If the participants are receiving cholinesterase inhibitors, memantine, or other dementia-related medications, they will have to take a therapeutic and stable dose for at least 3 months before screening.

### Exclusion Criteria

Participants will be excluded if they are experiencing any of the following conditions: (1) severe visual or auditory impairment; (2) serious medical conditions in major organs (such as the heart, lung, kidney, or liver) that limit the ability to participate in the

## Randomization and Allocation

Participants will be enrolled by dementia specialists. The randomization will be carried out by an independent research assistant who will not be involved in the enrollment,

assessment, or intervention of the participants. Random number sequences will be generated using SAS software version 9.4 (SAS Institute Inc., Cary, NC, USA). Sealed envelopes

with the serial number outside and group number inside will be produced and kept in a locked drawer that will be inaccessible to all the researchers. The envelopes will be

**FIGURE 3 |** The therapeutic device: a 630-nm red light device used for the treatment of AD patients. **(A)** The device is constructed of three main parts. opened sequentially by the independent research assistant after baseline assessments, and participants will be assigned to an intervention group and a control group at a ratio of 1:1 according to the group number printed inside the envelopes. Outcome evaluators and data analysts will be blinded to the group assignment.

Interventions

In addition to their routine treatments and personalized daily care, participants in the RLT group will receive the 24-week intervention of RLT with a frequency of 5 days per week for 30 min each time. The RLT treatment will be performed by researchers or caregivers who are trained to operate the RLT device in advance. The participants will be put on the LED helmet and the LED belly band and receive RLT therapy with concurrent transcranial and transabdominal illumination in the morning (Figure 3). The light parameters of the RLT device are shown in Table 1. The researchers or caregivers will be asked to keep a strict watch over the participants during the intervention process. A form of RLT treatment schedule will be made for each participant in the RLT group. The researchers or caregivers who perform the

Frequency of treatment	5 times per week

Abbreviation: AD, Alzheimer's disease; LED, light-emitting diode.

RLT intervention will be asked to sign on the report form after every session of treatment to ensure compliance of the intervention.

Participants in the control group will continue their routine treatments and personalized daily care during the 24-week study period, including usual medicine, recreational therapy, and management of behavioral disorders following current guidelines. Except for the RLT intervention for the RLT group, all the other treatment strategies for the two groups will be the same.

## Demographic Data Collection

Demographic characteristics of all participants including age, gender, educational level, as well as medical history, medication list, and comorbidities will be documented.

## Neuropsychological Assessments

A set of neuropsychological tests will be used to assess cognitive function and behavior/mood of all the participants, and their activities of daily living will also be measured. The assessments will be performed at baseline, 12 weeks, and 24 weeks during the study period. (1) The Mini-Mental State Examination (Katzman et al., 1988) is the most frequently used assessment to measure global cognitive function. It is a 30-point scale that assesses orientation, memory, attention and calculation, recall, and language, with higher scores indicating better cognitive function. (2) The AD assessment scale-cognitive subscale (ADAS-cog; Chu et al., 2000) is a 12-item scale that primarily measures word recall, ability to follow commands, constructional praxis, naming, ideational praxis, orientation, word recognition, comprehension of spoken language, word-finding, language ability, and attention. The scores range from 0 to 75 and higher scores indicate greater cognitive impairment. (3) The Geriatric Depression Scale (GDS; Yesavage et al., 1982) is a short questionnaire to identify depression in older people and it is validated in mild to moderate dementia. (4) The Neuropsychiatric Inventory (NPI; Wang et al., 2012) is an assessment of 12 different behavioral and psychological symptoms common in AD. Each symptom is rated and scored according to the frequency and severity reported by the informants. The distress level of the caregivers associated with each symptom is also rated. (5) The Barthel Index (Mahoney and Barthel, 1965), is a 10-item, ordinal scale used to measure performance in activities of daily living. It is also performed by interviewing the caregivers.

## fMRI

fMRI is a non-invasive brain imaging technique to measure and map brain activity. In this study, we will collect the data of resting-state fMRI (rs-fMRI) for the analysis of neurophysiological changes (Lee et al., 2013; Smitha et al., 2017). Participants will receive fMRI scans by using a Philips Ingenia 3.0 T magnetic resonance system at BGH at baseline and 24 weeks. The following sequences will be acquired: (1) High-resolution anatomic images using a 3D T1-weighted inversion recovery turbo field echo sequence with the following parameters: repetition time (TR) 7.9 ms, echo time (TE) 3.5 ms, contiguous 180 sagittal slices of 1 mm thickness, flip angle 8°, 1 × 1 × 1 mm voxels, 160 × 210 × 180 matrices, and field of view (FOV) 160 × 211 × 180 mm. (2) Single-shot field echo echo-planar imaging sequence for rs-fMRI images with the following parameters: 200 sets of contiguous 40 transverse slices, 4 mm thickness, TR 3,000 ms, TE 35 ms, flip angle 90°, 2 × 2 × 4 mm voxels, 120 × 116 × 40 matrices, and FOV 240 × 240 × 160 mm. The total acquisition time of rs-fMRI is 609 s. During the scanning process, participants will be asked to keep their eyes closed and remain motionless.

## Blood/Urine Biomarkers

The biomarkers of blood and/or urine of all participants will be measured at baseline and 24 weeks. The concentrations of blood A $\beta$ , total tau, and p-tau, which are related to the pathology of AD, will be quantified by human A $\beta$  and tau ELISA kits. Meanwhile, blood and urine FA levels and blood FDH activity will be measured.

## Outcomes

The primary outcome will be the ADAS-cog score. The secondary outcomes will be the GDS and NPI scores. The safety of the RLT will be evaluated according to the incidence and severity of adverse events such as headache, dizziness, or nausea. The adverse events will be immediately reported, and handled by experienced physicians. Details of these possible adverse events and the treatments they receive will be recorded by filling in the case report forms. Physical examinations and necessary laboratory examinations, such as blood routine examination, liver function, and renal function, will be completed at baseline and the end of this study.

## Sample Size Calculation

No studies have investigated the effects of RLT treatment on people with AD. However, there have been relevant published literature that reported positive effects of photobiomodulation (PBM) with 810 nm near-infrared light on people with dementia. For example, PBM was shown to reduce ADAS-cog scores by 6.73 points after a 12-week consecutive treatment (Saltmarche et al., 2017), and by 5.18 points in another report (Chao, 2019). In this study, we anticipate at least an effect size of 0.48 in ADAS-cog scores after 24-week RLT intervention. The sample size was calculated using Power Analysis and Sample Size software version 15.0 (NCSS, LLC)<sup>1</sup>. A total sample size of 48 participants is sufficient to detect the target effect size with 90% power ( $\beta = 0.10$ ) and a type I error of 5% ( $\alpha = 0.05$ ). Considering a dropout rate of 10%, a total of 54 participants is necessary. In this study, we intend to recruit 60 participants, with 30 participants in each group.

## Quality Control and Quality Assurance

At least three dementia specialists will work together to examine the participants and provide a diagnosis for each participant. All data will be monitored and reviewed by the principal investigator or research coordinators. Training will be provided to all researchers. Consistency coefficients in scoring assessment scales between researchers should be no less than 0.85. Data entry will be verified by a second researcher in the team. To protect participant confidentiality, only supervisors, researchers of this study, and the ethics committee will be authorized to access to the personal information and medical records of the participants.

## Statistical Methods

Statistical analysis of demographics and clinical characteristics will be performed using IBM SPSS Statistics for Windows, Version 20.0 (Release 2011, IBM Corp, Armonk, NY, USA).

<sup>1</sup><https://www.ncss.com/>

Continuous data will be reported as means  $\pm$  standard deviations or 95% confidence intervals, and as numbers with percentage for categorical data. The difference in demographic and baseline characteristics between two groups will be analyzed by using the independent *t*-test, and a *chi*-square test will be used for categorical variables.

The main analysis method for the safety and efficacy of RLT intervention in this study will use the intention-to-treat analysis including all randomized participants (Hollis and Campbell, 1999). Besides, a per-protocol analysis will be performed on individuals who complete the total study (Sedgwick, 2015). The repeated measures of variance analysis will be used to examine variations of scores of neuropsychological tests over time between two groups. The association between intervention and incidence of adverse events will be analyzed using the *chi*-square test.

fMRI data will be preprocessed by using Statistical Parametric Mapping version 12.0 (The Wellcome Trust Centre for Neuroimaging at UCL, London, UK) on the MATLAB platform (Release 2013b, The MathWorks Inc, Natick, MA, USA). There are several critical steps including motion correction, slice timing correction, spatial normalization, and smoothing. After fMRI data preprocessing, the fractional amplitude of low-frequency fluctuation and functional connectivity analysis will be analyzed by using the REST software version 1.8 (Song et al., 2011).

The level of significance for statistical analysis will be set at 5% ( $P < 0.05$ ). The researchers who perform the data analysis will be blinded to the allocation and the intervention.

## Patient and Public Involvement

The original research question and outcome measures were conceived by the authors and were then modified based on face-to-face screening interviews with 16 elderly volunteers with cognitive impairment by a research assistant. They were also invited to use the RLT device for 3 months during the design phase of this study. The duration of treatment per time and frequency of treatment was determined based on their feedback to ensure the tolerance and the applicability of the intervention. These volunteers will not be included in this study. Both the potential burden and benefit of this study will be assessed by the participants and their guardians before signing the informed consent. The findings of this study will be made available to the participants and their guardians.

## ETHICS AND DISSEMINATION

This study protocol has been approved by the ethical review committee of the Beijing Geriatric Hospital (approval number: 2019-024). Information leaflets of the study will be available at the public area of the Center for Cognitive disorders of BGH. The leaflets will explain in full detail the aims and objectives of the study, selection criteria, and the processes that the study will be adhering to. The research team will provide an individual face to face consultation to all potential participants and their guardians to answer any questions they may have before signing the consent form. Informed consent will be obtained from all

participants and/or their legal representatives. Participants will be allowed to withdraw from the study at any time and the reason for withdrawal will be recorded. The results of this study will be reported in peer-reviewed journals and presented at national or international conferences on aging and dementia.

## DISCUSSION

To our knowledge, this is the first RCT to investigate the safety and efficacy of RLT on AD. This 24-week study is designed to evaluate the effects of RLT intervention on cognitive function, mood, psychiatric and behavioral performances, and activities of daily living in older adults with mild to moderate AD. Also, neurophysiological changes assessed by fMRI and changes in blood/urine biomarkers associated with RLT will also be evaluated.

Preliminary evidence for the benefits of the RLT on AD has been obtained. The RLT can not only prevent early-stage memory decline but also rescue late-stage memory deficits in AD mice by reducing FA levels and oxidative stress (Zhang et al., 2019). Moreover, PBM with red to near-infrared light has been proposed as a non-invasive and innovative therapy for brain disorders. Some other beneficial effects of PBM have been reported, such as improved cerebral metabolic function (Oron et al., 2007; Rojas et al., 2012; Ferraresi et al., 2015), increased expression of neurotrophic factor expression, improved neurogenesis (Oron et al., 2006; Xuan et al., 2014, 2015), and reduced neuroinflammation (Lee et al., 2016; Aragona et al., 2017). Therefore, PBM appears to be a promising strategy for AD treatment.

There are limitations to this study. The first is that as the first preliminary clinical trial for the RLT device it is a single-center design. The second is the absence of a sham intervention for the control group for ethical and practical considerations. To minimize these shortcomings, the processes of randomization and blindness will be strictly carried out, and objective examinations including fMRI and blood/urine biomarkers will be conducted. Moreover, because of the cognitive impairments in patients with AD, the placebo effect can be greatly eliminated. The third is that follow-up assessment after cessation of the intervention is not planned in this protocol because the effects of the RLT are still unknown. If positive results are found in this initial study, future research will be conducted to assess the long-term influence of the RLT, which will help to identify the optimal RLT duration.

In summary, this RCT will explore the potential beneficial effects and safety of RLT on older adults with mild to moderate AD. The study will provide evidence for the clinical use of RLT on treatment for mild to moderate AD.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Medical Ethics Committee of the Beijing Geriatric Hospital (approval number:2019-024). The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

ZT and JL conceived and designed the study. All authors played a role in the development of the protocol. NH drafted the manuscript, and all authors participated in the preparation of this manuscript. All authors approved the submission of this manuscript.

## FUNDING

This study is funded by the Major Projects Fund of Beijing Institute for Brain Disorders (ZD2015-08); Beijing Municipal Administration of Hospitals Clinical Medicine Development of

Special Funding Support (ZYLX201834); the National Key R&D Program of China (2017YFE0118800)—European Commission Horizon 2020 (779238-PRODEMOS); Beijing Municipal Administration of Hospitals Clinical Medicine Development of Special Funding Support (ZYLX201837); and National Key R&D Program of China (2017YFC1310103).

## ACKNOWLEDGMENTS

We would like to thank all the participants and their guardians for their cooperation and contribution to the development of this protocol.

Mild cognitive impairment (MCI) is the clinical precursor of Alzheimer's disease (AD), which is considered the most common neurodegenerative disease in the elderly. Some MCI patients tend to remain stable over time and do not evolve to AD. It is essential to diagnose MCI in its early stages and provide timely treatment to the patient. In this study, we propose a neuroimaging approach to identify MCI using a deep learning method and functional near-infrared spectroscopy (fNIRS). For this purpose, fifteen MCI subjects and nine healthy controls (HCs) were asked to perform three mental tasks: *N*-back, Stroop, and verbal fluency (VF) tasks. Besides examining the oxygenated hemoglobin changes ( $\Delta\text{HbO}$ ) in the region of interest,  $\Delta\text{HbO}$  maps at 13 specific time points (i.e., 5, 10, 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, and 65 s) during the tasks and seven temporal feature maps (i.e., two types of mean, three types of slope, kurtosis, and skewness) in the prefrontal cortex were investigated. A four-layer convolutional neural network (CNN) was applied to identify the subjects into either MCI or HC, individually, after training the CNN model with  $\Delta\text{HbO}$  maps and temporal feature maps above. Finally, we used the 5-fold cross-validation approach to evaluate the performance of the CNN. The results of temporal feature maps exhibited high classification accuracies: The average accuracies for the *N*-back task, Stroop task, and VFT, respectively, were 89.46, 87.80, and 90.37%. Notably, the highest accuracy of 98.61% was achieved from the  $\Delta\text{HbO}$  slope map during 20–60 s interval of *N*-back tasks. Our results indicate that the fNIRS imaging approach based on temporal feature maps is a promising diagnostic method for early detection of MCI and can be used as a tool for clinical doctors to identify MCI from their patients.

**Keywords:** functional near-infrared spectroscopy (fNIRS), mild cognitive impairment (MCI), convolutional neural network (CNN), temporal feature, brain map, *N*-back, Stroop, verbal fluency task

## INTRODUCTION

Alzheimer's disease (AD) is authoritatively listed as the sixth leading cause of death in the United States (US), and it is also the fifth primary cause of death for those aged 65 years and above (Taylor et al., 2017). Seven hundred thousand people aged 65 years and above in the US were estimated death based on AD in 2019 (Hebert et al., 2013). As recently reported by Alzheimer Association, it estimated 18.5 billion hours of assistance (valued at \$233.9 billion) was provided by the caregivers of people with AD or other dementias (Alzheimer Association, 2019). It is thought that AD starts at least 20 years before the symptoms occur with small unnoticeable changes in the brain. Symptoms arise because of the damaged nerve cells (neurons) related to thinking, learning, and memory (Gordon et al., 2018). Symptoms tend to grow over time and gradually start to interfere with the ability of an individual to perform everyday activities until death. AD is considered a progressive, irreversible neurological brain disorder. Currently, no pharmacological treatment exists that can decelerate or prevent the symptoms of AD (Alzheimer Association, 2019). Many researchers suppose that the early stage in the AD process, at either the mild cognitive impairment (MCI) or preclinical stage, will be the most effective period for future treatments to slow down or prevent the progression of AD (Yiannopoulou and Papageorgiou, 2013). Thus, it is essential to assess biomarkers (i.e., the indication of the medical state observed from outside of patients; Strimbu and Tavel, 2010) for identifying individuals who are in these early stages of the disease and can receive appropriate treatment.

There are three categories of diagnostic biomarkers for AD, which are named  $\beta$ -amyloid- $A\beta$  deposits (A), hyperphosphorylated tau aggregates (T), and neurodegeneration or neuronal injury (N) (Jack et al., 2018). The ATN synopsis is widely assessed through cerebrospinal fluid (CSF) or medical imaging. Thus far, no evidence that supports the preeminence of any biomarker over another (CSF vs. imaging) for the diagnostic assessment of AD exists. The selection of biomarkers typically relies on the cost, availability, and convenience of tests (Khoury and Ghossoub, 2019). However, because medical imaging can identify the different stages of the AD temporally and anatomically, some researchers claim that the superiority of medical imaging over the biofluid biomarkers mentioned above (Márquez and Yassa, 2019).

Functional near-infrared spectroscopy (fNIRS) is a non-invasive neuroimaging technique, which is used to measure activation-induced changes in the cerebral hemoglobin concentrations of oxyhemoglobin ( $\Delta HbO$ ) and deoxyhemoglobin ( $\Delta HbR$ ) (Perrey, 2014; Shin and Im, 2018; Hong et al., 2020). The blood flow and oxygen metabolism are induced by the neural activity in the neighboring capillary network (Hong et al., 2014; Zafar and Hong, 2018; Ghafoor et al., 2019). In comparison with the existing neuroimaging techniques involving direct neural activation measurement methods such as magnetoencephalography (MEG) and electroencephalography (EEG) (Kumar et al., 2019), fNIRS offers the advantage of higher spatial resolution and lower susceptibility to the movement artifact (Naseer and Hong, 2015; Wilcox and Biondi, 2015; Hong et al., 2018; Pfeifer et al., 2018). In contrast, other well-established

neuroimaging techniques are typically associated with the metabolism of biochemical components during neural activity and exist a limitation in terms of temporal resolution. These techniques include positron emission tomography (PET), single-positron emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI) (Strangman et al., 2002). In particular, because of the property requirement of the radioactive isotopes, PET and SPECT do not allow continuous or repeated measurements, a factor that also limits their application in the cases of children and pregnant women (Irani et al., 2007). Although fMRI is non-radiative and involves no risk, it is physically constraining, is sensitive to movement artifacts, exposes participants to an excessively noisy environment, and is expensive (Ferrari and Quaresima, 2012). These features render fMRI inappropriate for certain research and many clinical applications (Santosa et al., 2014). In contrast, fNIRS is a novel neuroimaging modality with the following advantages: it is non-invasive, safe, less costly, portable, and tolerant of motion artifacts (Perrey, 2008); it also has great temporal resolution and moderate spatial resolution (Ghafoor et al., 2017; Zafar and Hong, 2020). In addition, fNIRS is in progress to improve the spatial and temporal resolutions with the development of bundled-optodes configurations (Nguyen and Hong, 2016; Nguyen et al., 2016), detection of the initial dip (Zafar and Hong, 2017; Hong and Zafar, 2018), and combination of adaptive method (Iqbal et al., 2018; Hong and Pham, 2019; Pamosoaji et al., 2019) to improve information transfer rate.

In the past decades, the fNIRS study of psychiatric or neural-disorder patients highly depended on mass-univariate analytical techniques such as statistical parametric mapping (Vieira et al., 2017). Traditionally, the research studies compared the hemodynamic response of a patient with that of healthy control (HC) and determined neuroanatomical or neurofunctional differences at the group level. Most AD/MCI detection studies typically employed the  $\Delta HbO/\Delta HbR$  (Jahani et al., 2017; Perpetuini et al., 2017; Vermeij et al., 2017; Katzorke et al., 2018; Yoon et al., 2019) and relative temporal features such as the mean value, slope value, number of active channels, peak location, skewness, and kurtosis (Yap et al., 2017; Li et al., 2018a), and they determined the significant differences for comparison. The straightforwardness and interpretability of this methodology has led to considerable advances in our comprehension of the neurological disorders. With the development of technology, the following limitations of mass-univariate analytical techniques have been revealed. (1) Statistical information is extracted according to each region of interest (ROI) channel based on the assumption that various brain regions perform independently. In practice, this assumption is inconsistent with brain function (Biswal et al., 2010). The network-level comparison explains the neurological symptoms better than the focal-level comparison (Mulders et al., 2015). (2) Statistical analysis cannot easily yield individual diagnosis results (Vieira et al., 2017). Mass-univariate techniques are suitable only for detecting differences between groups. According to the evaluation conducted in our initial study, the results of statistical analysis are not consistent with the classification results (Yang et al., 2019). Thus, an effective classification method based on fNIRS neuroimaging is crucial for the detection of MCI in the clinical stage.

Deep learning (DL) has allowed significant progress in the identification and classification of image patterns and is considered a promising machine-learning methodology (Ravi et al., 2017). Convolutional neural networks (CNNs), the most broadly used DL architecture, have delivered excellent performances in computer-aided prediction for neurological disorders (Mamoshina et al., 2016; Tanveer et al., 2019). The great success of CNNs in neural-image classification and analysis, which evidences their strong image-classification ability (Cecotti and Gräser, 2011; Ieracitano et al., 2018; Lin et al., 2018; Waytowich et al., 2018; Oh et al., 2019), motivated us to develop a CNN-based classification method for early-stage AD detection. So far, there are not any discussions in the literature, which used the DL method as an assistive tool for the diagnosis of early-stage AD by fNIRS signals, except for our group.

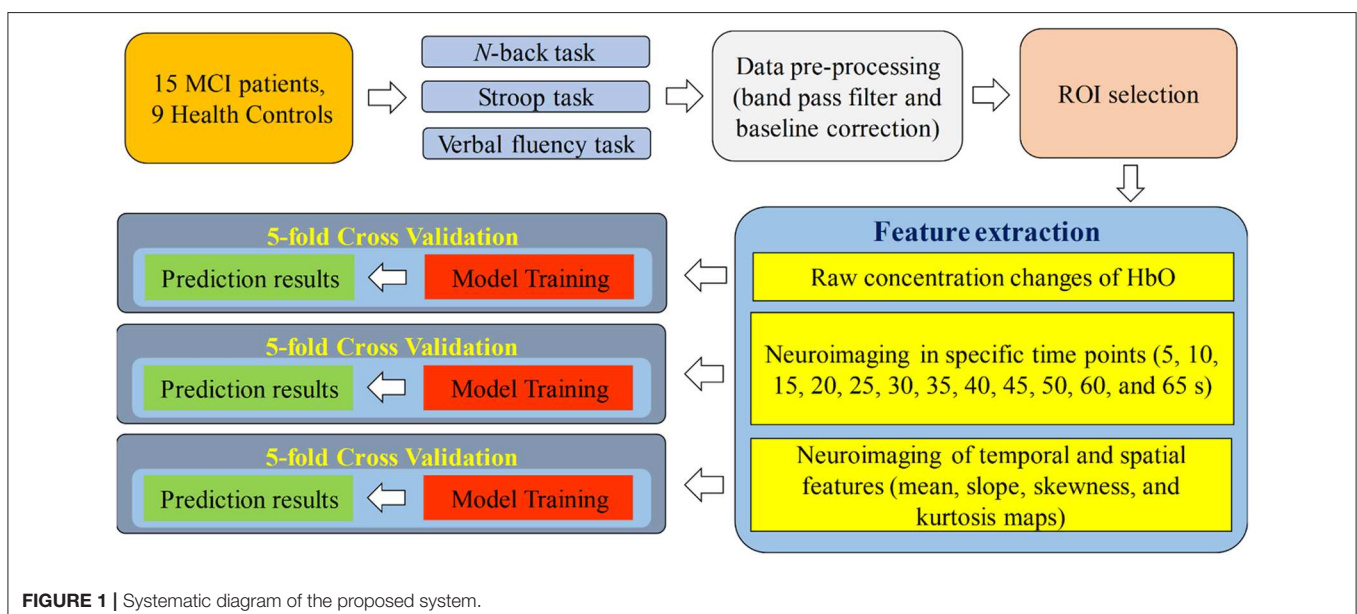

In our initial investigation (Yang et al., 2019), we compared the hemodynamic responses and statistical information between the groups of MCI and HC: We evaluated the digital biomarkers (i.e., mean, slope, peak, kurtosis, and skewness) and image biomarkers (i.e., *t*-map and connectivity map) for MCI identification. The MCI group showed decreased  $\Delta\text{HbO}$  responses in comparison with the HC group, which is consistent with the literature (Vermeij et al., 2017; Katzorke et al., 2018). As digital biomarkers, 15 features (i.e., mean value of  $\Delta\text{HbO}$  for 5–65 s, mean value of  $\Delta\text{HbR}$  for 5–65 s, mean value of  $\Delta\text{HbO}$  for 5–25 s, mean value of  $\Delta\text{HbR}$  for 5–25 s, mean value of  $\Delta\text{HbO}$  for 0–peak time, slope of  $\Delta\text{HbO}$  for 5–15 s, slope of  $\Delta\text{HbR}$  for 5–15 s, slope of  $\Delta\text{HbO}$  for 20–60 s, slope of  $\Delta\text{HbR}$  for 20–60 s, slope of  $\Delta\text{HbO}$  for 60–70 s, slope of  $\Delta\text{HbR}$  for 60–70 s, slope of  $\Delta\text{HbO}$  for 0–peak time, peak time itself, skewness of  $\Delta\text{HbO}$  for 5–65 s, and kurtosis of  $\Delta\text{HbO}$  for 5–65 s) were introduced for the statistical analysis and three brain regions (i.e., left, middle, and right prefrontal brain regions) were examined. Some of the features (e.g., mean value of  $\Delta\text{HbO}$  for 5–65 s in the right prefrontal brain region with *N*-back task) indicated a significant difference ( $p < 0.05$ ) between the MCI and

HC groups. For classification, linear discriminant analysis (LDA) was used. The highest accuracy out of three mental tasks (i.e., *N*-back task, Stroop task, and VFT) was 76.67% from *N*-back and Stroop tasks, which were based on manually selected ROI channels. Also, we evaluated the *t*-map and connectivity map as image biomarkers. The CNN result based on *t*-maps of the *N*-back task achieved the best performance of 90.62%. Based upon these findings, the conclusion was that image biomarkers like *t*-map or connectivity map provide a better classification accuracy than digital biomarkers. Motivated on this, we will investigate whether the combined digital biomarkers on a given space (i.e., mean-value image in a specified time interval, or slope-value image in a specific time interval, etc.) can provide an improved classification accuracy than the *t*-map result obtained in the previous work.

In this study, we investigated 63 types of neural images based on temporal (3 types), spatial (39 types), and temporal-spatial (21 types) features of fNIRS signals, which were acquired based on three mental tasks—the *N*-back, Stroop, and verbal fluency tasks (VFT)—for the early detection of AD via a CNN. The temporal features refer to the raw  $\Delta\text{HbO}$  in time series, neuroimaging in the spatial domain refers to the brain map generated at specific time points, and the temporal-spatial features represent temporal features (mean value, slope value, skewness, and kurtosis) in the spatial domain. To the best of the author's knowledge, this is the first fNIRS neuroimaging study integrating digital biomarkers in a spatial domain, in which the diagnosis performance for early AD detection via a DL approach has been explored.

## METHODS

**Figure 1** presents a diagram of the proposed system. fNIRS data were acquired while the subjects were performing the three aforementioned mental tasks. After the signal preprocessing, the ROI channels were selected for the subsequent steps. In the

feature-extraction step, the raw concentration changes in HbO, neuroimaging at a specific time point (i.e., 5, 10, 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, and 65 s) in the spatial domain and neuroimaging of temporal features (mean value of  $\Delta\text{HbO}$  for 5–65 s, mean value of  $\Delta\text{HbO}$  for 5–25 s, slope of  $\Delta\text{HbO}$  for 5–15 s, slope of  $\Delta\text{HbO}$  for 20–60 s, slope of  $\Delta\text{HbO}$  for 60–70 s, skewness of  $\Delta\text{HbO}$  for 5–65 s, and kurtosis of  $\Delta\text{HbO}$  for 5–65 s) in the spatial domain were generated for training the CNN model separately. Finally, 5-fold cross-validation was employed to assess the performance of the CNN model trained by the features mentioned above.

## Participants

In this study, 15 MCI patients (1 male and 14 females) and 9 HCs (2 males and 7 females) were recruited from the Pusan National University Hospital (Busan, South Korea). All 24 subjects are right-handed, able to communicate in Korean, similar ages, and educational backgrounds. The mental health state of each participant was assessed using three criteria: the Korean-mini-mental state examination (K-MMSE) (Han et al., 2008), the Seoul Neuropsychological Screening Battery (Ahn et al., 2010), and magnetic resonance imaging (MRI) data. **Table 1** shows the summarized demographic information for 24 participants, comprising age (mean  $\pm$  SD), gender, educational background (mean  $\pm$  SD), statistical information, and K-MMSE scores (mean  $\pm$  SD). The experiment was performed consistently with the

approval of the Pusan National University Institutional Review Board (General Assembly of the World Medical Association, 2013). All the subjects were provided with a comprehensive explanation of the whole experimental contents before the start of the experiment. After the introduction, they were asked to write consent agreeing of the test.

## Experimental Paradigm

As shown in **Figure 2**, the experiment comprised three mental task sections, where each section consisted of three trials. In this study, the *N*-back task was used to assess working memory (Kane et al., 2007). The ability to inhibit cognition was evaluated by the Stroop task. This suppression occurs when the other attribute of the same stimulus simultaneously effects during the processing of a stimulus (McVay and Kane, 2009; Scarpina and Tagini, 2017). The performance of semantic verbal fluency task indicated the ability of the vocabulary size, lexical access speed, updating, and inhibition for each subject (Shao et al., 2014).

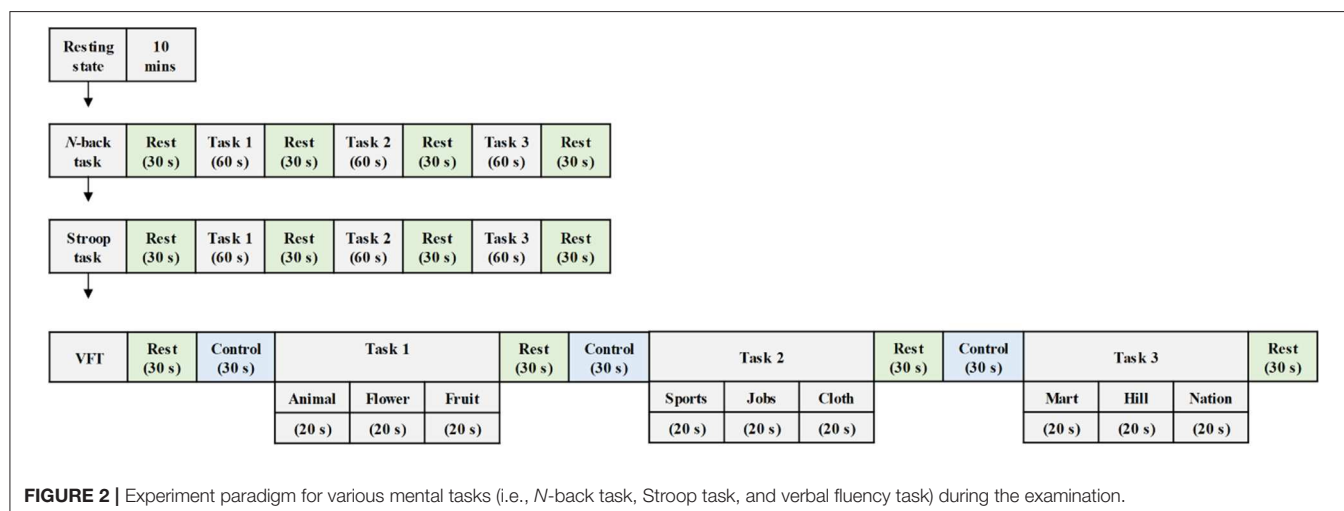

Participants were asked to sit on a comfortable chair and were directed to avoid movement. Each task trial took 60 s, and a 30 s rest was given between tasks. First, the subjects enjoyed a 10 min resting state before a task-based experiment section began. Then, they performed the 2-back version of the *N*-back task wherein a digital number between one and nine was randomly showed on the screen. When the current number matched the second to last number previously displayed on display, the participants were instructed to press the keyboard. The subjects were then asked to execute the Stroop task. The Korean-color word Stroop test (K-CWST) was utilized in this study. The participants were requested to read the color of letters within a limited time. Those letters were written by four different colors, i.e., red, blue, yellow, and black, respectively. Finally, the subjects executed the semantic VFT by generating as many words as possible within 1 min; the words should relate to the given semantic category. The amount of information of participants, which can be retrieved based on the categorization and memorial source of text during the limited time, were measured during this task.

**TABLE 1** | Demographic information of participants.

Characteristics	MCI (n = 15)	HC (n = 9)	p-value <sup>a</sup>
Gender (Male/Female)	1/14	2/7	0.44
Education [years]	11.2 ( $\pm$ 4.81)	10.56 ( $\pm$ 2.88)	0.36
Age [years]	69.27 ( $\pm$ 7.09)	68.33 ( $\pm$ 4.69)	0.36
K-MMSE Score	25.13 ( $\pm$ 2.33)	27.22 ( $\pm$ 1.98)	0.49

K-MMSE, Korea Mini-Mental State Examination.

<sup>a</sup>Two sample t-test with a significant level of 0.05.

**FIGURE 3 | (A)** The placement of Emitter and detector, **(B)** channel configuration with FpZ as a reference point based on the 10–20 international system.

## fNIRS Data Acquisition

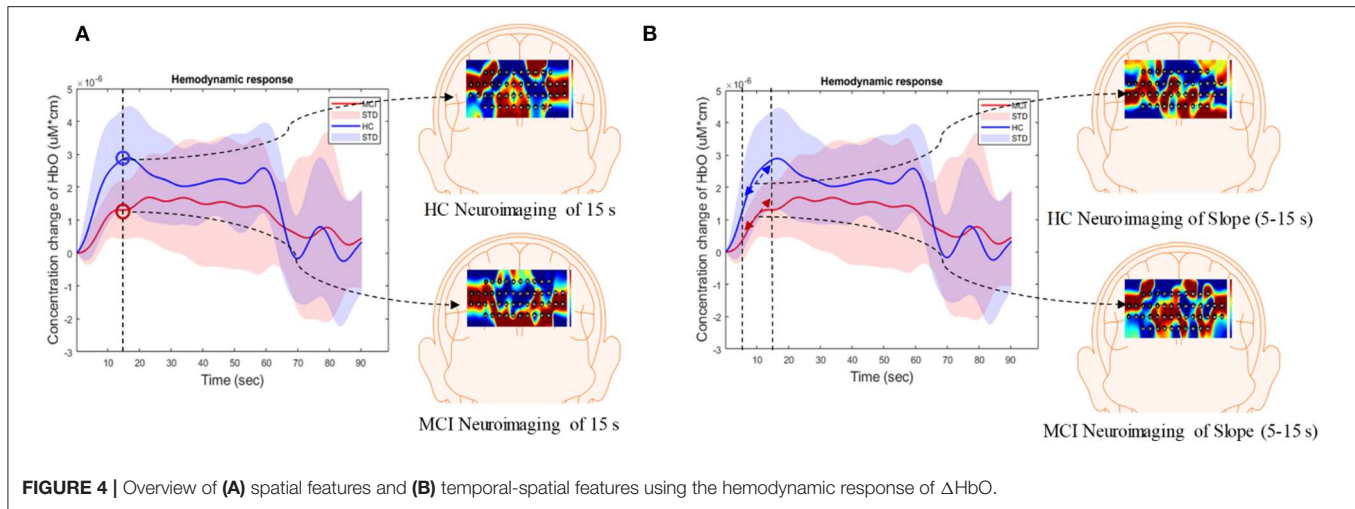

The data utilized in this study were acquired by NIRSIT (OBELAB Inc., Rep. of Korea), which is a near-infrared multi-channel continuous wave system using a sampling rate of 8.138 Hz. The wavelengths employed for detecting two chromophores (i.e., oxygenated hemoglobin and deoxygenated hemoglobin) were 780 and 850 nm, respectively. A total of 24 emitters and 32 detectors, the placements of which are illustrated in **Figure 3A**, were used to measure the neural activation of the prefrontal cortex comprehensively. In total, 48 channels were selected for covering the entire prefrontal cortex. The channel configuration, illustrated in **Figure 3B**, was set up in accordance with the international 10–20 EEG system with the reference point FpZ. The pairs of emitter and detector (one channel) were placed 30 mm apart.

## fNIRS Data Pre-processing

The modified Beer-Lambert law was utilized to convert the optical densities to  $\Delta\text{HbO}$  and  $\Delta\text{HbR}$  (Sassaroli and Fantini, 2004). The converted signals passed 4th-order Butterworth low- and high-pass filters (i.e., cutoff frequencies: 0.001 and 0.1 Hz, respectively) to remove physiological noise, i.e., cardiac noise—1 Hz, respiration—0.25 Hz, and Mayer signal—0.1 Hz (Naseer et al., 2016; Khan and Hong, 2017; Liu et al., 2018; Nguyen et al., 2018). In accordance with our previously published

evaluation results (Yang et al., 2019) and the relevant literature (Hoshi, 2007), it was observed that  $\Delta\text{HbO}$  is more sensitive and dependable than  $\Delta\text{HbR}$ . Besides,  $\Delta\text{HbO}$  shows a stronger correlation with the fMRI BOLD response than  $\Delta\text{HbR}$  (Cui et al., 2011; Li et al., 2018a). Therefore,  $\Delta\text{HbO}$  signals were used because their signal-to-noise ratio was higher than that of  $\Delta\text{HbR}$  signals.

As the limitation of the spatial resolution (as compared to fMRI), the ROIs—the areas that are active during the mental task—must be estimated. ROI analyses have been widely as a means of testing prior hypotheses about brain function in fMRI and PET areas; they enhance the statistical power as compared to entire brain area analyses and facilitate comparisons through multiple participants (Mitsis et al., 2008). In this study, the ROI was defined by the weighting factor ( $t$ -value) between the desired hemodynamic response function (dHRF) and the fNIRS measurement. The measurement ( $y$ ) can be represented by the linear relationship of the dHRF with the coefficients and the error ( $\epsilon$ ), as shown in Equation (1). The dHRF was generated by convoluting the canonical hemodynamic response function (using two gamma functions) with the stimulation duration (i.e., the 60 s task and 30 s rest period). The  $t$ -value ( $t$ ) was calculated using the *robustfit* function of MATLAB<sup>TM</sup>. The null hypothesis is  $\beta_1 = 0$ , and SE represents standard error. ROI channels (i.e., activated channel) were selected when the calculated  $t$ -value was higher than the critical  $t$ -value ( $t_{\text{crit}} =$

1.9632). The critical  $t$ -value was computed by the degree of freedom of the signals and statistical significance ( $p < 0.05$  for two-sided tests).

$$y = [1 \text{ dHRF}] \begin{bmatrix} \beta_0 \\ \beta_1 \end{bmatrix} + \varepsilon, \quad (1)$$

$$t = \left[ \frac{\beta_0}{SE(\beta)}, \frac{\beta_1}{SE(\beta)} \right]. \quad (2)$$

## Feature Extraction

In this study, the extracted features were divided into three categories: temporal, spatial, and temporal-spatial features. Temporal features referred to the raw  $\Delta\text{HbO}$  in the time series and were considered to contain the concentration change in  $\Delta\text{HbO}$  with time. The spatial feature describes neuroimaging at the specific time points. In this study, we selected 13 time points (i.e., 5, 10, 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, and 65 s) to create the neural image for comparison purposes. The spatial feature indicates the neural activation at a specific time point in the spatial domain (prefrontal brain cortex). **Figure 4A** illustrates an example of neuroimaging at the 15 s time point. In this study, the selected time windows between 5 and 65 s were considered the effect of initial time delay (3–5 s) during the hemodynamic response.

The temporal-spatial feature expresses the temporal information (mean value of  $\Delta\text{HbO}$  for 5–65 s, mean value of  $\Delta\text{HbO}$  for 5–25 s, slope of  $\Delta\text{HbO}$  for 5–15 s, slope of  $\Delta\text{HbO}$  for 20–60 s, slope of  $\Delta\text{HbO}$  for 60–70 s, skewness of  $\Delta\text{HbO}$  for 5–65 s, and kurtosis of  $\Delta\text{HbO}$  for 5–65 s) in the spatial domain as shown in **Figure 5**. In other words, they display the values of specific time points according to the channel placement in the prefrontal cortex. **Figure 4B** illustrates the neuroimaging of the slope map for the period between 5 and 15 s. The mean value distinguishes the difference in the neural activation of the MCI and HC. Since the initial peak time of the hemodynamic response typically occurs during the time windows of the first 20 s, the time interval of 5–25 s was chosen. The slope features, i.e., the

slope maps of 5–15 s, 20–60 s, and 60–70 s, were selected based on the characteristic from three intervals of the hemodynamic response: the initial increasing, plateau, and final period of  $\Delta\text{HbO}$ , i.e., 5–15 s, 20–60 s, and 60–70 s, respectively. The slope indicates the difference in speed of activation between two groups, MCI and HC. Lastly, the difference in the asymmetry and the point of the probability distribution were measured by skewness (i.e., from 5 to 65 s) and kurtosis (i.e., from 5 to 65 s). These measurements are intended to investigate the overall difference of hemodynamic responses between MCI patients and HCs. All temporal information (mean, slope, skewness, and kurtosis) was determined by utilizing functions of *mean*, *polyfit*, *skewness*, and *kurtosis*, respectively, based on the MATLAB™.

## Convolutional Neural Network

CNN is a special type of feedforward neural network. It takes advantage of local spatial coherence in the input, which allows the model to include fewer weights because of the parameter-sharing strategy (Cecotti and Gräser, 2011; Kim and Choi, 2019; Oh et al., 2019). In addition, CNN can learn features automatically from the input images by adjusting the parameters to minimize classification errors (Trakoolwilaiwan et al., 2017; Liu and Stathaki, 2018; Moon et al., 2018). Typically, CNN comprises convolutional, activation, pooling, and fully connected layers (Yi et al., 2018; Kim et al., 2019). Convolutional layers are the crucial component of CNN. Suppose the input is  $X$  with the 2-dimensional image ( $h \times w$ ), and the weight matrices (called kernels) have the size ( $k_1 \times k_2$ ), the local input region  $X_i$  can be converted to feature map ( $Y_j$ ) as shown in Equation (3), and size is  $y_1 \times y_2$ .

$$Y_j = f \left( \sum X_i \bullet K_j + \beta_j \right), \quad (3)$$

where ( $\bullet$ ) denotes the convolution operator, and  $\beta_j$  is the bias term. One feature map ( $Y_j$ ) would be generated based on the

**FIGURE 5 |** Time interval distribution of the temporal features (i.e., mean, slope, skewness, and kurtosis) for temporal-spatial neural images generation.

sharing parameters of the  $j$ -th kernel with stride  $s$ . Thus, the size of the feature map can be calculated by using:

$$y_1 = \frac{h - k_1 + 2 \times p}{s} + 1, \quad (4)$$

$$y_2 = \frac{w - k_2 + 2 \times p}{s} + 1, \quad (5)$$

where  $p$  refers to the parameter of zero padding. This parameter is applied to keep the size of the output and input the same by padding the input edges with zeros. The activation layers are utilized after the convolutional layer. Typically, a non-linear transfer function called rectified linear units (*ReLU*) is widely used to achieve a better performance in regard to generalization and learning time (Yarotsky, 2017; Ieracitano et al., 2018). The function is shown in Equation (6). Thus, the feature map transfers the negative activation to be zero.

$$f(x) = \max(0, x). \quad (6)$$

There are two options in the pooling layer—average pooling and maximum pooling—that are used to reduce the resolution of the input feature map. As discussed in the literature (Sun et al., 2017), the effectiveness of maximum pooling is significantly superior to average pooling because of the ability to capture invariant features and better generalization performance. For this reason,

we also employed maximum pooling in this study. The output ( $z_1 \times z_2$ ) of the pooling layer is as follows:

$$z_1 = \frac{y_1 - p_1}{s_p} + 1, \quad (7)$$

$$z_2 = \frac{y_2 - p_2}{s_p} + 1, \quad (8)$$

where  $s_p$  is the stride of maximum pooling, and  $p_1 = p_2$  represents the pooling size. Drop-out is applied for improving the CNN performance and avoiding overfitting. In this layer, the input and output are the same size. It is randomly initialized to turn the on or off of the corresponding neuron of the CNN at the beginning of the training iteration. As in the standard DL method, each neuron of a fully connected layer is connected with the previous layer. Since this is the issue of two group classification, there are two neurons for the last fully connected layer.

The architecture of the proposed CNN model contains four layers that two convolutional layers and two fully connected layers—as shown in **Figure 6**. In order for the input size to be consistent, the input neural image size is set to  $200 \times 200$ . The number of kernels is eight; the kernel size is  $4 \times 4$ ; the size of the pooling area is  $2 \times 2$ ; the value of the stride is 1. There were 128 neurons in the first fully connected layer with the activation function of *ReLU*. The loss function employed is categorical

**TABLE 2 |** Number of ROI channels of each subject for three mental tasks (i.e., *N*-back task, Stroop task, and verbal fluency task).

cross-entropy. Adam optimization was used to select the adaptive learning rate and the parameters during gradient descent.

In this study, the CNN model may have suffered from an overfitting problem because of the limitation of the sample data.

We employed 5-fold cross-validation to decrease the influence of this problem on the experiment results. The data were randomly divided into 5-folds. One subsample fold was selected to test the performance of the trained model, and the remaining 4-folds

were set to train the CNN model. This process was reiterated five times to ensure that each subsample was utilized as a validation set once.

## RESULTS

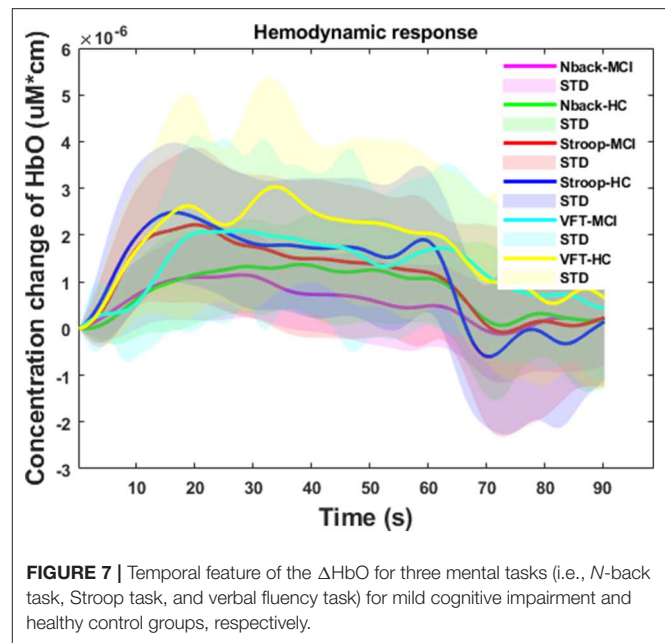

### Hemodynamic Response and Behavioral Result

As shown in **Table 1**, the statistical analysis of the behavioral measurement (i.e., the averaged K-MMSE score) was performed by two independent sample *t*-test with a significant level of 0.05. The result ( $p = 0.49$ ) presents a negative correlation between the behavioral state and the real subject mental state. In this study, we analyzed 3,456 fNIRS channels (i.e., 24 subjects  $\times$  3 trials  $\times$  48 channels) for each task. As shown in **Table 2**, the total number of selected ROI channels (activated channels) was 1,826 (*N*-back task), 1,609 (Stroop task), and 1,867 (VFT). The percentage of activation/deactivation was calculated by dividing the number of the ROI channels by the total number of channels. Therefore, the percentages of activated patterns are 52.83% (*N*-back task), 46.56% (Stroop task), and 54.02% (VFT), respectively.

**Figure 7** summarizes the averages and standard deviations (STDs) of the hemodynamic response from the ROI channels of the patients with MCI and the HCs during various mental tasks—*N*-back task, Stroop task, and VFT. The solid lines refer to the mean of the  $\Delta$ HbO, and shaded areas represent the STD of  $\Delta$ HbO among the subjects. To compare the unique patterns (i.e., an increase or a decrease) of the hemodynamic response of the HCs and the MCI individuals in the *N*-back task (MCI: solid magenta line and HC: solid green line), Stroop task (MCI: solid red line and HC: solid blue line), and VFT task (MCI: solid cyan line and HC: solid yellow line), respectively, we applied two independently sampled *t*-tests. The results indicate that the average hemodynamic response of MCI patients is significantly lower than that of HCs in the *N*-back task ( $p < 0.001$ ) and VFT task ( $p < 0.001$ ). In the Stroop task, the average hemodynamic change in MCI individuals appears to be similar to that of HCs ( $p = 0.06825$ ).

### Neural Images in Spatial and Temporal-Spatial Domain

The results of the neuroimaging that was conducted based on the concentration change in oxygen-hemoglobin of the specific time point (i.e., 5, 10, 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, and 65 s), are presented in **Figure 8**. The neural activation slightly changed over time in the entire prefrontal cortex. It is also easily observed that the MCI group displays a lower neural activation than the HCs in the three mental tasks. **Figure 9** illustrates the neuroimaging created by the temporal features (i.e., mean values from 5 to 65 s and from 5 to 25 s, slopes from 5 to 15 s, from 20 to 60 s, and from 60 to 70 s, skewness from 5 to 65 s, and kurtosis from 5 to 65 s) in the spatial domain. As compared to **Figure 8**, the patterns of the neural images of temporal features in the spatial domain area differ; for example, the neural images in **Figure 8** are highly correlated, and the neural images generated by each temporal feature in **Figure 9** have their individual

characteristics. Interestingly, the neural images generated by the mean values also display the same patterns as characteristics generated by the specific time points. Among the three mental tasks, the VFT task shows the highest neural activation pattern in the HC group. The lowest neural activation is shown by the Stroop task in the MCI group. In addition, the neural images at 5 s among the six groups show lower neural firing than the neural images at 10 s and at other time points. In contrast, neural images at 60 s and previous time points show higher neural firing than those at 65 s.

### CNN Results for Classification of Neural Images

The input dataset of the temporal feature contained 24 (subjects)  $\times$  3 (trials)  $\times$  ROI channels. In the neural images in the spatial and temporal-spatial domain cases, each category had a dataset of size 24 (subjects)  $\times$  3 (trials). To verify the CNN's capability to classify MCI individuals and HCs, we utilized the standard metrics (accuracy, recall, precision, and F1-score) (Powers, 2011; Lin et al., 2018) to assess the results. Their definitions are

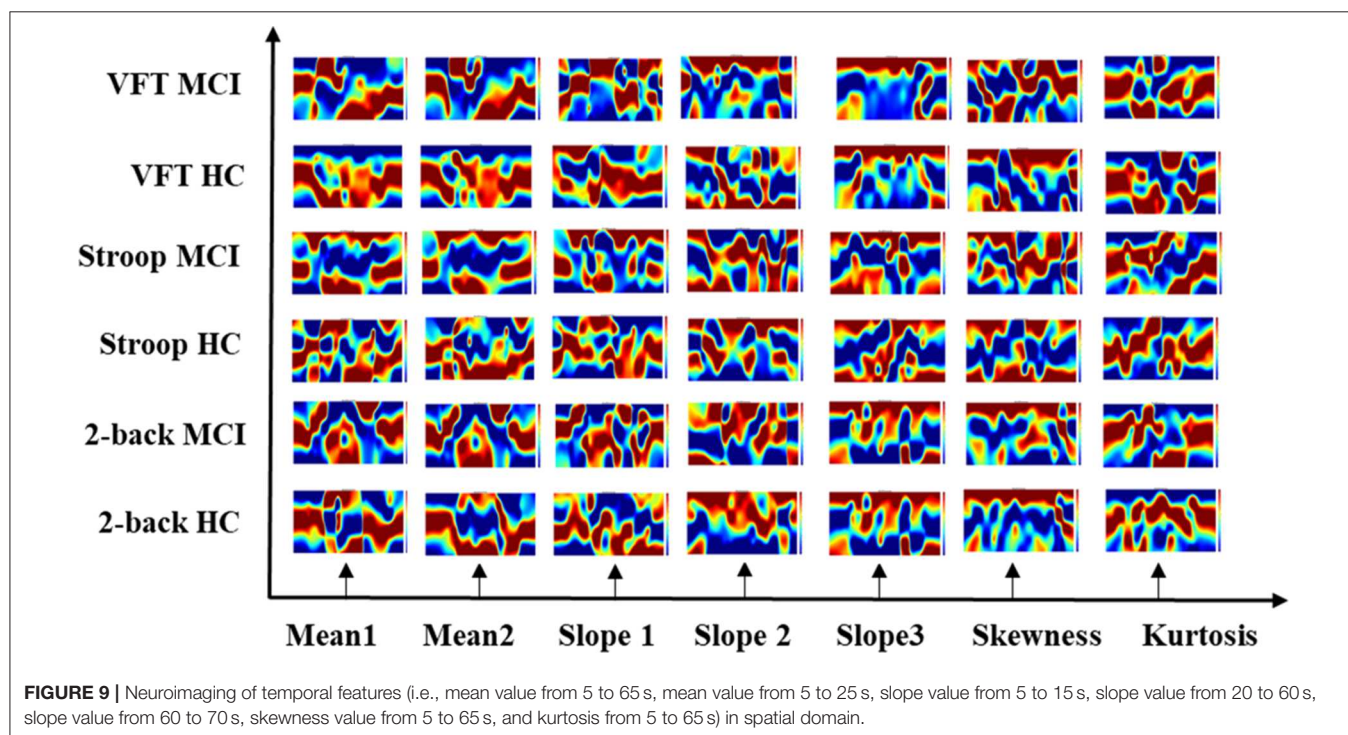

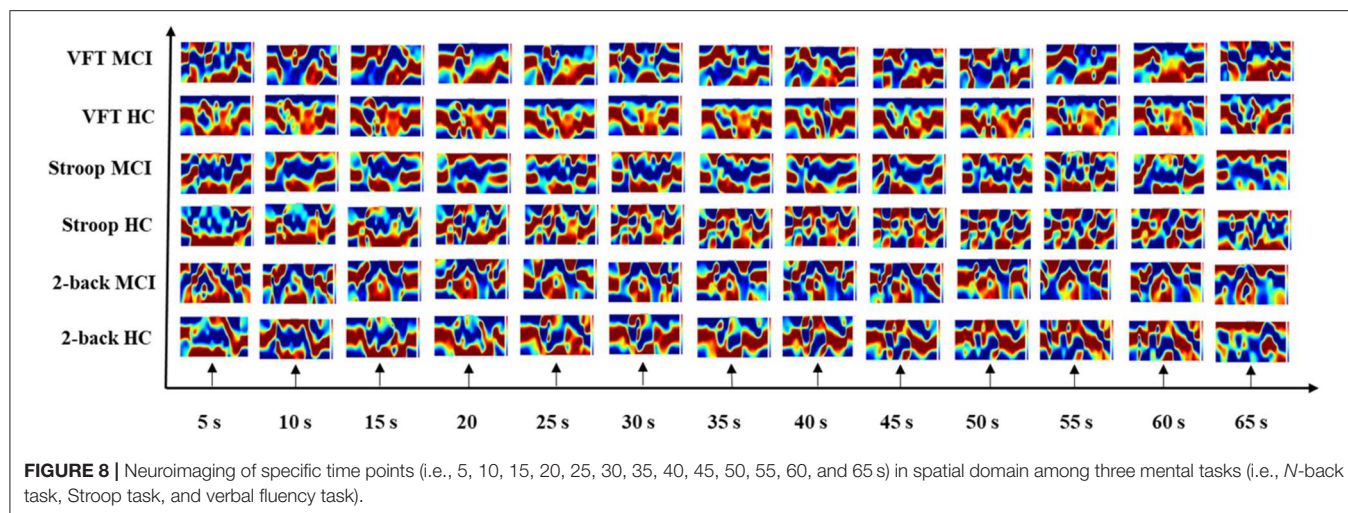

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}, \quad (9)$$

$$\text{Recall} = \frac{TP}{TP + FN}, \quad (10)$$

$$\text{Precision} = \frac{TP}{TP + FP}, \quad (11)$$

$$\text{F1score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}, \quad (12)$$

where TP, TN, FP, and FN represent the true positive, true negative, false positive, and false negative, respectively. In this study, TP indicated the number of MCI patients correctly

classified; TN is the number of HCs identified correctly; FP refers to the number misclassified as MCI patients, and FN is the number misclassified as HCs.

The CNN results for the dataset extracted by the temporal domain are listed in **Table 3**. The average accuracy among the three mental tasks is 80.15% with an STD of 3.95%, and the results of recall, precision, and F1-score are 73.26% (4.10%), 64.23% (6.63%), and 67.48% (5.40%), respectively. Stroop achieved a higher accuracy rate than both the *N*-back task and VFT: 84.70%.

**Tables 4–6** depicts the CNN's performance for neural images at various time points in the spatial domain of the *N*-back task, Stroop task, and VFT, respectively. CNN's classification

performance is divided into four different categories, as mentioned previously: accuracy (%), recall (%), precision (%), and F1-score (%). Furthermore, for each category, the results for specific time points are shown in the first column. **Table 4** represents CNN classification results of the *N*-back task. For the *N*-back task, the accuracy rate ranges from 65.28 to 93.06%, recall from 55.66 to 60%, precision from 41.11 to 86.43%, and F1-score from 46.34 to 87.83%. The classification result at the 15 s time point shows the best performance. The average accuracy rate is 82.59%. In the Stroop task case (shown in **Table 5**), the best performance appeared at the 60 s time point. Interestingly, this is consistent with the results for the hemodynamic response in

**TABLE 3 |** Convolutional neural network results of the temporal features among three mental tasks (i.e., *N*-back task, Stroop task, and verbal fluency task).

Task	Accuracy (%)	Recall (%)	Precision (%)	F1-score (%)
<i>N</i> -back task	77.90	70.00	58.95	63.22

Features	Accuracy (%)	Recall (%)	Precision (%)	F1-score (%)
HbO map at 5 s	77.78	70.00	58.86	63.15
HbO map at 10 s	91.67	90.00	86.00	87.50
HbO map at 15 s	93.06	90.00	86.43	87.83
HbO map at 20 s	84.72	80.00	72.43	75.33
HbO map at 25 s	76.39	70.00	58.43	62.83
HbO map at 30 s	77.78	70.00	58.43	62.83
HbO map at 35 s	77.78	70.00	58.43	62.83
HbO map at 40 s	91.67	90.00	86.00	87.50
HbO map at 45 s	77.78	70.00	58.43	62.83
HbO map at 50 s	93.06	90.00	86.43	87.83
HbO map at 55 s	84.72	80.00	72.43	75.33
HbO map at 60 s	65.28	55.66	41.11	46.34
HbO map at 65 s	81.94	78.00	71.00	73.36
Average	82.59	77.20	68.80	71.96

**Figure 7**, i.e., there is a peak at the 60 s time point in the case of the Stroop task. The lower accuracies occur at 5 s (76.86%), 20 s (75.43%), 35 s (78.57%), and 65 s (77.71%). The average accuracy is 85.03%. In contrast, at the 60 s time point, the worst results (65.28%) were obtained in the Stroop task. The higher accuracies appear at the time points of 5 s (91.43%), 15 s (92.00%), and 50 s (92.00%) during the VFT task (shown in **Table 6**). These results are in accordance with the hemodynamic response in **Figure 7** (solid yellow line and cyan solid line). The average accuracy is 82.20%. Among the results of the three mental tasks, the four verifying factors are always congruent. This means that when the accuracy rate is higher, the values of the corresponding recall, precision, and F1-score are also higher. For instance, when the highest accuracy is 98.57%, the highest recall (98.89%), precision (98.33%), and F1-score (98.50%) also appear for the same features.

The CNN classification results of neuroimaging of temporal features in the spatial domain are shown in **Tables 7–9**. The first column of “mean map (5:65 s),” “mean map (5:25 s),” “slope map (5:15 s),” “slope map (20:60 s),” “slope map (60:70 s),” “kurtosis map (5:65 s),” and “skewness map (5:65 s)” represents the neural map generated based on a mean value of 5–65 s, mean value of 5–25 s, slope value of 5–15 s, slope value of 20–60 s, slope value of 60–70 s, kurtosis of 5–65 s, and skewness of 5–65 s, respectively. In comparison, in the results of neural imaging of spatial features,

the average accuracies are higher for all three mental tasks (i.e., *N*-back task: 89.46%, Stroop task: 88.00%, and VFT: 90.37%) as shown in **Tables 7–9**, respectively. In the *N*-back task, the highest accuracy (98.61%) occurred in the slope map from 20 to 60 s, and the lowest accuracy appeared in the mean map (5–25 s). The highest accuracy is 98.57% in the slope map (5–15 s) during the Stroop task, and the lowest accuracy is 77.71% in the slope map (20–60 s). For the VFT task, the accuracy range is from 84.86% (mean map during 5–65 s and skewness map) to 98.57% (mean map 5–25 s).

## DISCUSSION

The objective of the study was to investigate the neuroimaging biomarkers and select the possible candidate biomarkers for

the early detection of AD. To attain this goal, we examined neural images that were generated based on 3 temporal features, 13 spatial features, and 7 temporal-spatial features for training the CNN model, respectively. Finally, we suggest the use of two temporal-spatial features (mean map, slope map) for identification of MCI patients due to the high classification accuracy (90.37%, the averaged accuracy of VFT, **Table 9**). Especially, the slope map from 20 to 60 s with the *N*-back task achieved the highest accuracy of 98.61%, see **Table 7**, Slope map (20:60 s). It is the first study to assess neural images obtained by fNIRS signals for early AD detection. Furthermore, the results obtained for MCI detection constitute the highest diagnosis performance in fNIRS areas. Interpretable, non-invasive, reliable, low cost, and portable biomarkers are

always the necessary tools for the identification of patients with MCI symptoms. The computer-aided neural imaging method could provide a novel direction for the clinical diagnosis of MCI.

fNIRS, a novel non-invasive neuroimaging modality, has proven its worth during the last decade, especially in the healthcare industries (Khan et al., 2018; Hong and Yaqub, 2019). The first article on the use of fNIRS for MCI detection appeared in 2006. This paper proposed that MCI patients show a decreased  $\Delta\text{HbO}$  in the right parietal cortex during the VFT (Arai et al., 2006), and it was the first study to suggest fNIRS as a potential tool for screening AD/MCI. After 7 years, more related papers were published. One of the articles proved that the difference in  $\Delta\text{HbO}$  of MCI individuals and HCs could also be measured in the prefrontal cortex (Doi et al., 2013). In addition, the  $\Delta\text{HbO}$  during the resting state (Viola et al., 2013) and *N*-back task (Niu et al., 2013) also presents signs of neurodegeneration in the MCI group. In 2014, abnormal metabolisms of MCI were observed by some clinical research groups (Babiloni et al., 2014; Liu et al., 2014), such as the hypercapnia effect, global brain hypoperfusion, oxygen hypometabolism, and neurovascular decoupling. Later, the verification of neurodegeneration was also extended to the other cerebral brain regions, i.e., prefrontal cortex (Uemura et al., 2016; Yeung et al., 2016b; Vermeij et al., 2017) inferior frontotemporal cortex (Katzorke et al., 2018), and lateral prefrontal cortex (Marmarelis et al., 2017). Meanwhile, some researchers (Yeung et al., 2016a; Yap et al., 2017; Li et al., 2018a,b,c; Zeller et al., 2019) started to explore reliable biomarkers, i.e., complexity, number of activated channels, mean value of  $\Delta\text{HbO}$ , time to reach peak value, and slope, and lateralization hyperactivation patterns. Interestingly, neurodegeneration symptoms similar to those mentioned above could be repeated. By virtue of these studies, novel directions for understanding the neurological information of MCI symptoms better were provided. Moreover, the relative results also proved that fNIRS is a promising tool for detecting the difference between MCI individuals and HCs. In this study, the hemodynamic responses (shown in **Figure 7**) of  $\Delta\text{HbO}$  during three tasks, the *N*-back task, the Stroop task, and VFT, were consistent with the result of the researches (Yap et al., 2017; Li et al., 2018b) related to AD/MCI detection. Interestingly, the percentages of the activated channels (i.e., *N*-back: 52.83%, Stroop: 46.56%, and VFT: 54.02%) were similar to Mandrick et al. (2013), in which the percentage of activation in the prefrontal cortex during the mental and motor tasks was 51%. However, the provision of a diagnostic decision based on the group difference presents a challenge, because a high STD exists between the two groups.

As mentioned above, researchers prefer to observe the hemodynamic response in time series. Typically, the fluctuation of concentration changes in oxygenated hemoglobin provides evidence for differences in metabolism between the two groups. However, this technique suffers from at least two limitations. (1) Poor robustness: Because of the disturbance of the noise and some intrinsic physiological causes, there is a high possibility that some channels will not be activated or fully activated by noise (Birn, 2012; Wald and Polimeni, 2017).

To a large extent, the affected channel would influence the fluctuation of  $\Delta\text{HbO}/\Delta\text{HbR}$ . (2) Loss of information from the brain network: According to the recent literature (Fornito and Harrison, 2012), the neural disorder is associated with subtle abnormalities distributed throughout the brain. Studies have implied that the neurodegeneration arises from disordered interaction in the connected neural system rather than in the focal channel (Breakspear and Jirsa, 2007). Thus, neglecting the spatial (network level) domain would lead to a significant loss in terms of understanding better the symptom of neural disorders. This comparison was also evaluated in our previous publication (Yang et al., 2019). As our initial investigation indicated, the digital biomarkers, which were obtained based on ROI channels, showed lower accuracy than the image biomarkers (network level). Similarly, the difference of the hemodynamic response for the MCI and HC groups is easy to observe in the spatial domain, which is demonstrated in **Figures 8, 9**.

To meet the demand for clinical diagnoses, it is crucial to converting the neural images into a form that allows an interpretable clinical decision (Martinez-Murcia et al., 2018). With the development of machine/deep learning methods, researchers have started to utilize machine/deep learning for identifying AD/MCI, because the natural images and brain images have similarities (Vieira et al., 2017). In the recent literature (Ieracitano et al., 2018; Ju et al., 2019), it was claimed that deep learning methods (e.g., CNN) would present a superiority for diagnosis for AD/MCI by using EEG and fMRI signals. Also, in our initial fNIRS study (Yang et al., 2019), we compared the statistical analysis, LDA, and CNN for identifying MCI patients from HCs. The results are consistent with the EEG (Ieracitano et al., 2018) and fMRI studies (Ju et al., 2019) that deep learning methods have a better performance than LDA/statistical analysis. Therefore, in this study, we employed the CNN and evaluated the temporal, spatial, temporal-spatial biomarkers for MCI diagnosis.

One of the first studies (Gupta et al., 2013) in which a CNN was applied to structural MRI data achieved classification accuracy rates of 94.7% for AD vs. HC and 86.4% for MCI vs. HC. Thus far, with the development of DL, the classification accuracy has reached a high accuracy for MRI (98/99%) (Khagi et al., 2019), EEG (98.4%) (Amezquita-Sanchez et al., 2016), and fMRI (97%) (Hojjati et al., 2018). According to the results shown in **Tables 4–9**, the average classification accuracy (i.e., *N*-back task: 89.46%, Stroop task: 88.00%, and VFT: 90.37%) in the temporal and spatial domain could prove that fNIRS is also a promising diagnostical modality. In comparison to our previous study, which utilized the image biomarkers (*t*-map and connectivity map) for MCI identification with fNIRS signals (Yang et al., 2019). Our current classification accuracy (highest accuracy: 98.61%) is further improved, and more reliable image biomarkers (e.g., mean map and slope map) are provided for the clinical diagnosis.

Among the three mental tasks, there was no significant difference based on the CNN classification performance. In

comparison with the results of the mental task, the feature selection seems considerably more informative. The performance yielded by the temporal-spatial feature is superior to that yielded by the temporal and spatial features. According to our results, the temporal feature (i.e., the slope map between 5 and 15 s) always showed a good performance. The possible reason is the lower hemodynamic response of people with MCI during the initial stage of the task, which in turn explains why the slope value of the HC group increases faster than that of the MCI group. To reach a more reliable and precise decision, we suggest utilizing a combination of features.

Although the present study has proposed and evaluated the imaging biomarkers for MCI detection with the fNIRS signals using the CNN method (i.e., the highest accuracy was 98.61%), some limitations need be mentioned. First, the fNIRS signals were measured only from the prefrontal cortex, since the benefit of no hair in the prefrontal region can minimize the scattering and attenuation effects. A different result with different biomarkers might also be observed from other brain regions (e.g., the parietal cortex). Derosière et al. (2014) have shown that the parietal cortex revealed a better classification accuracy than the prefrontal cortex for attention state classification. Therefore, a combination of both prefrontal and parietal cortices will provide an improved classification accuracy for MCI case too. Second, the exact location of the FpZ reference point in the International 10–20 System might not have been observed consistently, because the fNIRS device (NIRSIT, OBELAB Inc., Republic of Korea) had fixed emitter-detector distances, and the head shapes of individual subjects were not the same. In addition, data augmentation might be another way to avoid CNN overfitting issues. In this study, we used two drop out layers to overcome the overfitting problem, and the loss plot showed that the overfitting did not appear. The data augmentation method will be considered in our future work to deal with the overfitting issue. For the investigation of the spatial feature, we randomly selected 13 specific time points as features for conducting the comparison. Because of the limitation of the computation, it is difficult to list all the time points (i.e.,  $8.138\text{ Hz} \times 90\text{ s} = 732\text{ points}$ ) and conduct the process as mentioned above. This limitation could be compensated by using a real-time analysis system or dividing more time segments by a shorter time window (i.e., 5–15 s). Likewise, in the temporal-spatial features, the time point selection also presents a challenge. In general, a neural image based on the first 15 s always yields a good accuracy level. Driving more time points in the time windows between 5 and 15 s would like to be done in future work to reduce the processing time. In the real clinical application, the biggest challenge is data training: However, once the model gets appropriately trained, the system can be used as a reliable tool for diagnosing MCI patients.

## CONCLUSION

In this study, we highlighted the feasibility of using fNIRS for the early detection of AD by using neural imaging based

on the temporal, spatial, and temporal-spatial features. This systematically analyzed results indicate that neural imaging of the combined temporal and spatial features (i.e., the average accuracy of *N*-back: 89.46%, Stroop: 87.80%, and VFT: 90.37%) produces a more reliable performance than those when using temporal and spatial features separately. In particular, the slope map (20–60 s) during the *N*-back task achieved the highest accuracy of 98.61%. In the Stroop task and VFT case, the maximum accuracy is 98.57% by the slope map (5–15 s) and mean map (5–25 s). Besides that, all the mental tasks could achieve a good accuracy (>90%) within the time windows (5–15 s). This finding provides the possibility to use the short time windows for early detection of the AD. Conclusively, our results indicate that the CNN-aided temporal-spatial neuroimaging method could assist the clinical diagnosis of MCI. Additionally, the classification performance based on the spatial neural image also provides a possibility of reducing the diagnosis time in future studies.

The aim of this study is to explore functional and structural properties of abnormal brain networks associated with Parkinson's disease (PD). <sup>18</sup>F-Fluorodeoxyglucose positron emission tomography (<sup>18</sup>F-FDG PET) and T1-weighted magnetic resonance imaging from 20 patients with moderate-stage PD and 20 age-matched healthy controls were acquired to identify disease-related patterns in functional and structural networks. Dual-modal images from another prospective subject of 15 PD patients were used as the validation group. Scaled Subprofile Modeling based on principal component analysis method was applied to determine disease-related patterns in both modalities, and brain connectome analysis based on graph theory was applied to verify these patterns. The results showed that the expressions of the metabolic and structural patterns in PD patients were significantly higher than healthy controls (PD1-HC,  $p = 0.0039$ ,  $p = 0.0058$ ; PD2-HC,  $p < 0.001$ ,  $p = 0.044$ ). The metabolic pattern was characterized by relative increased metabolic activity in pallidothalamic, pons, putamen, and cerebellum, associated with metabolic decreased in parietal-occipital areas. The structural pattern was characterized by relative decreased gray matter (GM) volume in pons, transverse temporal gyrus, left cuneus, right superior occipital gyrus, and right superior parietal lobule, associated with preservation in GM volume in pallidum and putamen. In addition, both patterns were verified in the connectome analysis. The findings suggest that significant overlaps between metabolic and structural patterns provide new evidence for elucidating the neuropathological mechanisms of PD.

**Keywords:** Parkinson's disease, brain network, pattern, <sup>18</sup>F-FDG PET, MRI

## INTRODUCTION

Parkinson's disease (PD) is a complex, chronic, and neurodegenerative disorder, pathologically characterized predominately by a loss of substantia nigra pars compacta dopaminergic neurons, manifesting in functional and structural alterations throughout the brain (Lee and Trojanowski, 2006; Choi et al., 2013; Rocha et al., 2018). Pathological studies have shown

that the cortical and subcortical regions are widely involved in PD pathology (Braak et al., 2003). Current efficient diagnostic tools for PD neuroimaging—including magnetic resonance imaging (MRI), positron emission tomography (PET), and single-photon emission computed tomography (SPECT)—rely on different principles that could be useful depending on the research or clinical setting available (Politis, 2014). In particular,  $^{18}\text{F}$ -fluorodeoxyglucose positron emission tomography ( $^{18}\text{F}$ -FDG PET) has been used to localize and quantify abnormal brain energy metabolism *in vivo* and recently been used in metabolic connectivity studies to identify different disease-specific patterns (Titov et al., 2017). It is increasingly used in routine clinical practice (Teune et al., 2013). For instance, spatial covariance analysis of  $^{18}\text{F}$ -FDG PET data consistently reveals the presence of a stereotyped spatial covariance pattern associated with different stages of motor symptoms in PD patients. The metabolic Parkinson's disease-related pattern (PDRP) associated with motor symptoms is characterized by increased metabolism in the putamen, globus pallidus, bilateral thalamus, and pontine, and relatively decreased metabolism in the premotor and parieto-occipital cortex (Ma et al., 2007; Eidelberg, 2009; Spetsieris and Eidelberg, 2011; Spetsieris et al., 2013; Wu et al., 2013; Ko et al., 2017; Tomšić et al., 2017). The reproducibility of metabolic PDRP in different cohorts, according to the extensive literature, indicated that the metabolic PDRP was a reliable marker of disease across various ethnic groups and PET instrumentations as well as imaging protocols (Schindlbeck and Eidelberg, 2018). Moreover, the PDRP expression values (subject scores) from various studies have also shown significant positive correlations with disease progression and have decreased after effective treatments of motor symptoms (Huang et al., 2007; Peng et al., 2014b).

While metabolic PDRP can effectively reveal the abnormal metabolic function in PD, these functional abnormalities may also have corresponding changes in neuroanatomical structures. MRI, as a noninvasive examination and cost-effective imaging technique, has become more and more important to the study of neurodegenerative diseases, which revealed the structural and functional alterations underlying these conditions. For example, T1-weighted structural MRI is able to measure the volume/thickness alterations of the gray and white matters in the subcortical and cortical areas associated with PD (Wilson et al., 2019). Currently, imaging studies have provided preliminary evidence for structural abnormalities in the brain of PD patients, especially brain atrophy. Given that prolonged metabolic derangement causes atrophy, the spatial pattern of atrophy demonstrated an overlap with the metabolic PDRP topography, as well as with intrinsic networks present in healthy brain (Zeighami et al., 2015). However, it is still under speculation whether both spatial patterns of metabolic function and atrophy are effective to address PD progression at the same time.

In response to this issue, we explored the topographical relationship between both spatial patterns of metabolic function and atrophy. In addition, we also explored corresponding disease intrinsic networks defined using brain connectome analysis based on graph theory. This analysis method is an

innovative approach that has revealed fundamental aspects of brain structural or functional network organization, and it can reveal abnormalities in network characteristics associated with neurological diseases and the potential impact of the disease network on brain information processing (Fox, 2018). Currently, graph theory in conjunction with spatial covariance analysis was used to examine the topology of disease networks in metabolic PDRP (Ko et al., 2017). The results in that study showed that disease networks defined by the spatial covariance analysis in PD patients exhibit exaggerated small world property, suggesting that it is more beneficial to elucidate the pathological basis of PD from the perspective of PD-related metabolic functional alterations in disease intrinsic networks. Nevertheless, it remains to be determined whether such alterations also occur in PD-related structural networks.

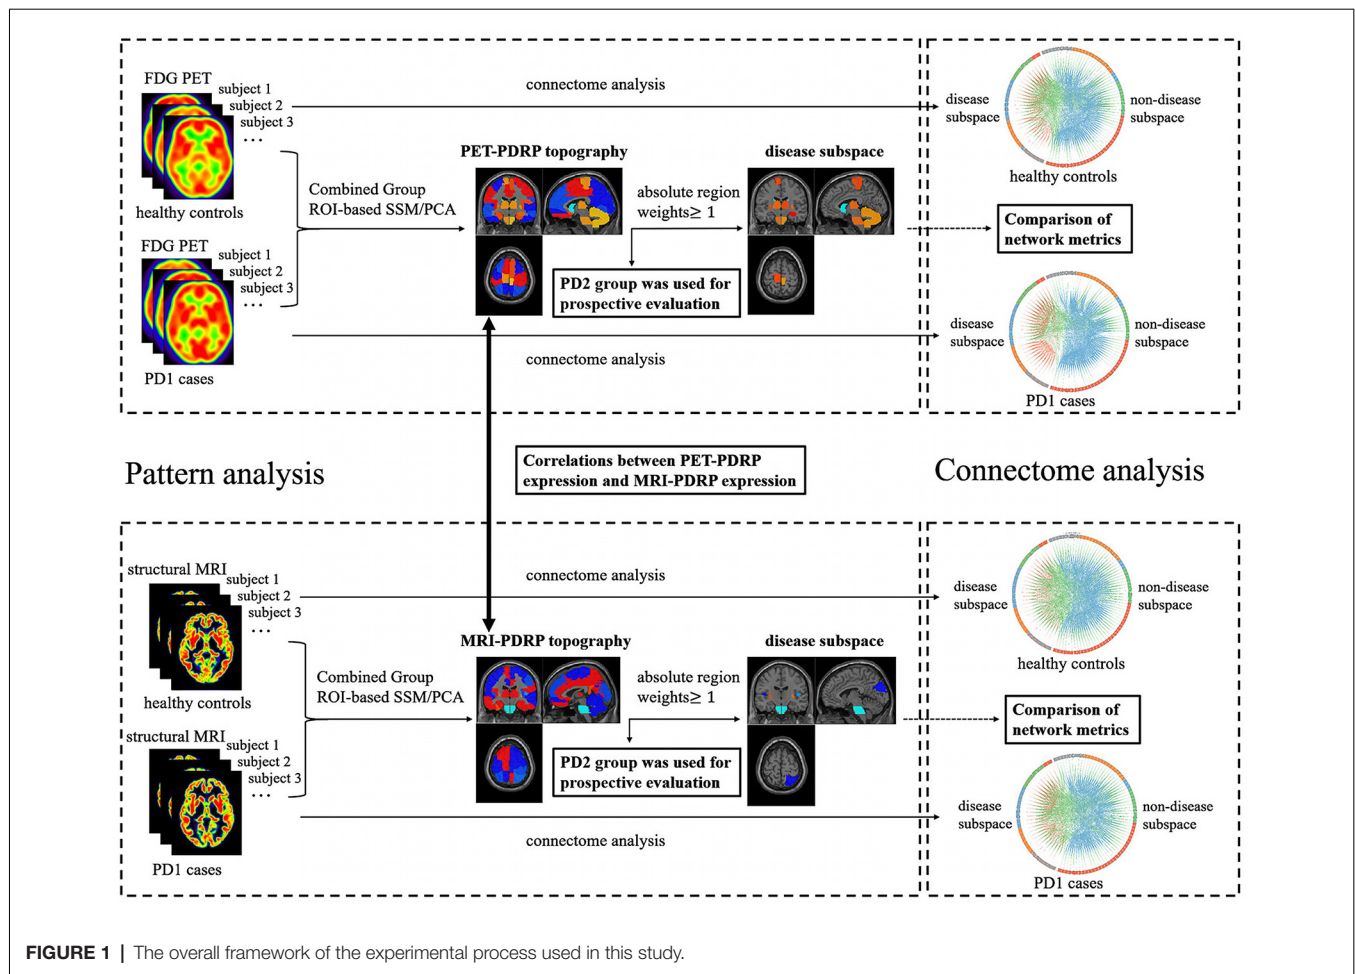

The primary objective of this work was to characterize inherently metabolic PDRP and structural PDRP together in PD patients and explore their correlations. A secondary aim was to explore whether the disease brain networks derived from metabolic or structural PDRP from graph theory has abnormal topological characteristics. We also hypothesized that there are abnormal topological characteristics in the disease structure and metabolic networks in the PD.

## MATERIALS AND METHODS

**Figure 1** provides the general framework of our study. First, both  $^{18}\text{F}$ -FDG PET and T1-weighted structural MRI scans from PD1 and HC subjects in cohort A were analyzed using spatial covariance analysis to identify a significant region-of-interest (ROI)-based metabolic PDRP (PET-PDRP) topography and a structural PDRP (MRI-PDRP) topography. Both topographies and corresponding pattern expression values were compared with each other. Data from PD2 subjects in cohort B were used for a prospective evaluation of both metabolic and structural PDRPs in single cases. Second, based on the customized criteria, we identified some salient abnormal brain regions from the PET-PDRP or MRI-PDRP topographies as network nodes in the disease subspace, and the remaining regions constituted the nondisease subspace. Finally, to explore network properties in the disease and nondisease subspaces in PD patients, connectome analysis based on graph theory was performed from each group. We calculated the corresponding network metrics between the disease and nondisease subspace and compared differences in network metrics for the PD groups relative to the corresponding control values.

## Subjects

This study included two different cohorts (cohort A and B) of healthy subjects and PD patients (**Table 1**). Cohort A included 20 nondemented patients with PD and 20 age-matched healthy controls recruited from Huashan Hospital (Shanghai, China) in one project conducted from January 2014 to September 2015. Cohort B included 15 nondemented patients with PD recruited from Huashan Hospital (Shanghai, China) in another project conducted from January 2013 to September 2013. All subjects in cohorts A and B underwent

**TABLE 1** | Demographic characteristics of PD patients and healthy controls.

	Cohort A		Cohort B		p value
	HC	PD1	PD2		
N	20	20	15	PD1-HC	PD2-HC
Age (years)	59.6 ± 7.2	62.4 ± 7.3	62.8 ± 4.9	0.230 <sup>a</sup>	0.148 <sup>a</sup>
Gender (F/M)	12/8	10/10	3/12	0.525 <sup>b</sup>	<b>0.018<sup>b</sup></b>

MMSE	-	28.8 ± 1.7	27.8 ± 1.9	-	-

Age and clinical rating are given as mean ± standard deviation. UPDRS, Unified Parkinson's Disease Rating Scale. <sup>a</sup>p value was obtained by the two-sample two-tailed t-test between healthy controls and PD patients. <sup>b</sup>p value was obtained by the  $\chi^2$  test between healthy controls and PD patients. Bold value indicated a significant difference between healthy controls and PD patients.

both <sup>18</sup>F-FDG PET and T1-weighted structural MRI scans. All patients were scanned and clinically examined by two senior neurologists specializing in dyskinesia before their inclusion in the study. The PD diagnosis was according to the United Kingdom Brain Bank criteria (Hughes et al.,

1992). Patients with PD have no dementia, supranuclear gaze abnormalities, or ataxia, and are not caused by encephalitis or antipsychotic medication. The Unified Parkinson's Disease Rating Scale (UPDRS) motor examination was administered at least 12 h after the cessation of antiparkinsonian

medications. Mini-mental State Examination (MMSE) was administered synchronously.

All healthy controls received the same clinical scanning procedures as PD patients. Exclusion criteria for all subjects included: (a) primary psychiatric illness; (b) central nervous system comorbidities; and (c) abnormal neurological examination.

Ethical permission for the study was obtained from the Research Ethics Committee of Huashan Hospital, Shanghai, China (approval number: KY2013-336). Written informed consent was obtained from each subject after providing detailed instructions of the procedures.

## Acquisition Protocol

### <sup>18</sup>F-FDG PET

All subjects underwent <sup>18</sup>F-FDG PET examination at resting state. PET scans were performed with a Siemens Biograph 64 HD PET/CT (Siemens, Germany) in three-dimensional (3D) mode. All subjects were fasted for at least 6 h before scanning. After intravenous injection of 185 MBq <sup>18</sup>F-FDG, the PET scan was started after a 45-min rest in a quiet and dimly lit environment. Prior to the PET scan, a low-dose CT transmission scan was performed for attenuation correction. The PET scan was performed in 3D mode for 10 min. All PET data were reconstructed using a 3D ordered subset expectation maximization algorithm and corrected for random coupling, scattering, and radioactive decay.

### T1-Weighted Structural MRI

All MRI measurements were obtained on a 3-T GE Discovery MR750 Scanner (Milwaukee, WI, USA) equipped with a circular polarized eight-channel head matrix coil at the Department of Radiology of Huashan Hospital of Fudan University, China. High-resolution, T1-weighted, 3D anatomical brain images were obtained using an inversion recovery prepared fast spoiled gradient recalled sequence (repetition time = 11.1 ms; echo time = 5.0 ms; flip angle = 20°; matrix resolution = 256 × 256; voxel size = 1 × 1 × 1 mm<sup>3</sup>; field of view = 240 mm<sup>2</sup>; slice thickness = 1.0 mm; 146 slices without slice gap, transverse acquisition), with the scan range from the calvarium to foramen magnum.

## Data Preprocessing

Data preprocessing for both PET and MRI images was done using Statistical Parametric Mapping 12 (the Wellcome Department of Neurology, London, UK) package implemented in Matlab2016b (Mathworks Inc.). First, <sup>18</sup>F-FDG PET scan for each subject was aligned with corresponding T1-weighted MRI scan. Second, MRI images were segmented into gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF) tissue probability maps. Then, the GM map was registered to the Montreal Neurological Institute (MNI) stereotaxic template using nonlinear transformation parameters. The aligned PET image was also normalized to the MNI template using the same transformation parameters. Finally, the normalized MRI and PET images were smoothed equivalent to a convolution

with an isotropic Gaussian kernel of 8 mm to increase signal-to-noise ratios.

## Pattern Analysis

Pattern analysis was performed using ScanVP 7.0w package implemented in Matlab2016b<sup>1</sup> (Eidelberg, 2009; Spetsieris and Eidelberg, 2011). The PD-related covariance pattern was generated using ROI-based spatial covariance mapping algorithms known as Scaled Subprofile Modeling based on principal component analysis (SSM/PCA). In this step, the smoothed <sup>18</sup>F-FDG PET data from the combined PD1 patients and healthy subjects in cohort A was used as inputs. First, we performed a logarithmic transformation on the mean glucose metabolism within each region for each subject, and the subject × ROI data matrix was obtained. Second, the PCA was executed on the matrix to identify a disease-related spatial covariance pattern reflected major sources of variation. This pattern was a linear combination of selected principal components (PCs), so that the expression values corresponding to the pattern could maximally separate the PD patients from the control subjects. The number of PCs was determined by the lowest Akaike information standard (AIC) value in the logistic regression model. Third, the regional weights of the pattern were z-scored based upon the mean and standard deviation of all regions (Spetsieris et al., 2013). Therefore, the subject expression of this pattern in a prospective subject can be computed using an ROI-based topographic profile rating (TPR) algorithms (Eidelberg, 2009; Spetsieris et al., 2013). Finally, the resulting expression was Z-transformed using the subject expressions of the control subjects participating in the pattern identification. In this study, we preselected 95 ROIs. In addition to 90 ROIs from the automated anatomical labeling (AAL) atlas (Tzourio-Mazoyer et al., 2002), we also included five other regions where functional imaging studies in PD commonly report altered metabolism, including bilateral cerebellum, bilateral pons, and cerebellar vermis. The MRI images were analyzed by the same process as above.

As a result, a significant ROI-based metabolic PDRP (and structural) topography was identified from <sup>18</sup>F-FDG PET (and T1-weighted GM MRI) scans of combined PD1 and HC subjects in cohort A. Subject expressions of corresponding PDRP were then computed for all scans in the combined PD1 and HC subjects and Z-scored using subject expressions of the HC. We validated corresponding PDRP topography by computing its expression in the <sup>18</sup>F-FDG PET (and T1-weighted GM MRI) scans from PD2 subjects in cohort B. The corresponding PDRP expressions of PD2 subjects were Z-scored the same way as above and then compared with those of the original subjects in PD1 and HC. The diagnostic power of the corresponding PDRP expressions for discriminating PD patients from healthy controls was evaluated by the area under the curve (AUC) in the receiver operating characteristic (ROC) curves. ROC analysis in cohort B was obtained by comparing PD2 and HC groups. ROC analysis in cohorts A and B (cohort A + B) was obtained by comparing combined PD1 and PD2 groups compared to HC

<sup>1</sup><http://www.feinsteinneuroscience.org>

group. We also evaluated whether the combination of PET-PDRP and MRI-PDRP expressions could improve diagnostic power. In addition, correlation analysis of corresponding PDRP expression and clinical ratings in PD patients in cohorts A and B were also performed.

## Correlation Analysis Between PET-PDRP and MRI-PDRP Topographies

The metabolic and structural topographies were assessed by ROI-based correlation of regional weights in a set of salient abnormal brain regions. The correlation between the two patterns was calculated using only the regions with absolute values  $\geq 1.0$  (Ge et al., 2018). The pattern expression for PET-PDRP was also correlated with corresponding MRI-PDRP expression in combined PD1 (or PD2) and HC samples.

## Brain Connectome Analysis

Graph theory was used to explore network properties in brain connectome analysis. Globally normalized glucose metabolism within each ROI was used to construct a region  $\times$  region correlation matrix across each of three individual groups (PD1, PD2, and HC groups). In each correlation matrix, functional connectivity (FC) between each pair of regions was calculated by partial correlation coefficient between ROI values for local FDG uptake in each pair of regions, across participants, to conduct for the control of age and gender effects (Lo et al., 2010; Duan et al., 2017; Jiang et al., 2017). We used a sparsity (or named cost, representing present connections as a percentage of all possible connections) threshold to generate a series of undirected graphs (Baggio et al., 2014; Duan et al., 2017). The correlation matrices were thresholded at a range of sparsity thresholds, in 0.01 steps (sparsity<sub>min</sub>: 0.01: sparsity<sub>max</sub>). The minimum sparsity guaranteed that networks of all groups (HC, PD1, and PD2) were fully connected, and no nodes were fragmented. The maximum sparsity selected 0.5 because the randomness of the network larger than this threshold would increase, and the results would be unreliable (Hosseini et al., 2012). At each threshold, we calculated the following network metrics: (1) the clustering coefficient (*C*, quantification of the degree to which nodes in a graph tend to cluster together and a representation of network segregation, measuring the local information transmission capability in a network); (2) the characteristic path length (*L*, the average number of connections on the shortest path between any two regions in a network and a marker of network integration, measuring the global information transmission capability in a network); and (3) small worldness (*S*, the balance between local segregation and global integration).

Next, we divided the brain into disease subspace and nondisease subspace based upon the PET-PDRP topographies for further analysis. The nodes in the disease subspace consisted of the salient abnormal brain regions (absolute regional weight  $\geq 1.0$ ; high local contributions to overall PDRP activity) identified by the PDRP topography and the remaining regions constituting the nondisease subspace (absolute regional weight  $< 1.0$ ; low local contributions to overall PDRP activity). We calculated the corresponding network metrics among disease subspace, nondisease subspace, and whole brain, and we compared

differences in network metrics for the PD1/PD2 groups relative to HC control values.

The graph theoretical analyses of brain structural network were the same as in the procedure for metabolic brain network but based on T1-weighted GM imaging data. It was worth noting that disease subspace and nondisease subspace in brain structural network were divided according to MRI-PDRP topography.

Brain connectome analysis was performed using Brain Connectivity Toolbox<sup>2</sup> and Graph Analysis Toolbox (Hosseini et al., 2012) implemented in Matlab2016b.

## Statistical Analysis

Differences in PET-PDRP (and MRI-PDRP) expressions between patients and healthy controls were evaluated using two-sample *t*-tests. PDRP expressions of patients were correlated with corresponding MMSE, UPDRS, and six motor items (speech, facial expression, static tremor, postural tremor, rigidity, and gait) by computing Pearson's correlations. Regional weight and pattern expression between the two PDRPs identified in the <sup>18</sup>F-FDG PET scans and structural MRI scans was compared using Pearson's correlations. In order to determine the significance of the differences in network metrics between the patient group and HC group in each subspace, a permutation test repeated 1,000 times was used (Hosseini et al., 2012; Ko et al., 2017). All statistical tests were performed using Matlab2016b ( $p < 0.05$ , two-tailed).

## RESULTS

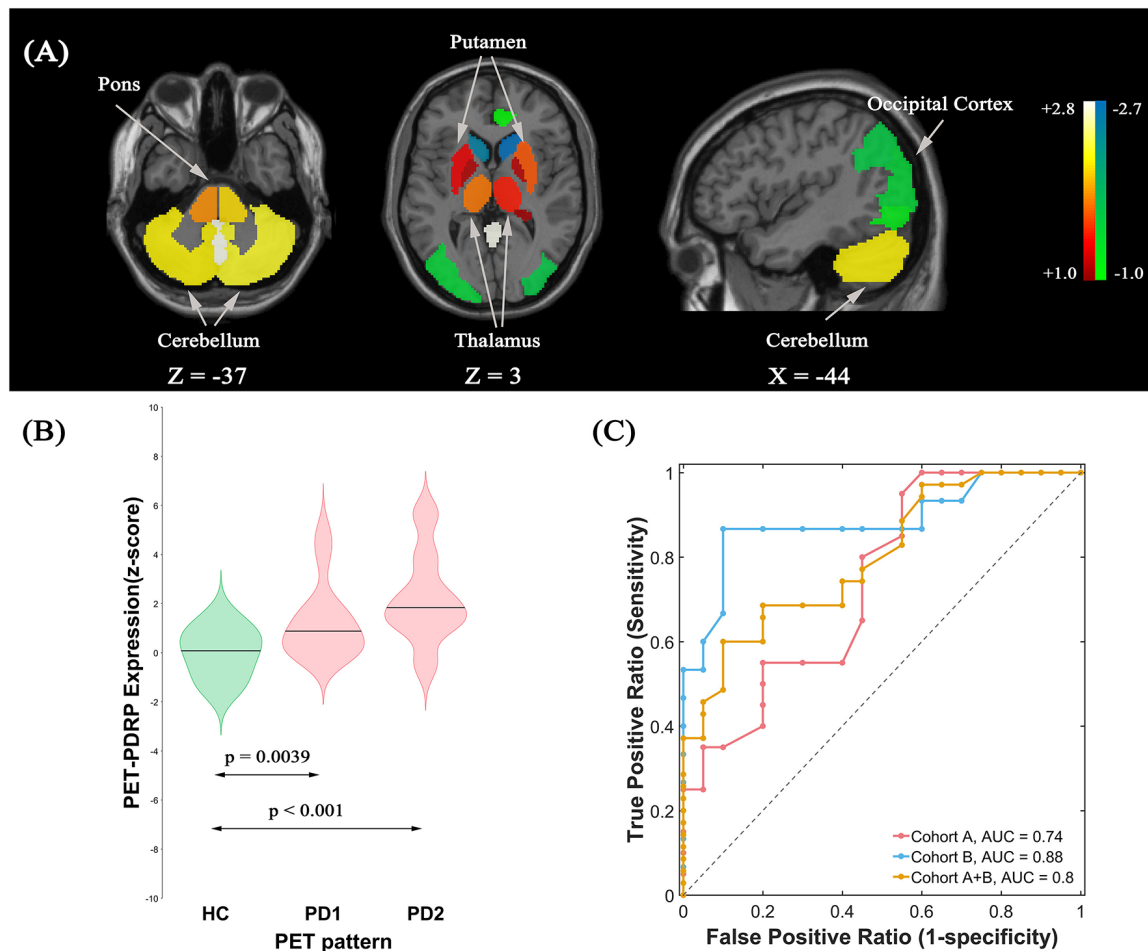

### Abnormal Disease Topographies in Pattern Analysis

#### PET-PDRP Identification and Validation

The ROI-based SSM/PCA multivariate analysis of <sup>18</sup>F-FDG PET data from cohort A investigated the first four PCs that explained 55.4% of the subject  $\times$  ROI variance. The PET-PDRP topography generated from a linear combination of PC1, PC3, and PC4 with expression successfully discriminated PD1 patients and healthy controls, and produced the lowest AIC value in the logistic regression model. The pattern was characterized by relative increased metabolic activity in pallidothalamic, pons, bilateral putamen, and cerebellum, associated with metabolic decrease in parietal-occipital areas (**Figure 2A**). Subject expressions for the PET-PDRP topography were significantly elevated ( $p = 0.0039$ ) in PD1 compared to HC subjects (**Figure 2B**). Significant increases in pattern expression were also seen in PD2 validation subjects with respect to HC control values ( $p < 0.001$ ). Subject PET-PDRP expressions were without a difference between PD1 and PD2 subjects ( $p = 0.097$ ). ROC analysis revealed an AUC = 0.74 (95% confidence intervals of 0.59–0.89; **Figure 2C**) to distinguish the PD patients from the controls in cohort A. The ROC curves also showed that PET-PDRP expression accurately distinguished PD patients from the control individuals in cohorts B and A + B. The AUC values were 0.88 (95% confidence intervals of 0.75–1.00) and 0.80 (95% confidence intervals of

**FIGURE 2 | (A)** Metabolic Parkinson's disease-related pattern (PET-PDRP) identified by Scaled Subprofile Modeling (SSM) multivariate analysis of  $^{18}\text{F}$ -FDG PET scans from 20 (PD) patients in PD1 and 20 age- and gender-matched healthy controls. The pattern was characterized by relative increased metabolic activity in the pallidothalamic, pons, bilateral putamen, and cerebellum, associated with metabolic decreased in parietal-occipital areas. **(B)** Subject expressions for the PET-PDRP topography measured using violin plots in the HC, PD1, and PD2 scans (horizontal lines indicate group medians). Significant increases in pattern expression were seen in PD1 original derivation subjects and PD2 validation subjects with respect to HC control values. **(C)** Receiver operating characteristic (ROC) curve for discriminating PD patients from healthy controls.

0.68–0.92) for subjects in cohorts B and A + B, respectively (**Figure 2C**).

### MRI-PDRP Identification and Validation

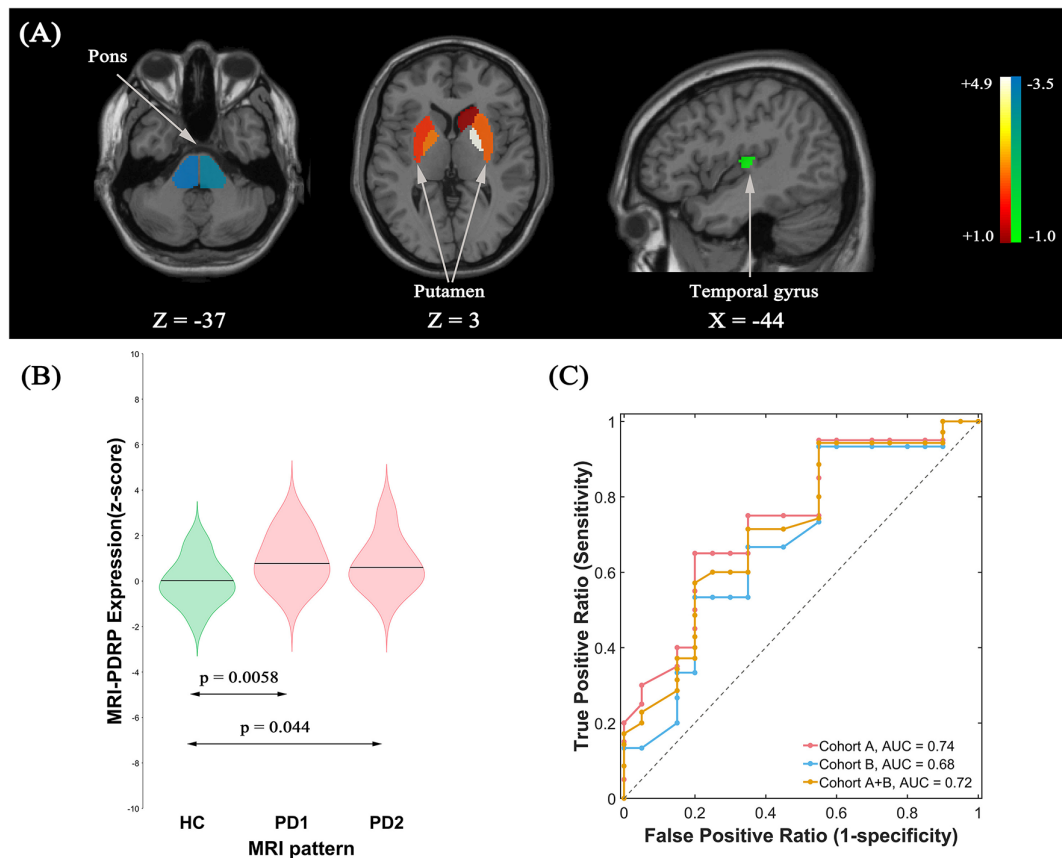

The pattern analysis of MRI images examined the first four PCs accounting for 52.4% subject  $\times$  ROI variance. An MRI-PDRP was generated by a linear combination of PC2 and PC3. The pattern was characterized by relative decreased GM volumes in bilateral pons, bilateral transverse temporal gyrus, left cuneus, right superior occipital gyrus, and right superior parietal lobule, associated with preservation in GM volumes in bilateral pallidum and bilateral putamen (**Figure 3A**). Subject expressions for the MRI-PDRP topography were significantly elevated ( $p = 0.0058$ ) in PD1 compared to HC subjects (**Figure 3B**). Significant increases in pattern expression were seen in PD2 validation subjects with respect to HC control values ( $p = 0.044$ ). Subject

MRI-PDRP expressions were not different between PD1 and PD2 subjects ( $p = 0.599$ ). As for ROC curves distinguishing the PD patients from the normal controls, AUC values were 0.74 (95% confidence intervals of 0.59–0.90), 0.68 (95% confidence intervals of 0.50–0.86), and 0.72 (95% confidence intervals of 0.57–0.86) for subjects in cohorts A, B, and A + B, respectively (**Figure 3C**).

### Correlation Analysis

#### Correlations Between PDRP and Clinical Scales

PET-PDRP and MRI-PDRP expressions were not correlated with MMSE in the PD group. The correlations between PET-PDRP expressions and the corresponding UPDRS within each PD group are shown in **Figure 4**. In PD1 group, PET-PDRP expressions in patients correlated positively with UPDRS motor ratings ( $r = 0.55$ ,  $P = 0.01$ ; **Figure 4A**). In PD2 group,

**FIGURE 3 | (A)** Structural Parkinson's Disease-Related Pattern (MRI-PDRP) derived from the same subjects. The pattern was characterized by relative decreased gray matter (GM) volume in bilateral pons, bilateral transverse temporal gyrus, left cuneus, right superior occipital gyrus, and right superior parietal lobule, associated with preservation in GM volume in bilateral pallidum and bilateral putamen. **(B)** Subject expressions for the MRI-PDRP topography measured using violin plots in the HC, PD1 and PD2 scans (horizontal lines indicate group medians). Significant increases in pattern expression were seen in PD1 original derivation subjects and PD2 validation subjects with respect to HC control values. **(C)** ROC curve for discriminating PD patients from healthy controls.

PET-PDRP expressions in patients also correlated with UPDRS motor ratings ( $r = 0.60$ ,  $P = 0.02$ ; **Figure 4B**). In a combined PD group from PD1 and PD2, PET-PDRP expressions had positive correlations with UPDRS motor ratings ( $r = 0.54$ ,  $P < 0.001$ ). MRI-PDRP expressions were also associated with UPDRS motor ratings in PD1 group ( $r = 0.51$ ,  $P = 0.02$ ) but not PD2 group. In a combined PD group (PD1 + PD2), MRI-PDRP expressions were not correlated with UPDRS motor ratings. The correlation results between PET-PDRP expressions, MRI-PDRP expressions, and the six motor items of UDRPS are shown in **Figure 5**. PET-PDRP expressions in patients correlated positively with the scores of speech ( $r = 0.485$ ,  $P = 0.003$ ), facial expression ( $r = 0.336$ ,  $P = 0.0049$ ), postural tremor ( $r = 0.379$ ,  $P = 0.025$ ), rigidity ( $r = 0.361$ ,  $P = 0.033$ ), and gait ( $r = 0.360$ ,  $P = 0.034$ ). MRI-PDRP expressions in patients correlated positively with the scores of static tremor ( $r = 0.505$ ,  $P = 0.002$ ).

### Correlations Between PET-PDRP and MRI-PDRP

In the two PDRPs, six regions were salient abnormal brain regions (absolute region weight  $\geq 1.0$ ) in both patterns,

including bilateral pons, bilateral pallidum, and bilateral putamen (**Supplementary Tables S1, S2**). Regional weights between the two PDRPs of these regions were negatively correlated ( $r = -0.88$ ,  $P = 0.02$ ; **Figure 6A**). Two pattern expression of the combined PD1 patients and healthy controls showed positive correlations ( $r = 0.45$ ,  $P = 0.0038$ ; **Figure 6B**) but not associated with combined PD2 and HC subjects or combined PD1, PD2, and HC subjects. The correlations between two pattern expressions in the single PD1 group was found ( $r = 0.42$ ,  $P = 0.064$ ) but not found in single PD2 group or combined PD1 and PD2 subjects.

## Brain Connectome Analysis

### PD-Related Metabolic Network

Connectome analysis was used to reveal abnormalities in network features associated with PD. In our study, in order to determine whether this feature is different between PD patients and healthy subjects, we separated each group's network into two discrete subspaces. Eventually, 25 nodes constituted the disease subspace, which had a higher local contributions to

**FIGURE 4 |** PET-PDRP expressions in individual patients correlated with UPDRS motor ratings in the (A) original derivation subjects as well as in the (B) subsequent validation subjects. Shaded areas represent 95% confidence of intervals. UPDRS, Unified Parkinson's Disease Rating Scale.

overall PET-PDRP activity (for more details, please refer to **Supplementary Table S1**). The remaining 70 brain regions served as nodes in the nondisease subspace. The sparsity<sub>min</sub> (ensuring both the disease subspace and nondisease subspace are fully connected) of the HC, PD1, and PD2 groups was 15, 38, and 28%, respectively. Network metrics in each group were computed with a sparsity threshold ranging from 38% to 50%. At sparsity 38%, the clustering coefficient for the disease subspace in the PD1 group was significantly ( $P < 0.05$ ) increased compared with the HC group (PD1, 0.80; HC, 0.50; **Figures 7A,B,D**). The characteristic path length had a tendency to increase in PD1 compared to HC (PD1, 2.42; HC, 1.67; **Figures 7A,B,E**). However, significant differences were not observed for the small-worldness coefficient. Indeed, permutation analysis showed that, in the entire sparsity threshold range (38–50%), the clustering coefficient of PD1 group in the disease space increased significantly ( $P < 0.05$ ); in the sparsity threshold range of 41–50%, the characteristic path length also increased significantly ( $P < 0.05$ ; **Supplementary Figure S1**).

The clustering coefficient for the disease subspace was significantly ( $P < 0.05$ ) increased in PD2 compared to HC over the sparsity range of 38–42% (for example, at sparsity 38%, C in PD2 is 0.76; C in HC is 0.50; **Figures 7A,C,D**). The small world coefficient for the disease subspace in PD2 group increased significantly ( $P < 0.05$ ) at sparsity range of 39–41% (**Supplementary Figure S2**) and had an increasing trend at sparsity 38% (S in PD2, 1.91; S in HC, 1.19; **Figures 7A,C,F**). The characteristic path length (had a tendency to increase, such as, at sparsity 38%, L in PD2 is 2.16; L in HC is 1.67; **Figures 7A,C,E**) did not show group differences (**Supplementary Figure S2**). Group differences of network metrics were not significant for the nondisease subspace or for the whole brain.

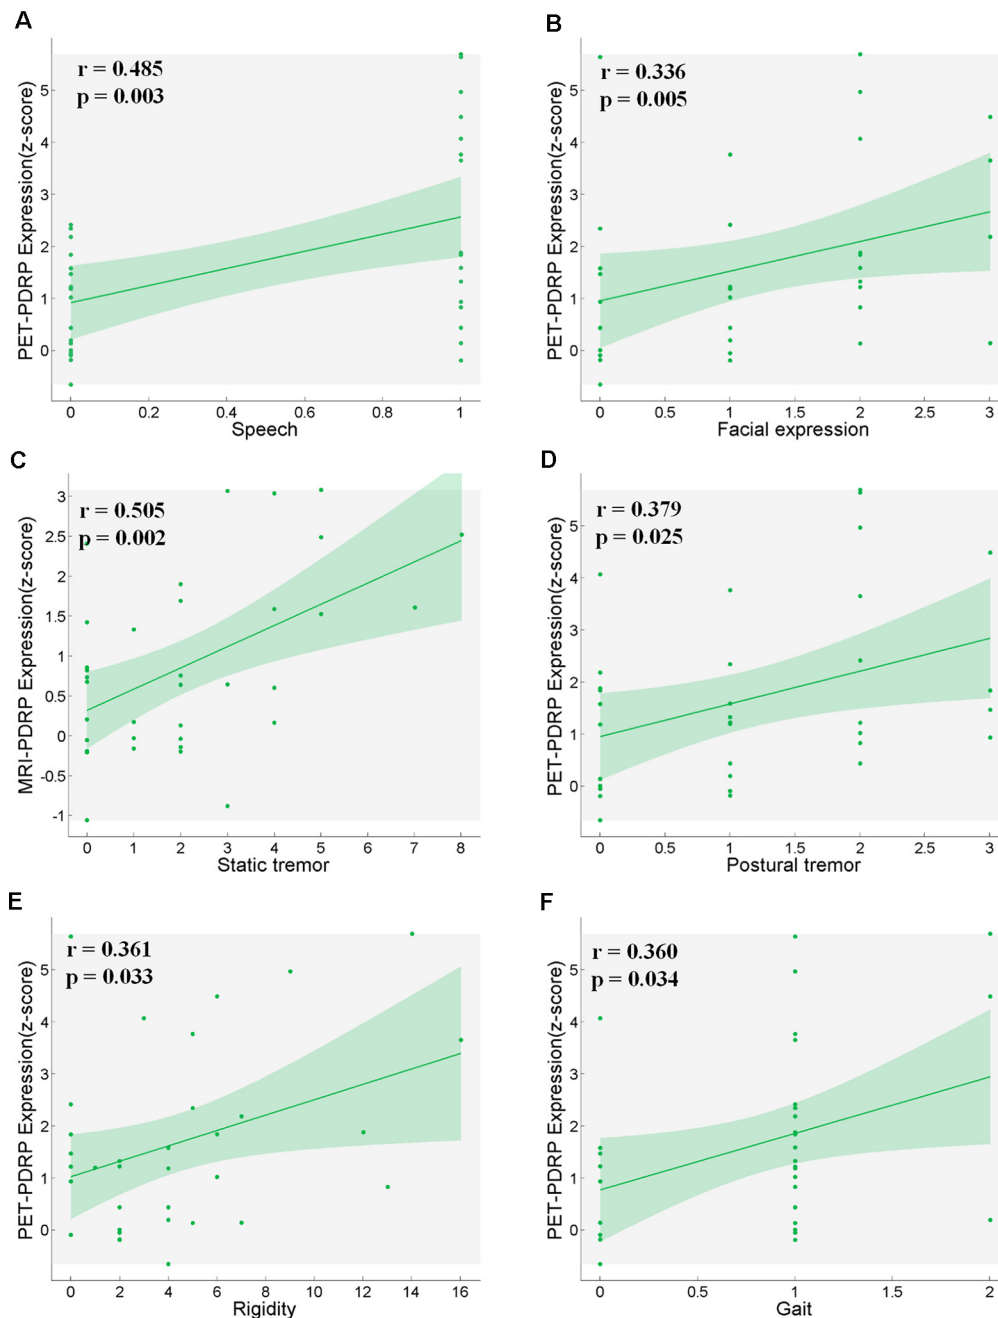

### PD-Related Brain Structural Network

According to the local contributions to overall MRI-PDRP activity, 11 nodes constituted the disease subspace

(**Supplementary Table S2**), and the remaining 84 brain regions served as nodes in the nondisease subspace. PD-related brain structural network was also analyzed based on T1-weighted GM imaging data in different spaces. In the HC group, the minimum sparsity in which all nodes became fully connected in both the disease subspace and nondisease subspace was 20%, PD1 group was 32%, and PD2 group was 17%. Network metrics were computed at a sparsity range of 32–50% for the comparisons between PD1 (or PD2) and HC. At sparsity 32%, increased path length and slightly elevated small-world coefficients for the disease subspace were observed in PD1 group but not PD2 group (L in PD1, 2.15; L in PD2, 1.70; L in HC, 1.42; S in PD1, 2.88; S in PD2, 1.05; S in HC, 1.28; **Supplementary Figure S3**). As above, in the nonparametric permutation test analysis, we also found that increased path length (in the sparsity range of 38–47% and 49–50%) and slightly elevated small-world coefficient (at sparsity 39% and 50%) over corresponding sparsity range for the disease subspace in PD1 group but not PD2 group (**Supplementary Figures S4, S5**). Group differences of network metrics were not significant for the nondisease subspace or for the whole brain.

## DISCUSSION

In this study, we investigated  $^{18}\text{F}$ -FDG PET-based metabolic covariance pattern (PET-PDRP) and T1 MRI-based structural covariance pattern (MRI-PDRP) associated with PD for the same patients. The MRI-PDRP topography revealed brain region-level abnormalities containing a large number of cortical neurons that partially overlap with the metabolic pattern derived from  $^{18}\text{F}$ -FDG PET scans. Connectome analysis also showed that the topological organization for the disease network in the PET-PDRP and MRI-PDRP topographies were significantly disrupted. These findings provide new evidence for elucidating the neuropathological mechanisms of PD.

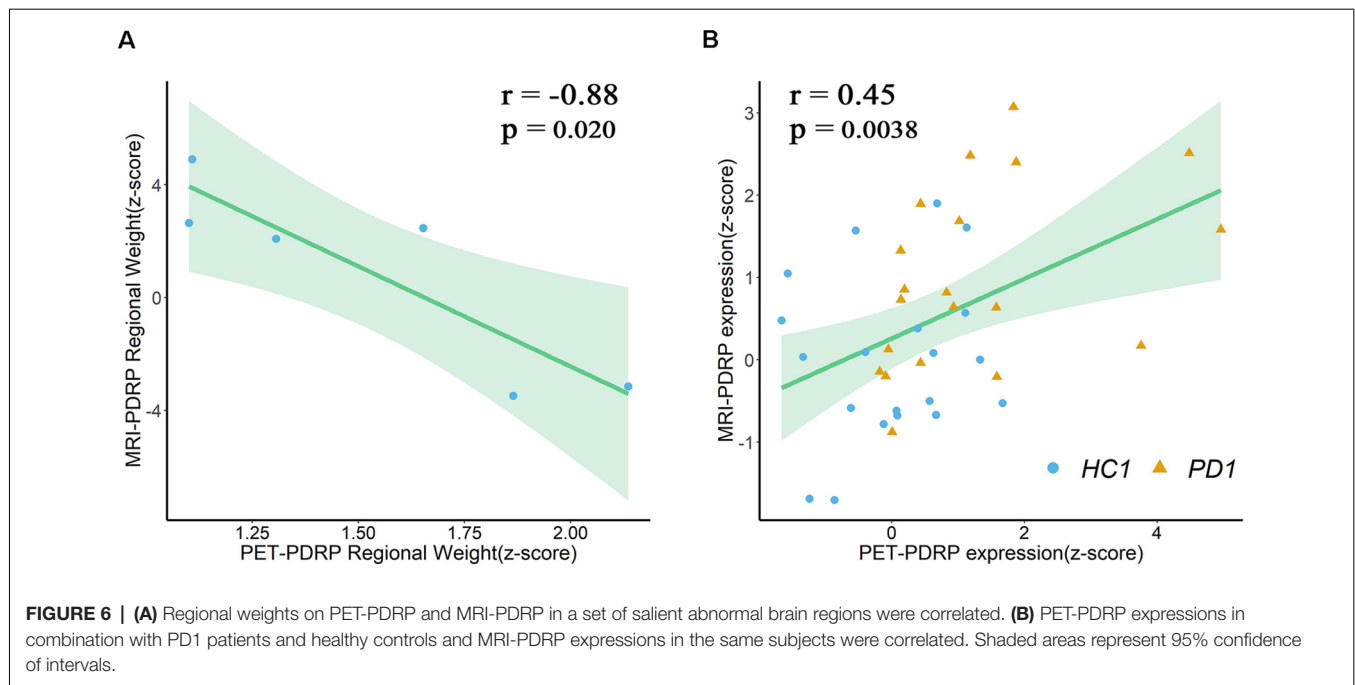

**FIGURE 5 |** PET-PDRP expressions in PD patients correlated with their levels of (A) speech, (B) facial expression, (D) postural tremor, (E) rigidity and (F) gait. MRI-PDRP expressions in PD patients correlated with the levels of (C) static tremor. Shaded areas represent 95% confidence of intervals.

## Reproducible Metabolic PDRP Topography

Using spatial covariance analysis, we reproduced a metabolic PDRP topography (PET-PDRP) that was compatible with previous imaging studies in both American and Chinese PD patients (Ma et al., 2007; Wu et al., 2013; Ko et al., 2017; Schindlbeck and Eidelberg, 2018). In our study, the PET-PDRP expression in PD patients was significantly

elevated in the original derivation subjects and the subsequent validation subjects. The regional metabolic dysfunction within this abnormal topography could describe abnormal cerebral metabolism or blood flow and reveal clinical disability and treatment response in patients with PD (Hirano et al., 2008; Eidelberg, 2009; Wu et al., 2013; Ko et al., 2017). This topography revealed the presence of

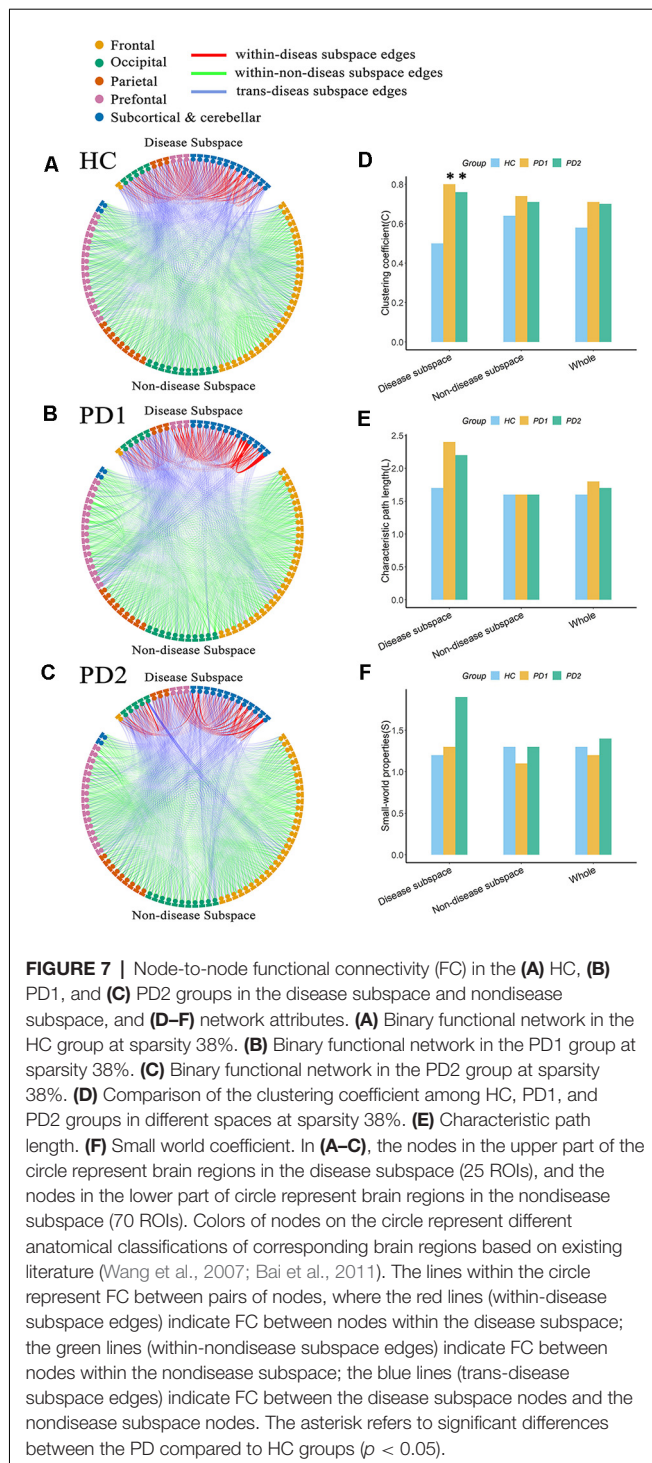

abnormal metabolic changes at key nodes of the cortico-striato-pallido-thalamo-cortical (CSPTC) loops and other related anatomical/functional pathways, which is in line with previous reports (Eidelberg, 2009; Poston and Eidelberg, 2009; Tang and Eidelberg, 2010). The abnormalities in the CSPTC circuits are commonly associated with the clinical manifestations of akinetic rigid in PD patients, but they do not fully explain other disease manifestations, such as tremors (Wichmann and Delong, 2007; Zaidel et al., 2009; Wu et al., 2013). By contrast, relative hypermetabolism in the cerebellum/dorsal pons, putamen, and primary motor cortex captured the abnormal activity in the cerebello-thalamo-cortical (CbTC) circuits, which was associated with the generation of tremor (Timmermann et al., 2002; Wu et al., 2013). Particularly, the cerebellum, pons, thalamus, and putamen evident overlaps in both CSPTC and CbTC circuits were considered as regions of severe involvement of these circuits. In this study, the dysfunction of CSPTC circuits was involved in functional network abnormalities of PDRP topography. The premotor area receives less excitatory impulses from the thalamus, resulting in a decrease in parietal lobe metabolism (Wu et al., 2013). On the other hand, posterior cortical dysfunction is considered as the imaging marker of PD patients with the risk of dementia (Wu et al., 2013; Peng et al., 2014a). However, understanding the contributions of different brain regions to motor and cognitive impairments requires more relevant cross-sectional and longitudinal studies.

### Structural PDRP Topography

We demonstrated for the first time that spatial covariance analysis can reveal a wide range of regions affected by PD

using T1-weighted structural MRI. In this study, a reduced GM volume in PD was observed in bilateral pons, bilateral transverse temporal gyrus, left cuneus, right superior occipital gyrus, and right superior parietal lobule, associated with preservation in GM volume in bilateral pallidum and bilateral putamen. In PD patients, more than 70% of dopamine (DA) terminals were lost when motor symptoms occur (Fearnley and Lees, 1991), and in the early stages of PD, human dyskinesia might be due to the compensatory mechanism that promoted the release and renewal of DA and reduced the uptake of DA so that the DA concentration was stable at normal levels (Silverdale et al., 2003). Besides, there are other possible compensatory changes, including the increase or appearance of striatum TH+ neurons and enhanced DA synthesis by alternative biochemical pathways, etc. These changes might preserve the GM volume in pallidum and putamen in early PD patients (Blesa et al., 2017). Pathological studies related to PD also indicated that the progression of lesions begins with the brainstem (which includes pons) and the substantia nigra (Braak et al., 2003). An decrease in gray volume in the pons has also been reported in previous studies (Jubault et al., 2009). Therefore, the finding in this study is consistent with the pons as the anatomical starting point of PD pathology according to Braak et al. (2003, 2004) and Jubault et al. (2009). In our study, morphological abnormalities in other cortical regions were also found. In cognitively intact PD patients, cortical morphology may be normal (Tessitore et al., 2012) or abnormal in the frontal lobe (Biundo et al., 2011) or in a wider range of cortical regions, including the parietal, temporal, and occipital lobes (Jubault et al., 2011). Uncoordinated results may be caused by different experimental methodologies or the heterogeneity of PD disease.

## Correlations Between PDRP and Clinical Scale

There was no significant correlation between PET-PDRP and MMSE, MRI-PDRP and MMSE, but there were significant positive correlations with UPDRS and six motor items, suggesting that the abnormal metabolic and structural characteristics of nondemented PD patients are related to

their dyskinesias, but not to cognitive dysfunction. The injury of PD patients on speech, facial expressions, tremors, rigidity, and gait became worse with the increase in PD pathology, which was consistent with clinical manifestations. Postural tremor is associated with metabolic abnormalities, while stationary tremor is associated with structural abnormalities, indicating that the causes of postural tremor and stationary tremor in PD patients may be different and therapeutic interventions for primary tremor in PD patients need to distinguish postural tremor from resting tremor.

## Correlations Between PET-PDRP and MRI-PDRP

The ROC curves revealed that PET-PDRP and MRI-PDRP expressions significantly discriminated PD patients from the control individuals with approving sensitivity and specificity. Since PET-PDRP expression value was demonstrated reliable diagnosis power, it revealed that MRI-PDRP may be also a promising diagnostic biomarker for the non-inferiority compared to PET-PDRP. However, further validation work should be followed.

As expected, several overlapping regions were identified between the metabolic PET-PDRP topography and the structural MRI-PDRP topography, including the bilateral pons, bilateral pallidum, and bilateral putamen. Surprisingly, the regional weights between the two PDRPs identified in the two imaging modalities were correlated within these regions ( $r = -0.88$ ,  $P = 0.02$ ), and the two pattern expressions were also correlated in patients and normal subjects. In a structural MRI study in combination with deformation-based morphometry and independent component analysis (ICA), researchers identified that the PD-ICA atrophy pattern in a larger number of participants showed a certain spatial topography overlap with the metabolic PD-related pattern derived from spatial covariance analysis using  $^{18}\text{F}$ -FDG PET (Zeighami et al., 2015). These included the globus pallidus, thalamus, putamen, premotor and supplementary motor regions. Our study obtained a consistent result. The consistent findings indicate a possible link between brain function and structure dysfunction of the related anatomical and functional circuit in PD, particularly the cortico-basal ganglia-thalamocortical motor circuit. In addition, our study demonstrated the potential value of the integration of different neuroimaging techniques to improve the neuropathological understanding of PD. Consistent abnormalities in brain structure and function, and causal relationships between them, in patients with PD await further investigation and understanding.

## Structurally and Functionally Disrupted Network Topology in PD

Brain connectome analysis can reveal abnormalities in network characteristics associated with PD and the potential impact of the disease network on brain information processing. We found that the functional brain network in the two independent PD groups exhibited a disrupted network topology in the disease subspace. Compared with the HC group, the clustering coefficient for the disease subspace was significantly increased, the characteristic

path length in the PD1 group was significantly increased, and the small-worldness attribute in the PD2 group was significantly elevated. Similarly, we also found a significantly increased characteristic path length for the brain structure network in PD1 group. An earlier study has used  $^{18}\text{F}$ -FDG PET data to identify an ROI-based metabolic PD-related pattern, and the disrupted network topology (increased clustering coefficient, reduced characteristic path length, and exaggerated small-worldness attribute) in the disease network consisting of brain regions with significant abnormalities in this pattern has also been confirmed in four independent patient subjects and in an experimental nonhuman primate model (Ko et al., 2017). Consistent with our results, significantly increased clustering coefficients in the disease space could be observed in both studies. However, changes of characteristic path length in the disease space in both studies were against. This may result from different disease spaces in morphological topography and nation differences between the western and eastern populations in the two studies. Interestingly, these descriptor changes are limited to the space occupied by the disease network, which might correspond to the relatively intact anatomy of other spaces (nondisease subspace and the whole brain).

## LIMITATIONS

There are several issues that still need to be further considered in this study. First, in the pattern analysis, we used the ROI-based rather than the voxel-based SSM/PCA algorithm for the subsequent determination of the disease subspace. The effect of the two different analytical methods on the results needs further investigation. Second, due to limited experimental subjects, for prospective evaluation of PET-PDRP and MRI-PDRP, we only used another new set of PD subjects but did not include both HC and PD subjects. Third, we did not further examine the intrinsic link between pattern and connectome analyses, for example, to see whether the correlation between the metabolic PET-PDRP pattern and structural MRI-PDRP can be further explained from the perspective of connectome analysis.

## CONCLUSIONS

In this study, we investigated  $^{18}\text{F}$ -FDG PET-based metabolic covariance pattern and MRI-based structural covariance pattern associated with PD in the same patients. The metabolic pattern is highly consistent with the disease-related metabolic brain patterns previously described in different cohorts of PD patients. This structural pattern was characterized by relative decreased GM volume in bilateral pons, bilateral transverse temporal gyrus, left cuneus, right superior occipital gyrus, and right superior parietal lobule, associated with preservation in GM volume in bilateral pallidum and bilateral putamen. Expectantly, we found a significantly negative correlation regional weight between metabolic and structural patterns in a set of salient abnormal brain regions, which provides a new perspective for insight into disrupted brain abnormal metabolism and structure in PD patients. In order to verify the effectiveness of two

patterns, we used connectome analysis methods to explore the brain metabolic network constructed by PET and the brain structural network. The results showed that more obvious changes could be found in these two patterns. In summary, significant overlaps between metabolic and structural patterns, as well as the convergence of metabolic network and structural network disruption, provide new evidence for elucidating the neuropathological mechanisms of the disease.

Aging Neurosci.* 12:155. doi: 10.3389/fnagi.2020.00155

**Objective:** To investigate the efficacy and safety of three *H. erinaceus* mycelia (EAHE) capsules (350 mg/capsule; containing 5 mg/g erinacine A active ingredient) per day for the treatment of patients with mild Alzheimer's Disease (AD).

**Methods:** This study comprised a 3-week no-drug screening period, followed by a 49-week double-blind treatment period with 2-parallel groups in which eligible patients were randomized to either three 5 mg/g EAHE mycelia capsules per day or identical appearing placebo capsules. Cognitive assessments, ophthalmic examinations, biomarker collection, and neuroimaging were followed throughout the study period.

**Results:** After 49 weeks of EAHE intervention, a significant decrease in Cognitive Abilities Screening Instrument score was noted in the placebo group, a significant improvement in Mini-Mental State Examination score was observed in the EAHE group and a significant Instrumental Activities of Daily Living score difference were found between the two groups. In addition, EAHE group achieved a significantly better contrast sensitivity when compared to the placebo group. Moreover, only the placebo group observed significantly lowered biomarkers such as calcium, albumin, apolipoprotein E4, hemoglobin, and brain-derived neurotrophic factor and significantly elevated alpha1-antichymotrypsin and amyloid-beta peptide 1–40 over the study period. Using diffusion tensor imaging, the mean apparent diffusion coefficient (ADC) values from the arcuate fasciculus region in the dominant hemisphere significantly increased in the placebo group while no significant difference was found in the EAHE group in comparison to their baselines. Moreover, ADC values from the parahippocampal cingulum region in the dominant hemisphere significantly decreased in the EAHE group whereas no significant

difference was found in the placebo group when compared to their baselines. Lastly, except for four subjects who dropped out of the study due to abdominal discomfort, nausea, and skin rash, no other adverse events were reported.

**Conclusion:** Three 350 mg/g EAHE capsules intervention for 49 weeks demonstrated higher CASI, MMSE, and IADL scores and achieved a better contrast sensitivity in patients with mild AD when compared to the placebo group, suggesting that EAHE is safe, well-tolerated, and may be important in achieving neurocognitive benefits.

**Clinical Trial Registration:** ClinicalTrials.gov, identifier NCT04065061.

**Keywords:** erinacine A-enriched *H. erinaceus* mycelia, Alzheimer's disease, pilot study, prevention, magnetic resonance imaging

## INTRODUCTION

The pace of population aging across the world over the past half-century is increasing dramatically, triggering a Silver Tsunami of chronic age-related diseases. Among these diseases, Alzheimer's Disease (AD) is the fifth-leading cause of death among adults aged 65 years and older and is also a leading cause of disability and morbidity (Alzheimer's Association, 2019). Unlike other major diseases for which there have been steady progress in the development of novel therapies, no new pharmacologic treatment for AD has been approved since 2003 (Hung and Fu, 2017). One theory as to why many intervention trials have failed is that the pathophysiological process of AD is thought to begin many years before the onset of clinical symptoms, and the use of interventions later in the disease may not effectively slow its progression due to established pathological burden (Sperling et al., 2011). As a result, there has been a shift in the clinical research field, with the focus to develop safe and effective interventions in early and presymptomatic AD stages (Graham et al., 2017). To date, several prevention trials have been carried out and shown promising results, suggesting the potential feasibility of implementing non-pharmacological approaches, including dietary interventions (Ngandu et al., 2015; Andrieu et al., 2017).

In a recent study, the lifestyle of 633 Chinese seniors living in Singapore between 2011 and 2017 was analyzed, and it was revealed that various mushrooms have therapeutic effects in combatting AD by exerting neuroprotective and antioxidant effects (Feng et al., 2019). Mushrooms and their extracts have been well-known for their nutritional and culinary values, which may be regarded as novel nature-based nutraceuticals to mitigate AD and other age-related neurodegenerative disorders. In fact, a number of mushrooms including *Hericium erinaceus* (Bull.: Fr.) Pers., *Dictyophora indusiata* (Vent.) Desv., *Grifola frondosa* (Dicks.: Fr.) S.F. Gray, *Tremella fuciformis* Berk, *Tricholoma* sp., *Termitomyces albuminosus* (Berk.) R. Heim, *Lignosus rhinocerotis* (Cooke) Ryvarden, *Cordyceps militaris* (L.:Fr.) Link, *Pleurotus giganteus* (Berk.) Karunarathna and K.D. Hyde, *Ganoderma lucidum* P. Karst, and *Ganoderma neo-japonicum* Imazeki have been reported to have activities related to nerve and brain health (Phan et al., 2017). Among these, the neurohealth properties of *Hericium erinaceus* (Bull.:Fr.) Pers., or its common names

Lion's mane or Monkey's head mushroom, have been most extensively studied.

Hericenones and erinacines are the two important classes of constituents isolated from the fruiting body and mycelium of *H. erinaceus*, respectively (Kawagishi et al., 1991, 1992, 1994, 1996a,b; Lee et al., 2000). Both hericenones and erinacines are low-molecular weight, relatively hydrophobic compounds, and proven to stimulate nerve growth factor (NGF) synthesis and promote NGF-induced neurite outgrowth in nerve cells *in vitro* (Lai et al., 2013). However, hericenones failed to promote NGF gene expression in 1321N1 human astrocytoma cells (Mori et al., 2008) while erinacine A successfully upregulated the NGF level in the locus coeruleus and hippocampus of rats (Shimbo et al., 2005). To date, only erinacines A (unpublished results) and S (Hu et al., 2019) but not hericenones have been verified to cross the blood-brain-barrier, suggesting a greater likelihood of them targeting the central nervous system. Furthermore, the *in vivo* neuroprotection of erinacine A-enriched *H. erinaceus* (EAHE) mycelia has been demonstrated in several studies against stroke, Parkinson's disease, AD, depression, and aging (Li et al., 2018b). Based on these findings, it is highly suggestive that erinacine A is one of the key components responsible for the neurotrophic and neuroprotective activities of *H. erinaceus*.

A previous human pilot study has been carried out to investigate the efficacy of oral administration of *H. erinaceus* with 50- to 80-year-old Japanese men and women diagnosed with mild cognitive impairment. The subjects in the *H. erinaceus* group took four *H. erinaceus* tablets three times a day for 16 weeks and showed an improvement in cognitive functions (Mori et al., 2009). However, in this study, the active constituents, representative markers, and major chemical constituents of *H. erinaceus* tablets have not been extensively addressed. While there is still a controversy regarding whether hericenones in the *H. erinaceus* fruiting body have neuroprotective activities *in vivo*, erinacine A in the *H. erinaceus* mycelia, on the other hand, confers neuroprotective effects and attenuates the oxidative stress against stroke (Lee et al., 2014), AD (Tzeng et al., 2018), Parkinson's disease (Kuo et al., 2016), depression (Chiu et al., 2018), and aging (Li et al., 2019) in mouse models. As there is an urgent need to translate basic discovery research to clinical evaluation, this is the first clinical investigation of

three *H. erinaceus* mycelia capsules (350 mg/capsule; containing 5 mg/g erinacine A active ingredient) per day for the treatment of patients with early AD.

## MATERIALS AND METHODS

### Sample Preparation and High-Performance Liquid Chromatography (HPLC) Analysis

*Hericum erinaceus* mycelia enriched with 5 mg/g erinacine A were prepared and evaluated according to a procedure described previously (Li et al., 2014b). In brief, EAHE mycelia was grown in a submerged liquid medium comprised of 0.25 % yeast extract, 4.5% glucose, 0.5% soybean powder, 0.25 % peptone, and 0.05 % MgSO<sub>4</sub> with an initial pH set to 4.5 at 26°C for 5 days. This process is then scaled up in 500-L and 20-ton fermenters for 5 days and 12 days, respectively. Following mass production, the mycelia were lyophilized, extracted with methanol, and analyzed by HPLC to quantify 5 mg/g erinacine A in EAHE mycelia. For study's intervention, 350 mg EAHE mycelia were encapsulated in each gelatin capsule and used as treatments.

### Study Design

The present study was a 1-year, double-blind, randomized, placebo-controlled, fixed-dose intervention pilot trial conducted at Chung Shan Medical University in patients with mild AD. The study protocol was approved by the Institutional Review Board of Chung Shan Medical University and registered with ClinicalTrials.gov under the number NCT04065061. This study comprised of a 3-week no-drug screening period, followed by a 49-week double-blind treatment period with 2-parallel groups in which eligible patients were randomized to either three 350 mg/capsules containing 5 mg/g erinacine A per day or identical appearing placebo capsules with meals. This dose was chosen according to a previous study design (Li et al., 2019) and converted to human dose as specified by FDA guidelines (FDA, 2005). Cognitive assessments, ophthalmic examinations, biomarker collection, and neuroimaging were followed throughout the study period. Written informed consent from all patients or their legal representatives was obtained before their enrollment.

### Participants, Randomization, and Blinding

The inclusion criteria for enrollment included patients with age >50 years and diagnosis of probable AD according to the Diagnostic and Statistical Manual of Mental Disorders (fourth edition, DSM-IV) (American Psychiatric Association, 2013) and National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders Association (McKhann et al., 1984) criteria. The exclusion criteria included patients with severe somatic or psychiatric comorbidity as they may significantly impair cooperation with the study. Once a participant met the study's eligibility criteria, a baseline visit was

planned, and thorough somatic and neurological examinations were carried out.

Following the baseline assessments, participants were randomly assigned to receive either the placebo or three EAHE mycelia capsules per day according to a randomization list produced by a computerized random-number generator. Except for two trial-independent statisticians that were unmasked, all patients, caregivers, raters, and investigators were blinded to the interventions until the database was finalized. The schedule of trial enrollment, interventions, and assessments according to the Standard Protocol Items: Recommendations for Interventional Trials (SPIRIT) Statement (Chan et al., 2013) is presented in Figure 1.

### Efficacy and Safety Parameters

All participants received either three EAHE mycelia capsules per day or placebo for 49 weeks and were assessed by a rater at 0, 13, 25, and 49 weeks after commencing the treatment. The efficacy of EAHE mycelia was determined by the mean change from baseline to the final analysis and was evaluated by a comprehensive battery, which included cognitive assessments, ophthalmic examinations, biomarker collection, and neuroimaging.

The cognitive assessments were performed at baseline, week 13, week 25, and week 49. Reference measures for cognition included the Neuropsychiatric Inventory (NPI) (Cummings et al., 1994), Cognitive Abilities Screening Instrument (CASI) (Teng et al., 1994), Mini-Mental State Examination (MMSE) (Folstein et al., 1975), and Instrumental Activities of Daily Living (IADL) (Nygard, 2003). These standard tests are used extensively in both clinical practice and research to measure treatment effects in patients with mild to moderate dementia.

A complete ophthalmologic examination including the measurement of best-corrected visual acuity (BCVA) and contrast sensitivity (CS) was conducted at baseline, week 25, and week 49. Monocular and binocular best-corrected distant visual acuity were determined using a standard clinical Snellen eye chart at a 5-meter distance from the chart. The contrast sensitivity test was performed with a standard Pelli-Robson chart under the same conditions for all the patients.

Blood biomarkers were collected at baseline, week 25, and week 49. After overnight fasting, blood samples from each patient were drawn through 22-gauge needles and transferred into either ethylene diamine tetraacetic acid-potassium (EDTA-K2) tubes for hematological analysis or stored in tubes without anti-coagulants for biochemical analysis. For hematological analysis, homocysteine (Hcy) and hemoglobin (Hb) were measured using an automated hematology analyzer (Gen-STM, Beckman Coulter, Inc., United States) while the serum biochemistry parameters including albumin and calcium were performed using an automated biochemistry analyzer (LX<sup>®</sup>-20, Beckman Coulter, Inc., United States). Quantitative determination of other blood biomarkers such as alpha1-antichymotrypsin ( $\alpha$ -ACT; ab171574, Abcam, United Kingdom), amyloid-beta peptide 1–40 ( $\beta$ -amyloid; CEA864Hu, Wuhan USCN Business Co., Ltd., China), apolipoprotein E4 (APOE4; K4699, BioVision Inc., United States), dehydroepiandrosterone-sulfate

(DHEAS; ab108669, Abcam, United Kingdom), brain-derived neurotrophic factor (BDNF; KA0329, Abnova, Taiwan), and superoxide dismutase (SOD; #19160, Sigma-Aldrich, United States) were measured using commercially available enzyme-linked immunosorbent assay (ELISA) kits.

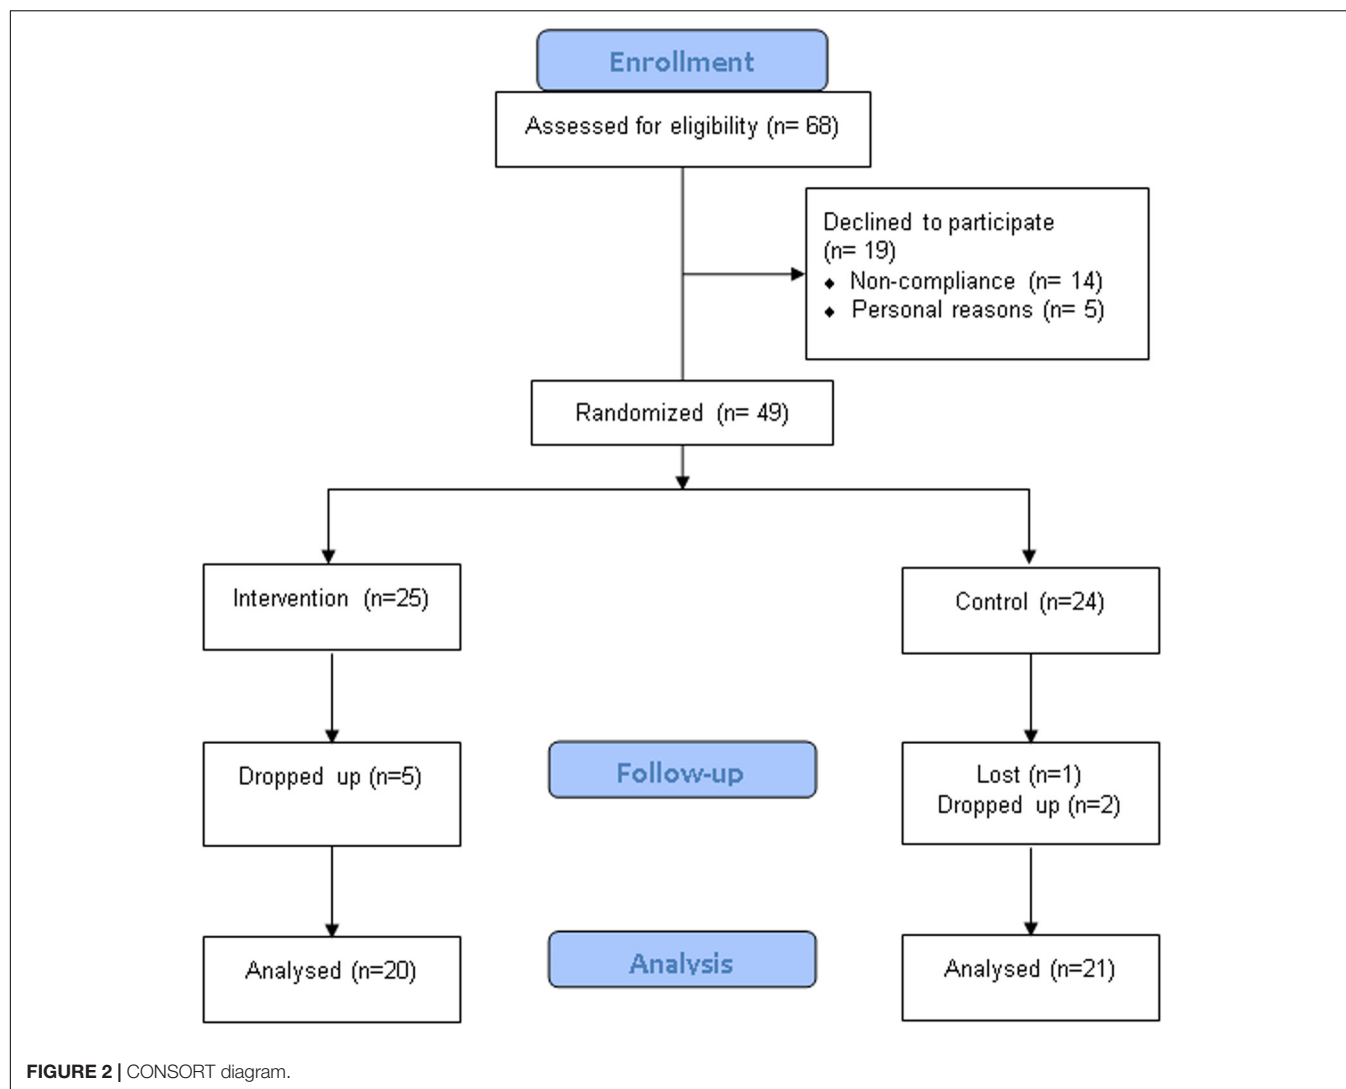

Neuroimaging such as magnetic resonance imaging (MRI) assessment was performed before and after the intervention period. All subjects had brain imaging using diffusion tensor imaging (DTI) through a Siemens Magnetom Skyra three-tesla (3T) scanner. Diffusion datasets were collected with the following parameters: repetition time (TR) = 4800 ms, echo time (TE) = 97 ms, field of view (FOV) = 25 cm, image matrix = 128 × 128, slice number = 35, thickness = 4 mm, flip angle = 90°, 4 *b*-values = 0, 1000, 1500, 2000 s/mm<sup>2</sup>, diffusion direction = 64, and bandwidth = 1562 Hz/pixel. The fiber number, the fractional anisotropy (FA), and the apparent diffusion coefficient (ADC) from the arcuate fasciculus (ARC), parahippocampal cingulum (PHC), inferior fronto-occipital fasciculus (IFOF), and uncinate fasciculus (UNC) regions in

the dominant and non-dominant hemispheres were determined based on the diffusion tensor analyzed through using the specialized software nordicICE v4.0.2.

Safety was evaluated by monitoring adverse events according to the Food and Drug Administration regulations (Behrman Sherman et al., 2011). Moreover, adverse event reporting was also reviewed by an independent safety monitoring committee systematically throughout the study.

## Sample Size and Statistical Analysis

Considering this study is a pilot study to assess the cognitive efficacy of EAHE mycelia in patients with mild AD and the feasibility of a further larger clinical trial, a total of at least 60 people were recruited based on a simulation study to maintain adequate power while keeping the overall sample size of the pilot and main trial together to a minimum (Teare et al., 2014). Statistical analyses were performed using SPSS software (version 18). Data are presented as means ± standard deviation (SD). The Mann-Whitney U test was used to compare the data between

the two study groups while the Wilcoxon signed-rank test was used to compare variables before and after the intervention. The statistically significant value was set at  $p < 0.05$ .

## RESULTS

### Participants

A total of 68 participants who had been diagnosed with mild AD were recruited in this study. Participants were randomly assigned to either the EAHE intervention group or the placebo control group. Of the 68 patients who participated in the surveillance, 19 declined to participate due to personal reasons ( $n = 5$ ) and non-compliance ( $n = 14$ ). Forty-nine participants were randomized, of whom seven subjects withdrew consent and one subject lost to follow-up. In the end, 41 subjects completed the study, and the data from 17 male and 24 female study participants were analyzed (Figure 2). Demographic and baseline characteristics are shown in Table 1. There were no statistical differences between the

EAHE group and the placebo group in gender, age, and education characteristics at baseline.

### Cognitive Assessments

The NPI, CASI, MMSE, and IADL tests were performed at baseline, after weeks 13, weeks 25, and weeks 49 of supplementation with EAHE. The means scores of each parameter in the EAHE and placebo group are presented in Table 2. For the NPI test, the mean NPI scores at all time-points

**TABLE 1 |** Participant demographics.

Variables	EAHE group ( $n = 20$ )	Placebo group ( $n = 21$ )	$p$ -Value
Gender (male/female)	6/14	11/10	–
Age (years)	$74.3 \pm 7.15$	$77.05 \pm 8.2$	0.261
Education (years)	$6.35 \pm 4.74$	$6 \pm 5.36$	0.826

Values are given as mean  $\pm$  SD.

decreased in both the EAHE and placebo groups compared to the baseline. Although subjects who received EAHE has a lower mean NPI score than the placebo group at week 49 ( $0.67 \pm 1.15$  vs.  $2.25 \pm 3.3$ ), the comparison to baseline values showed no significant difference in both groups ( $p = 0.077$  and  $0.163$ , respectively). Moreover, when compared to the baseline values and different time points of CASI scores, subjects in the EAHE group showed an increasing trend with marginal significance ( $71.75 \pm 17.12$  to  $75.35 \pm 15.86$ ;  $p = 0.058$ ) whereas the subjects in the placebo group showed a decreasing trend from the baseline to 49 weeks ( $73.52 \pm 14.51$  to  $69.67 \pm 16.62$ ;  $p = 0.064$ ). However, there was no significance in relation to the intra-group and inter-group CASI analysis except for the difference between the baseline and week 25 of the placebo group ( $p = 0.043$ ). Furthermore, MMSE scores significantly increased ( $21.75 \pm 6.1$  to  $23.2 \pm 5.92$ ;  $p = 0.035$ ) in the EAHE group from the baseline to week 49 whereas the comparison of all time-points showed no significant change in the placebo group. Nevertheless, all the pairwise comparisons of the MMSE test were not statistically significant ( $p > 0.05$ ). Finally, for the IADL test, no baseline differences between the EAHE and placebo groups at any time points were observed except for the pairwise comparison at week 49 which was statistically significant ( $6.7 \pm 2.47$  vs.  $5 \pm 2.7$ ;  $p = 0.012$ , respectively).

### Ophthalmologic Examination

**Table 3** summarizes the ophthalmologic examination for the EAHE and placebo groups after 25 and 49 weeks of intervention. The analysis of BCVA in OD (right eye), OS (left eye), and OU (both eyes) of the EAHE and placebo groups showed no difference from their baselines to the end of the study. Although significant baseline differences in BCVA of OD, OS, and OU were found between the groups, these differences remained unchanged throughout the study period except for BCVA OS at week 25 ( $p = 0.101$ ). Meanwhile, subjects with EAHE treatment showed improvements in the mean monocular CS (OD:  $0.84 \pm 0.19$  to  $0.90 \pm 0.08$ ; OS:  $0.83 \pm 0.2$  to  $0.86 \pm 0.13$ ) and binocular CS (OU:  $0.88 \pm 0.15$  to  $0.89 \pm 0.11$ ) values following 49 weeks of intervention whereas the placebo group showed an upward trend in the CS OD ( $0.72 \pm 0.32$  to  $0.77 \pm 0.27$ ), a downward trend in the CS OS ( $0.83 \pm 0.18$  to  $0.78 \pm 0.17$ ), and remained unchanged ( $0.85 \pm 0.19$  to  $0.85 \pm 0.08$ ) in the CS OU at the end of the study. Nevertheless, all these groups did not reach statistical significance except for the changes in CS OU from baseline to 49 weeks in the placebo group ( $0.85 \pm 0.19$  to  $0.85 \pm 0.08$ ;  $p = 0.033$ ) and differences of CS OS at week 49 between treatment groups ( $p = 0.046$ ).

### Blood Biomarker Assessments

With further analysis of the blood biomarkers over the 49-week study period within the groups (**Table 4**), significant improvements of Hcy at week 25 and 49 ( $p = 0.007$  and  $p = 0.012$ , respectively) were observed in the EAHE group while significant negative effects in calcium at week 25 ( $p = 0.004$ ), albumin at week 49 ( $p = 0.004$ ), Hb at week 25 and 49 ( $p = 0.003$  and  $p = 0.009$ , respectively), and BDNF at week 25 ( $p = 0.012$ ) were noted in the placebo group. Moreover, although both groups showed

significant decreases in SOD and APOE4 as well as significant increases in  $\alpha$ -ACT and  $\beta$ -amyloid ( $p < 0.05$ ), APOE4,  $\alpha$ -ACT, and  $\beta$ -amyloid had an improving trend in the EAHE group than the placebo group at week 49. No significant difference, however, was observed for all other parameters.

### Magnetic Resonance Imaging (MRI) Assessments

The total fiber number, FA, and ADC values from the ARC, PHC, IFOF, and UNC regions in the dominant and non-dominant hemispheres of the EAHE and control group are listed in **Table 5**. After 49 weeks of EAHE intervention, the total fibers were significantly less decreased than those in the placebo group. Nevertheless, they did not reach statistical significance between groups ( $p = 0.715$ ). In addition, compared to their baselines, the mean ADC values from the ARC region in the dominant hemisphere significantly increased in the placebo group while the ADC values from the PHC region in the dominant hemisphere significantly decreased in the EAHE group at week 49. No statistically significant differences were found in other parameters.

### Adverse Events

During the study, 1 subject lost to follow-up while 7 subjects (7/49; 14.3%) left the study. Reasons for dropout that have been investigated include unsatisfactory efficacy (2 from EAHE group and 1 from the placebo group) and the presence of side effects (3 from EAHE group and 1 from the placebo group). Possible or probable side effects related to the intervention included nausea in the placebo group and abdominal discomfort, nausea, and skin rash in the EAHE group.

## DISCUSSION

Diet is an important modifiable risk factor for AD (Sindi et al., 2018) as it is able to modulate structural brain connectivity (Park et al., 2018), cause positive changes in brain function and behavior (Bolton and Bilbo, 2014), as well as help regulate cognition and emotion (Spencer et al., 2017). As benefits of EAHE associated with brain and nerve health have been well-studied (Li et al., 2018b), this is the first study to endorse its potential in mitigating neurodegenerative disorders. Based on the results of this pilot, randomized, double-blinded, controlled study, subjects with mild AD showed a significant benefit in reducing cognitive decline and improving contrast sensitivity after oral administration of three 5 mg/g EAHE mycelia capsules per day for 49 weeks when compared with placebo.

In this study, through random allocation, the baseline demographic information including age, gender, and education level between EAHE and placebo groups showed no significant differences before the intervention. Nevertheless, after the intervention, a significant deterioration in CASI from baseline to week 25 was noted in the placebo group, a significant improvement in MMSE from baseline to week 49 was observed in the EAHE group, and a significant IADL difference at week 49 were found between the two groups. Higher CASI and

Values are given as mean ± SD. NPI = Neuropsychiatric Inventory; CASI = Cognitive Abilities Screening Instrument; MMSE = Mini mental state Examination; IADL = Instrumental Activities of Daily Living. \*p < 0.05.

MMSE scores represent better cognition, and higher IADL scores represent a lower level of dependence (Chiu et al., 2016). Although there were no significant differences in CASI and MMSE between the EAHE and placebo groups, the scores were higher in the EAHE group compared to those in the placebo group for participants with mild AD, implying that subjects could achieve more benefits from the intervention.

To date, human studies on *H. erinaceus* are scarce. Only three trials were found to examine the efficacy of oral administration of *H. erinaceus* for improving brain pathology. In one double-blind placebo-controlled study, 50- to 80-year-old Japanese men and women (n = 30) diagnosed with mild cognitive impairment showed marked improvement in cognitive function when compared to controls, using a cognitive function scale based on the revised Hasegawa Dementia Scale and following the effects of oral intake of four 250 mg tablets containing 96% of *H. erinaceus* fruiting body dry powder three times a day for 16 weeks (Mori et al., 2009). In another randomized, double-blind placebo-controlled study, administration of 0.5 g *H. erinaceus* fruiting body in cookies over 4 weeks showed a reduction in anxiety and depression in menopausal women (n = 30) compared to those taking placebo, as measured by the Center for Epidemiologic Studies Depression Scale and Indefinite Complaints Index (Nagano et al., 2010). In the third randomized, double-blind, placebo-controlled parallel-group comparative study, the consumption of cookies containing 0.8 g of *H. erinaceus* fruiting body dry powder alleviated the deterioration of short memories and improved the cognitive functions in 31 participants with an average age of 61.3 years

old over the period of 12 weeks, as measured by MMSE (Saito et al., 2019). Prior studies have reported that NGF could enhance neurogenesis-inducing effects, which led to antidepressant and anxiolytic activities (Shohayeb et al., 2018). Although hericenones C and D from the fruiting body of *H. erinaceus* have shown to induce neuroprotective properties (Kawagishi et al., 1991) in rats by stimulating NGF synthesis via activation of the c-jun N-terminal kinase (JNK) pathway, they failed to promote NGF gene expression in 1321N1 human astrocytoma cells (Mori et al., 2008). This result suggested that *H. erinaceus* fruiting body may contain other active compounds and/or hericenones that can potentially improve mild cognitive impairment as well as reduce depression and anxiety.

On the contrary, erinacines isolated from the mycelium of the mushroom are able to pass through the brain-blood barrier into the brain (Hu et al., 2019) to promote NGF synthesis *in vivo* (Shimbo et al., 2005). During normal physiological conditions, NGF is released by the postsynaptic cortical and hippocampal neurons to activate further signaling cascades that include cell survival, maintenance, and proliferation (Bian et al., 2014). However, NGF has been found to be reduced during the pathological conditions of AD, resulting in induced loss of cortical synapses and atrophy of cholinergic neurons in the basal forebrain (Iulita and Cuello, 2014). Moreover, analyzing AD11 anti-NGF transgenic mice that express NGF antibodies in the brain, it was observed that NGF deprivation leads to early inflammation and Alzheimer's neurodegeneration (Capsoni et al., 2011). In this regard, as erinacine A has been proven to promote NGF synthesis *in vivo*, it may contribute to the

survival and regeneration of cholinergic neurons as well as revive cholinergic signaling in the cortex and hippocampus, thereby improving the cognitive ability in subjects with mild AD. However, the precise mechanism of its action needs further investigation.

Not only could NGF markedly protect degenerating neurons in the brain, studies have also shown that NGF administration could modulate the development and differentiation of the retina and the optic nerve, as well as promote the survival and recovery of retinal ganglion cells (Aloe et al., 2012). To our knowledge, this is the first study to examine the efficacy of EAHE on visual acuity and contrast sensitivity. No significant differences were observed in the ophthalmologic examination in this study except for a higher CS OS at week 49 after EAHE treatment. This finding of EAHE as a NGF stimulator in improving CS but not VA in subjects with mild AD is consistent with previous studies. They have found that contrast sensitivity was significantly reduced in patients with AD compared to elderly control subjects while no significant difference in visual acuity were found between the patients with AD and control subjects (Crow et al., 2003) suggesting that EAHE targeting astrocytes only responded to an injury or damaged area by maintaining neurogenesis as a mechanism of repair (Poulose et al., 2017). Future studies, however, are required to further explore this possible mechanism.

With EAHE consumption, it is important to note that an altered diet or a multiplicity of environmental changes could change the blood proteome as well as ions (Te Pas et al., 2013). In different studies, EAHE treatment was accompanied by improvements in blood biomarkers in subjects with mild AD. Biomarkers monitoring based on biochemical analysis of blood during or after the intervention period could offer considerable promise for improving the treatment of AD (Cummings et al., 2019). Recent studies have identified a biomarker panel that included blood-based markers that significantly increased alpha-1-Antichymotrypsin,  $\beta$ -amyloid, superoxide dismutase, and homocysteine levels as well as decreased calcium, albumin, dehydroepiandrosterone sulfate, apolipoprotein E, hemoglobin, and BDNF levels in AD (Dekosky et al., 2003; Laske et al., 2011; Doecke et al., 2012; Ng et al., 2019; Pan et al., 2019). Consistent with the current study, biomarkers such as calcium, albumin, APOE4, Hb, and BDNF were significantly lowered while  $\alpha$ -ACT and  $\beta$ -amyloid were significantly elevated during the study period in the placebo group. However, there were no significant changes in calcium, albumin, Hb, and BDNF compared to the baseline and a trend toward improving SOD, APOE4, and  $\alpha$ -ACT levels were observed in the EAHE group, indicating that EAHE may have possible effects in arresting or delaying further neurodegenerative processes.

Values are given as mean ± SD. Hb = hemoglobin; Hcy = homocysteine; SOD = superoxide dismutase; BDNF = brain-derived neurotrophic factor; DHEAS = dehydroepiandrosterone-sulphate; α-ACT = alpha 1-antichymotrypsin; APOE4 = apolipoprotein E4; β-amyloid = amyloid-beta peptide 1–40. \**p* < 0.05.

The effects of EAHE on the rate of neurodegeneration could also be detected using advanced MRI, such as DTI, to probe human brain microstructures (Cho et al., 2008). DTI provides quantitative measures of FA and ADC, which enable the assessment of the cellular microstructure and fiber tract integrity in live tissues. Fiber tracts such as PHC and UNC contribute to learning and memory, and IFOF and AF contribute to language functioning (McDonald et al., 2008). These were evaluated in each subject to depict their global white matter status. In this

study, although a statistical significance was not found between the groups, the total fibers of six fiber tracts calculated were significantly less decreased than those in the placebo group after EAHE intervention, suggesting that EAHE ameliorates the loss of fiber numbers by stimulating NGF synthesis and inducing neurogenesis. Moreover, within the six fiber tracts, the mean ADC values from the ARC region in the dominant hemisphere significantly increased in the placebo group while no significant difference was found in the EAHE group in comparison to their

**TABLE 5 |** Comparison of MRI assessments between EAHE and placebo groups.

Values are given as mean ± SD. D = dominant; N = Non-dominant; ARC = arcuate fasciculus; PHC = parahippocampal cingulum; IFOF = inferior fronto-occipital fasciculus; UNC = uncinate fasciculus; FA = Fractional Anisotropy; ADC = apparent diffusion coefficient. \**p* < 0.05.

baselines, implying that there was a greater disorganization in the neural structure observed in the placebo group. Moreover, ADC values from the PHC region in the dominant hemisphere significantly decreased in the EAHE group whereas no significant difference was found in the placebo group when compared to their baselines, indicating that there was a more well-organized neural structure noted in the EAHE group. These results tie well with a previous study wherein the ADC values increased in the ARC and PHC of patients with mild AD when compared with a control group (Mayo et al., 2019), signifying that EAHE could improve structural deterioration of ARC and PHC in patients with mild AD.

Lastly, despite four subjects who dropped out during the study period due to reported adverse events such as abdominal discomfort, nausea, and skin rash, no other adverse event were reported. The overall incidence was 8.2% during the entire 49-weeks. However, due to the increasing trend in clinical practice to treat elderly patients with multiple medications (Poleksic and Xie, 2019), it remains a challenge to identify if these adverse events were caused by EAHE consumption. Yet, reports on genotoxicity (Li et al., 2014a), acute toxicity (Li et al., 2018a), 28 days subchronic toxicity (Li et al., 2014b) 90 days subchronic toxicity (Lee et al., 2019) and teratotoxicity (Li et al., 2018a) have been conducted in animals and showed no adverse effects. Moreover, no adverse events have been reported after the launch of EAHE products into the Taiwanese market since 2015 (Li et al., 2018b). Nevertheless, further studies, especially the serum biochemical and hematological data along with urinalysis values after long-term consumption in humans, are important to consider.

In comparison to the placebo group, the intake of EAHE for 49 weeks showed higher CASI, MMSE, and IADL scores and achieved a better contrast sensitivity in patients with mild AD. The benefit of EAHE in reducing cognitive decline may be associated with improved blood biomarkers such as calcium,

albumin, Hb, Hcy, SOD, BDNF, APOE4, and  $\alpha$ -ACT, as well as reduced structural deterioration in the ARC and PHC regions of patients with mild AD. However, further studies on the mechanism of action of EAHE at the biochemical and molecular levels are necessary. In addition, although EAHE is safe and well-tolerated, a larger study is required to determine the benefits of EAHE consumption for patients with MCI or mild AD.

## DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article/supplementary material.

## ETHICS STATEMENT

The study protocol was approved by the Institutional Review Board of the Chung Shan Medical University and registered with ClinicalTrials.gov under the number NCT04065061. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

I-CL analyzed the data and wrote the manuscript. H-HC, C-HL, and T-HL conceived and performed the experiments. W-PC, L-YL, Y-WC, and Y-PC provided the reagents. C-CC and DP-CL provided the expertise and feedback.

## ACKNOWLEDGMENTS

The authors thank Hsin Yun Yang for editing the manuscript.

**Background:** Mild cognitive impairment (MCI) is the early phase of Alzheimer's disease (AD). The aim of early intervention for MCI is to decrease the rate of conversion from MCI to AD. However, the efficacy of multiple interventions in MCI, and the optimal methods of delivery, remain controversial. We aimed to compare and rank the treatment methods for MCI in AD, in order to find an optimal intervention for MCI and a way to prevent or delay the occurrence of AD.

**Methods:** Pair-wise and network meta-analysis were conducted to integrate the treatment effectiveness through direct and indirect evidence. Four English databases and three Chinese databases were searched for international registers of eligible published, single or double blind, randomized controlled trials up to September 31st 2019. We included nine comparative interventions: pharmacological therapies which incorporated cholinesterase inhibitors (ChEI), ginkgo, nimodipine, and Chinese medicine; non-pharmacological therapies comprising of acupuncture, music therapy, exercise therapy, and nutrition therapy; and a placebo group. The primary outcome was the Mini-Mental State Examination (MMSE) score. The secondary outcome was the AD Assessment Scale-cognitive subscale (ADAS-cog).

**Results:** Twenty-eight trials were eligible, including 6,863 participants. In the direct meta-analysis, as for the Mini-Mental State Examination scale, the ChEIs (MD:  $-0.38$ ; 95% CI:  $-0.74$ ,  $-0.01$ ), Chinese medicine (MD:  $-0.31$ ; 95% CI:  $-0.75$ ,  $0.13$ ), exercise therapy (MD:  $-0.50$ ; 95% CI:  $-0.65$ ,  $-0.35$ ), music therapy (MD:  $-1.71$ ; 95% CI:  $-4.49$ ,  $1.07$ ), were statistically more efficient than placebo. For AD Assessment Scale-cognitive subscale outcome, ChEIs (MD:  $1.20$ ; 95% CI:  $0.73$ ,  $1.68$ ), Acupuncture (MD:  $1.36$ ; 95% CI:  $1.28$ ,  $1.44$ ), Chinese medicine (MD:  $0.61$ ; 95% CI:  $0.49$ ,  $0.73$ ) and exercise (MD:  $0.61$ ; 95% CI:  $0.49$ ,  $0.73$ ) were better than placebo. In the network meta-analysis, the MMSE outcome ranked music therapy (59%) as the best and Acupuncture (26%) as second. Nutrition and Ginkgo treatment had the lowest rank among all interventions. For ADAS-cog outcome, acupuncture (52) ranked the best.

**Conclusion:** Among the nine treatments studied, music therapy appears to be the best treatment for MCI, followed by acupuncture. Our study provides new insights into potential clinical treatments for MCI due to AD, and may aid the development of guidelines for MCI in AD.

**Keywords:** acupuncture, Alzheimer's disease, mild cognitive impairment, multiple interventions, music therapy, network meta-analysis

## INTRODUCTION

Mild cognitive impairment (MCI) has been defined as a “transitional” state to describe individuals who are not cognitively “active” for their age, but who would not meet a clinical diagnosis of early dementia (Brendan and Kelley, 2015). It is an intermediate clinical condition with a number of sub-types and multiple pathologies (Petersen, 2004; Rountree et al., 2007).

MCI is currently an area of considerable clinical and research interest because a large proportion of patients with MCI develop Alzheimer's disease (AD). In order to delay the progress of AD, it is important to recognize the key neurobiological difference between MCI and AD. Several journal articles have demonstrated that MCI patients progress to AD at a higher rate (10–15% per year) than normal elderly patients (1–3% per year). Furthermore, two-thirds of patients with AD were previously recognized as having MCI (Rubin et al., 1989; Almkvist et al., 1998; Wolf et al., 1998; Kluger et al., 1999; Petersen et al., 1999, 2001; Collie and Maruff, 2000; Morris et al., 2001). Therefore, patients who have MCI are considered to be at a greater risk for AD. Unfortunately, treatment options for AD are currently suboptimal, especially in the advanced stage of AD where the brain damage is irreversible. Thus, it is important to start treatment for AD as early as possible, and intervention during the MCI stage may prevent or delay the occurrence of AD.

Several treatments have been used for MCI, including cholinesterase inhibitors (ChEIs), complementary and alternative medicine, lifestyle and nutrition interventions, and Chinese medicine. However, which of these interventions work, and to what extent, remains unknown.

Pairwise meta-analysis have previously been conducted to assess the efficacy of ChEIs, including donepezil, galantamine, and rivastigmine (Cooper et al., 2013; Tricco et al., 2013; Matsunaga et al., 2019). These studies suggested that ChEIs have a low efficacy in the treatment of MCI and many safety issues were raised. Therefore, before using ChEIs for MCI, other methods should be considered.

Other studies (Andreas et al., 2015; Liang et al., 2018) have suggested that physical exercise and computerized cognitive training could improve cognitive function and neuropsychiatric symptoms. Furthermore, non-pharmacological therapies might perform more effectively than pharmacological therapies. However, these studies were incomplete and provide insufficient data, because they were unable to introduce clear hierarchies among treatments and a number of interventions were not analyzed. Therefore, the aim of this article was to conduct a network meta-analysis to thoroughly compare and rank different

treatments for MCI that help to improve cognitive function and prevent or delay the occurrence of AD.

## METHODS

### Search Strategy

Four English databases (Medline [via Ovid], Embase [via Ovid], Cochrane Library [Central Register of Controlled Trials], and Web of Science [via Ovid]) and three Chinese databases (China Science Journal Citation Report [VIP], China National Knowledge Infrastructure [CNKI], and Wanfang) were searched for all relevant citations published from the date of the respective database onset to September 31st 2019. We established search strategies which combined subject word (keyword) and random words related to MCI, interventions of interest (drug therapy, diet/lifestyle therapy, physical activity/exercise, complementary therapies, sham/placebo) and randomized controlled trial (RCT). Furthermore, the reference lists of the included studies were manually reviewed to look for additional relevant manuscripts. The specific search strategies are shown in **Supplementary Datasheet 1**.

### Selection and Exclusion Criteria

The RCTs which met the following criteria were included: (1) participants had mild cognitive impairment due to AD; (2) the interventions were pharmacological therapies including Cholinesterase inhibitors, Memantine, Ginkgo biloba, Huperzine A, Piracetam, Nimodipine, and Chinese medicine, or non-pharmacological therapies including acupuncture, music therapy, lifestyle therapy, exercise therapy, and nutrition therapy; (3) the comparisons were placebo, no intervention, usual care control, or other comparable interventions; (4) the study included at least one cognitive performance outcome measure in the form of either the MMSE (Mini-Mental State Examination) or ADAS-cog (AD Assessment Scale-cognitive subscale) and the efficacy of the studies must include mean changes from baseline to endpoint.

Studies with the following characteristics were excluded: (1) participants with a diagnosis of MCI due to diseases other than AD; (2) irrelevant outcomes or deficient data; and (3) case reports, review articles, clinical protocols, conference abstracts, and animal experimental studies.

### Data Extraction and Quality Assessment

Two investigators (XL and YL) screened the articles and extracted the data and related statistics independently. Basic information was organized into a standard table, including information on the characteristics of the population, intervention(s), comparison(s),

treatment duration, event(s), and outcome. The Cochrane Risk of Bias Tool (Savovic et al., 2014) was used by two researchers (XL and YL) to assess the risk of bias and quality of included trials. A third reviewer (HW) was consulted to recheck studies when the first two reviewers had disagreements and discrepancies.

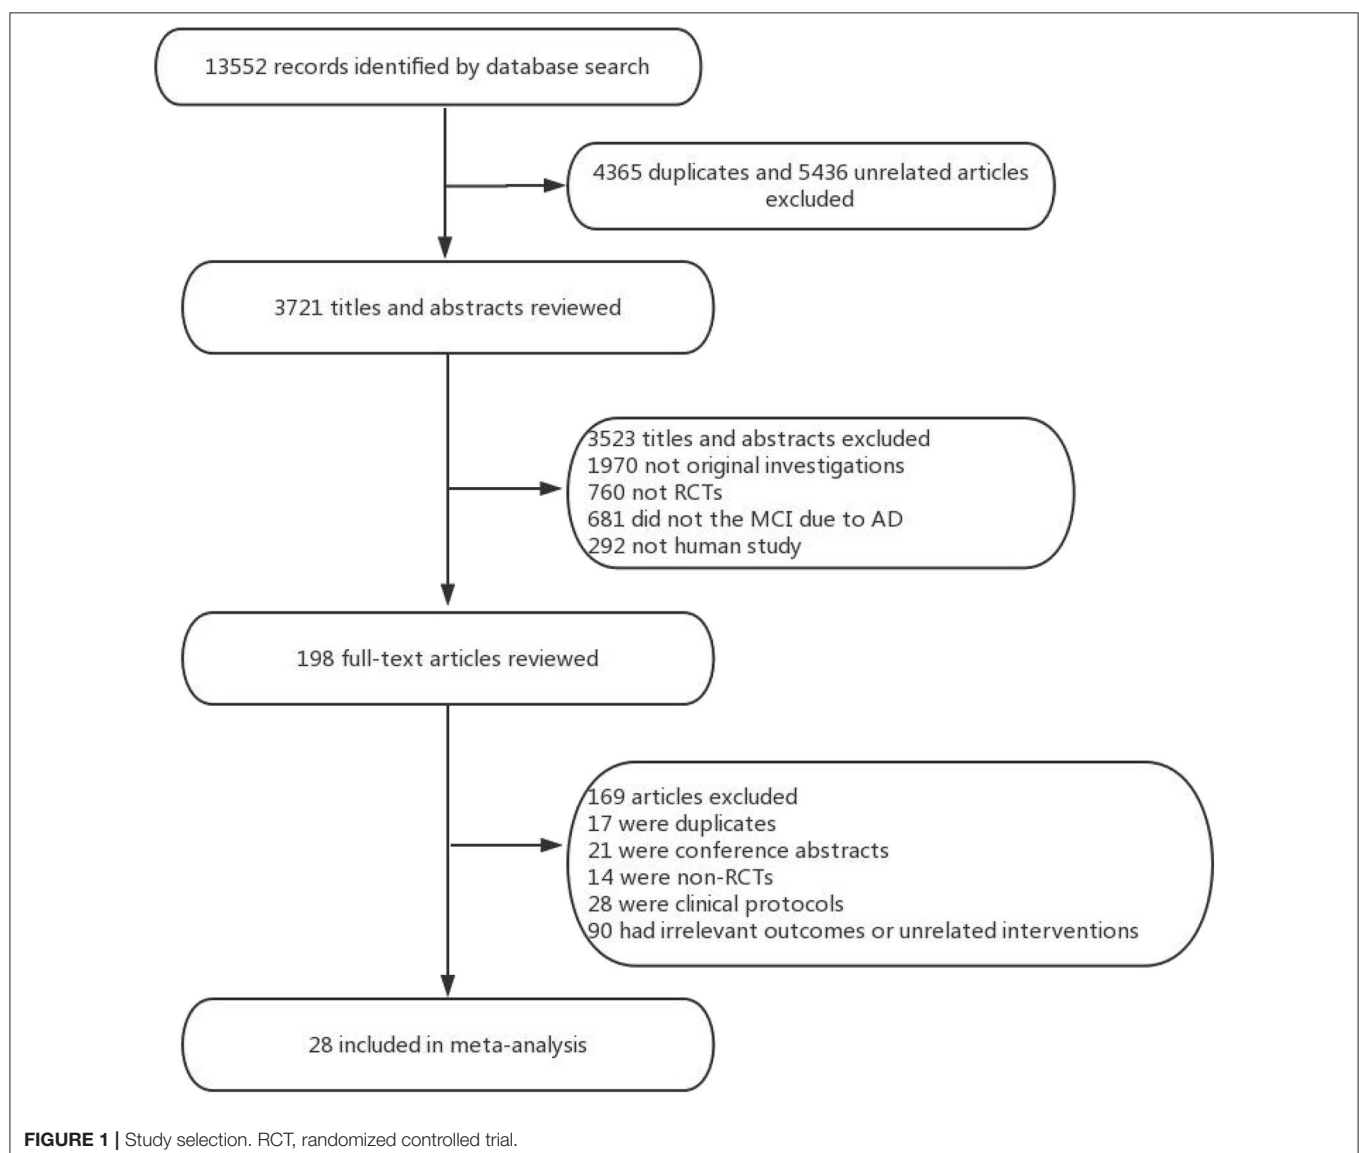

## Outcomes

Our network meta-analysis used Mini-Mental State Examination (MMSE) as the primary outcome to measure global cognition, with higher MMSE scores meaning better cognitive function. The second outcome was the AD Assessment Scale-cognitive subscale (ADAS-cog), in which lower scores mean better cognitive function. If the complete data on outcomes were not reported in the original article, we contacted authors via email to obtain the raw data, otherwise studies lacking such data were eliminated. The data were independently collected by two reviewers (XL and YL) and rechecked by a third investigator (HW).

## Statistical Analysis

Firstly, a pair-wise meta-analysis was used to compare the compliance of different therapies. By using the Aggregate Data Drug Information System (ADDIS ver. 1.16.8, available at: <https://drugis.org/software/addis/index>) with a random-effects model, the odds ratio (OR) was measured for discontinuous outcomes along with 95% credible intervals (CI). Statistical heterogeneity was calculated in the pair-wise comparisons with an  $I^2$  statistic and the  $p$ -value.

Furthermore, we conducted a network meta-analysis. This network meta-analysis was set up with a Bayesian framework using the Aggregate Data Drug Information System (ADDIS ver. 1.16.8, available at: <https://drugis.org/software/addis/index>) to determine the cognitive outcomes of nine interventions. This software uses the Bayesian framework as a base combined with the Markov chain Monte Carlo method to evaluate research data. A random-effects model was used to evaluate the effect sizes

in this network meta-analysis. Random-effect model attempted to generalize findings beyond the included studies by assuming that the selected studies are random samples from a larger population (Cheung et al., 2012). The mean difference (MD) was the effect size for continuous outcomes. The models used to estimate the effect size in ADDIS were “consistency” and “inconsistency.” The consistency model aims to evaluate effect sizes of the interventions, which was used to calculate the ranking probabilities for the whole group of interventions. Node-splitting analysis helps to determine the consistency test with an inconsistency model. For instance, a consistency model was chosen when the  $p$ -value of the node-splitting analysis was  $>0.05$ . If the  $p$ -value of the node-splitting analysis was  $<0.05$ , an inconsistency model was selected. In order to evaluate the convergence of the model, the potential scale reduction factor (PSRF) was used. If the PSRF value was close to 1, the convergence of the model was more desirable. If the PSRF value was  $<1.2$ , it was still considered as acceptable. For each intervention, the ranking probabilities were estimated for every treatment at every possible rank.

## RESULTS

### Study Identification and Selection

Overall, a total of 13,522 studies were identified from the seven electronic databases using the search strategy, and 198 relevant full-text articles were evaluated for eligibility. There were 169 citations excluded, including 17 duplicates, 21 conference abstracts, 28 clinical protocols, 14 non-RCTs, and 90 unrelated intervention or outcome articles. Ultimately, 28 studies including 6,863 patients were clinical eligible to be included in this network meta-analysis (Figure 1). The characteristics of the selected studies were listed in Table 1.

### Study Quality

The Cochrane Risk of Bias Tool was used to assess the quality of all 28 trials included in our study (Figure 2 shows the summary risk of bias for selected studies). Among the 28 trials, 19 (66%) represented a random sequence generation process using a computer random number generator or a random number table. Fourteen trials (48.3%) described the use of allocation

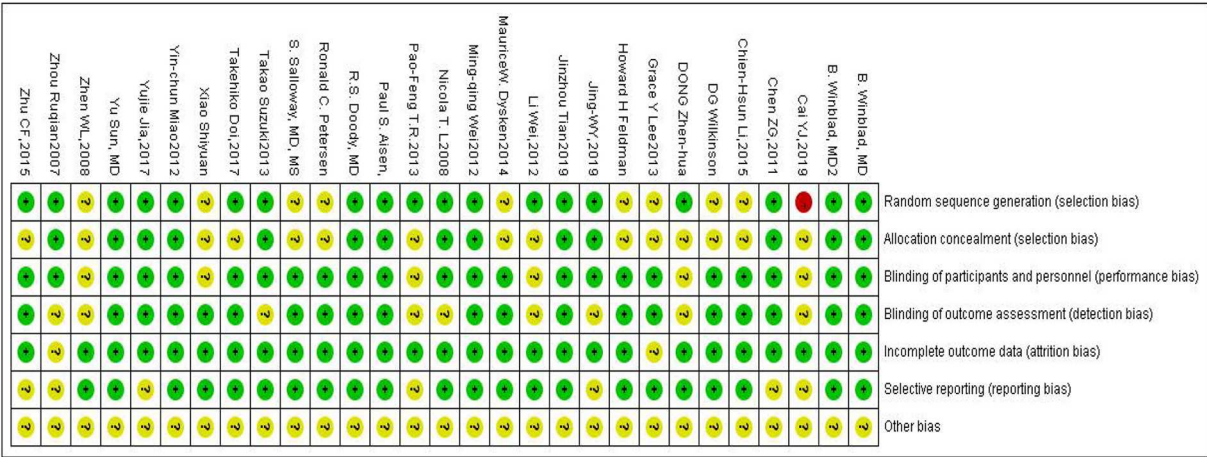

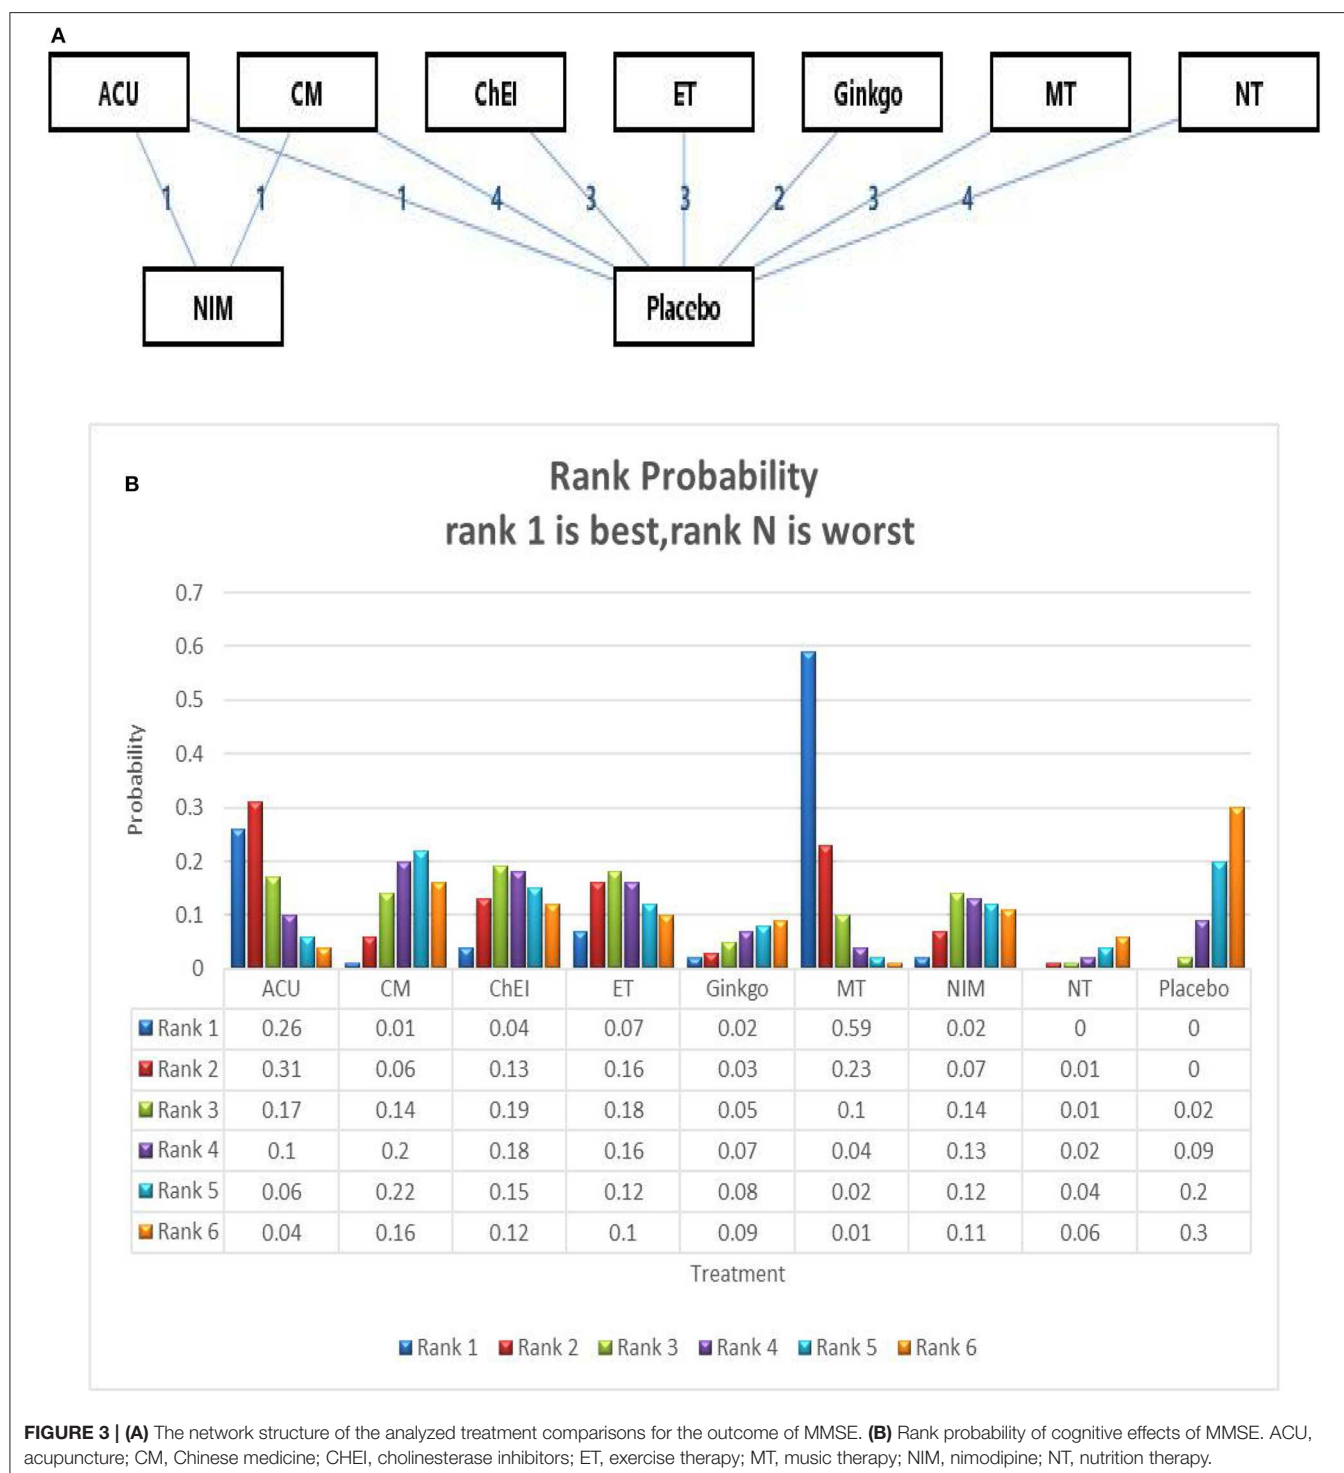

FIGURE 2 | Quality assessment of included studies.

concealment methods, and 22 trials (75.9%) described the blinding methods for researchers and participants. Acupuncture, music therapy, and exercise therapy are non-pharmacologic therapies, therefore some participants and researchers involved in these studies were not able to be blinded. Six trials (21.4%) had an uncertain risk of outcome assessment and 25 trials (86.2%) had a low risk of attrition bias.

## Pair-Wise Meta-Analysis

We conducted a classic pair-wise meta-analysis using a random-effects model to synthesize studies with the same pair of interventions. All interventions, except for nimodipine, had at least one placebo controlled trial. As for the MMSE outcome, the ChEIs (MD:  $-0.38$ ; 95% CI:  $-0.74, -0.01$ ), Chinese medicine (MD:  $-0.31$ ; 95% CI:  $-0.75, 0.13$ ), exercise therapy (MD:  $-0.50$ ;

95% CI:  $-0.65, -0.35$ ), music therapy (MD:  $-1.71$ ; 95% CI:  $-4.49, 1.07$ ), were worse than placebo, and other interventions were statistically more efficient than placebo. For ADAS-cog outcome, ChEIs (MD:  $1.20$ ; 95% CI:  $0.73, 1.68$ ), Acupuncture (MD:  $1.36$ ; 95% CI:  $1.28, 1.44$ ), Chinese medicine (MD:  $0.61$ ; 95% CI:  $0.49, 0.73$ ) and exercise (MD:  $0.61$ ; 95% CI:  $0.49, 0.73$ ) were better than placebo. The detailed results of the pair-wise meta-analysis are shown in **Supplementary Datasheet 2**.

## Network Meta-Analysis

### Primary Outcome: MMSE

We ran a network meta-analysis to thoroughly compare and assess different treatment rankings for MCI, the network of MMSE include 23 trails and 15 interventions, the network plot presented in **Figure 3A**. Node-splitting analysis was used to assess consistency, and all  $p$ -values between the direct and indirect effects were  $> 0.05$ . A PSRF value of 1 indicated that the model was convergent and the result was stable. Therefore, the consistency model was selected for the subsequent network analysis.

The network meta-analysis for the primary outcome (MMSE) is shown in **Table 2**. In terms of efficacy music therapy (MD:  $1.74$ ; 95% CI:  $0.21, 3.26$ ), Acupuncture (MD:  $1.22$ ; 95% CI:  $-0.97, 3.39$ ), and exercise therapy (MD:  $0.52$ ; 95% CI:  $-1.22, 2.28$ ) achieved better than placebo. Ginkgo (MD:  $-0.40$ ; 95% CI:  $-2.34, 1.57$ ) and nutrition therapy (MD:  $-0.75$ ; 95% CI:  $-2.04, 0.61$ ) were significantly less effective than other interventions and placebo. Other pharmacological therapies including Chinese medicine (MD:  $0.27$ ; 95% CI:  $-0.96, 1.52$ ) and ChEIs (MD:  $0.46$ ; 95% CI:  $-1.02, 1.96$ ) showed a slight improvement in MMSE scores; however, their efficacy in MCI needs further investigation. The ranking probability of MMSE is presented in **Figure 3B**, the results showed that music therapy had the highest

probability (59%) of being the best treatment for MCI, followed by Acupuncture (26%) and then exercise (7%).

### Secondary Outcome: ADAS-cog

In relation to the secondary outcome (ADAS-cog score), 17 trails and 6 treatments were involved, 2 arms of Acupuncture, 6 arms of ChEIs, 3 arms of Chinese medicine, 2 arms of exercise therapy and 4 arms of nutrition therapy (presented in **Figure 4A**). After Node-splitting analysis, we adopted the consistency model to compare these different interventions. Chinese medicine (MD:  $-2.72$ ; 95% CI:  $-4.83, -0.56$ ), Acupuncture (MD:  $-2.84$ ; 95% CI:  $-5.61, -0.34$ ), exercise therapy (MD:  $-0.71$ ; 95% CI:  $-3.12, 1.68$ ), and ChEIs (MD:  $-0.88$ ; 95% CI:  $-2.23, 0.53$ ) were better than placebo. Nutrition therapy (MD:  $1.43$ ; 95% CI:  $-0.34, 3.14$ ) was least effective compared to other interventions and placebo (shown in **Table 3**). The ranking probability of ADAS-cog is presented in **Figure 3B**. Acupuncture ranked the best (52%), it might be the most effective way to change the ADAS-cog score.

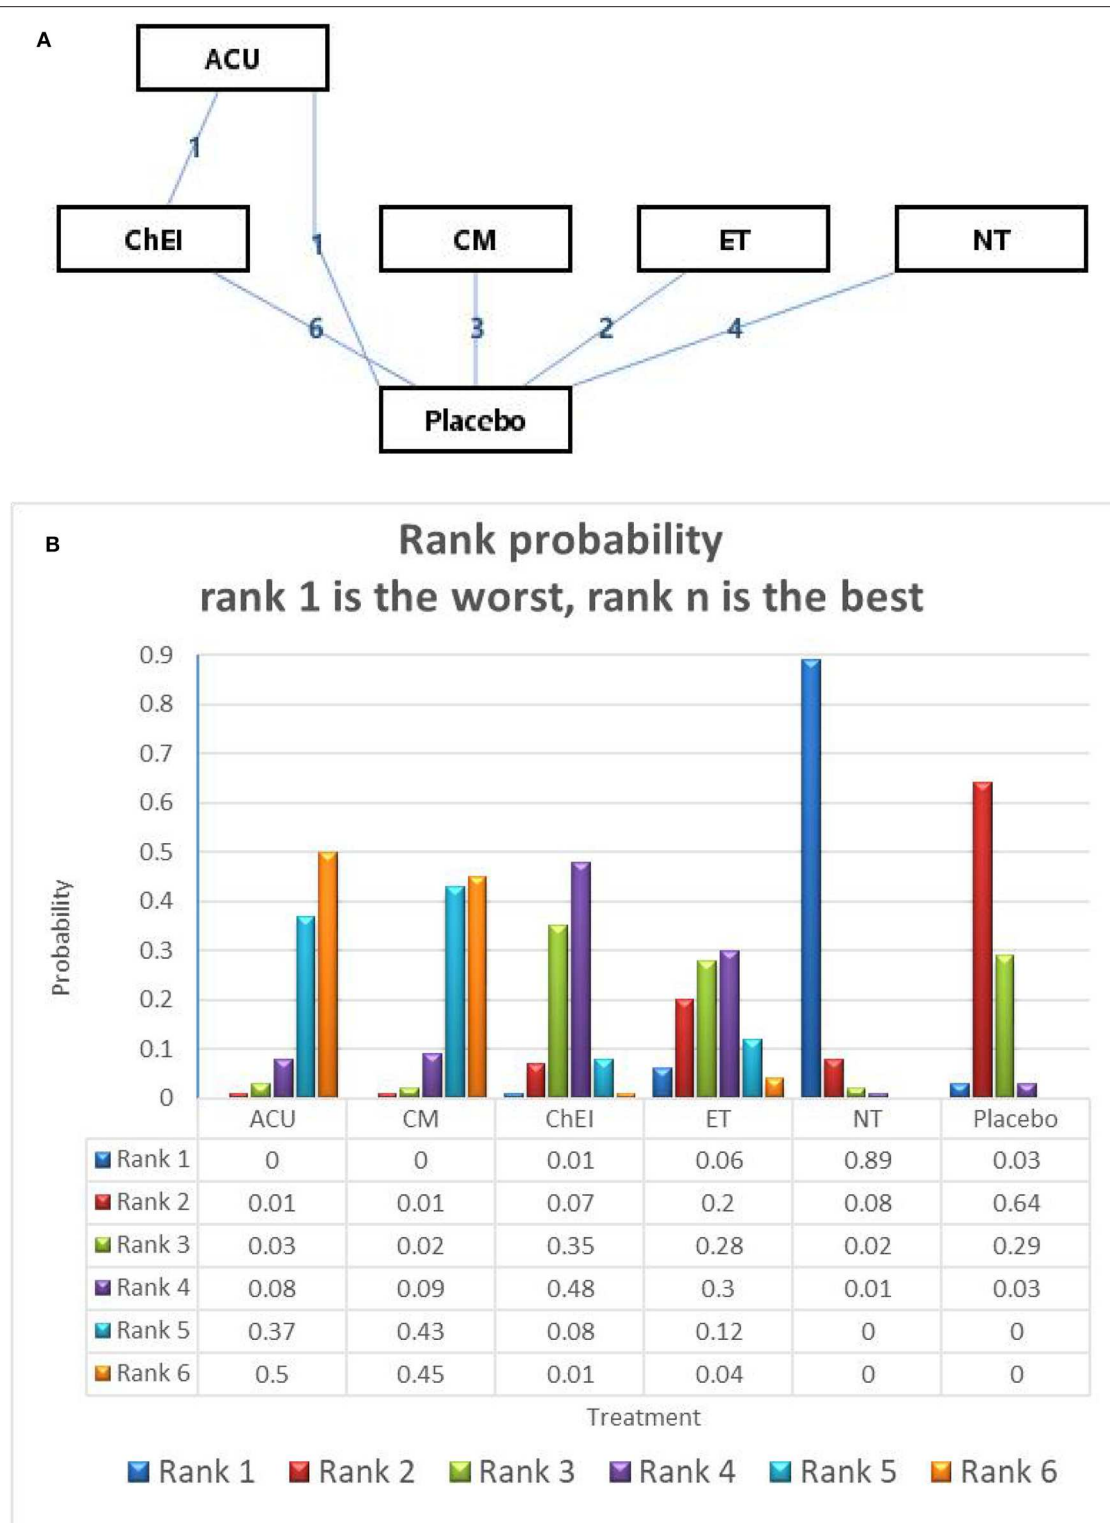

### Adverse Events

Out of 28 trials, 13 trails reported adverse events occurred, 14 trails did not mention whether there was adverse events and one trial stated no injuries reported (**Table 1**). 9 out of 13 trails reported adverse events related to gastrointestinal discomforts such as diarrhea, nausea, vomiting and anorexia, these interventions were mainly ChEIs, nutrition therapy and Chinese medicine. 8 out of 13 trails reported insomnia as adverse effect which mainly related to ChEIs and nutrition interventions. 1 out of 13 trails reported cardiovascular problem due to exercises intervention and 1 out of 13 trails reported Acupuncture-fainting due to Acupuncture intervention.

## DISCUSSION

This study is the first network meta-analysis performed on potential pharmacological and non-pharmacological treatments for MCI, and has incorporated the most comprehensive data. The Bayesian statistical methods that we used allowed us to rank many different treatments by measuring comparable probability and then reporting them as the best, the second best, and so on. Through this method, we found that among all interventions, both pharmacological therapies (ChEIs, ginkgo, nimodipine, and Chinese medicine) and non-pharmacological therapies (acupuncture, music therapy, exercise, and nutrition therapy), music therapy and acupuncture were better than other treatments. Some pharmacological treatments like ChEIs such as donepezil, galantamine, and rivastigmine showed a slight efficacy to improve MMSE scores and cognitive function, but have many safety issues which require further clarification and study. In addition, ginkgo and nutrition therapy might be ineffective for MCI, which are thus not strongly recommended in clinical medicine.

Music therapy is one of the non-pharmacological therapies which incorporates active and passive therapy. Active music therapy can be defined as therapeutic music activities which involve active participation by clients, such as singing, dancing with music, playing an instrument, composing, and discussing clients' thoughts and feelings in regards to music-related activities in order to reach the optimal treatment effect. Passive music therapy, on the other hand, means achieving the treatment effect by listening and enjoying music. Passive music therapy is also called receptive music therapy and is widely used (Chang et al., 2015; Han et al., 2017; Claudia et al., 2019). Previous research has shown that music can activate some brain regions that govern cognitive function, affective function, and motor skills, and activate neurological stimulation which may develop new neural networks (Raglio et al., 2014; Mofredj et al., 2016). Evidence has shown that, in the context of patients with cognitive function decline, music therapy intervention increases cerebral blood flow and pre-frontal cortex activity (Shimizu et al., 2018).

Acupuncture has been shown to be a good management option in neurological diseases, with studies demonstrating

acupuncture is associated with activation in motor-related brain regions as shown in functional magnetic resonance imaging (fMRI) (Chen et al., 2008, 2012; Chae et al., 2009). Other studies supplemented that Acupuncture is able to regulate the emotional components of the pain matrix, and inducing brain activation which provides a neurobiological basis of acupuncture (Shangjie et al., 2014; Shan et al., 2018). Research also suggests that acupuncture can activate resting brain networks, which incorporate anti-nociceptive, memory, and emotion brain regions. Our network meta-analysis suggests that music therapy is the optimal intervention to treat MCI patients and improve their cognitive function, whereas acupuncture was the second best option. Further research is required to assess other interventions not included in this meta-analysis. A recent study found that mindfulness therapy improved inflammatory biomarkers in patients with MCI (Ng et al., 2020). This provides an interesting perspective on the current management paradigms for MCI.

The adverse events reports showed that some participants experienced gastrointestinal reactions and insomnia due to ChEIs, nutrition and Chinese medicine interventions. However, none of these events was related to cognitive distress. Other small samples such as exercise and Acupuncture reported therapy related adverse effects such as cardiovascular problems and Acupuncture fainting respectively. Music therapy didn't report any adverse events.

There were limitations to our study. Firstly, a few RCTs showed potential bias because of the small number of participants and elective reporting. Fortunately, there was no obvious inconsistency or heterogeneity shown in this network meta-analysis, but there is a possibility that some included articles might have overestimated the effectiveness of treatments, and this might have influenced our results. Secondly, a few included reports were non-pharmaceutical therapies which cannot be blinded to participants, especially acupuncture. However, blinding of outcome assessment and single-blind methodologies should be used where possible to reduce the potential for any bias. Thirdly, we have excluded some drug interventions because of our selection criterion of outcome measures, which may influence the strength of evidence.

## CONCLUSION

The findings of this comprehensive network meta-analysis provide some evidence that music therapy and acupuncture might improve the cognitive function of patients with MCI. Our results indicate that music therapy and, to a lesser extent, acupuncture may be the preferred options for treatment of MCI. Ginkgo and nutrition therapy do not seem to be adequate as regular treatment options. Our study provides new insights into the clinical treatments available for MCI, and may help the development of guidelines for the management of MCI.

Hu W, Li Y, Zhao Y, Dong Y, Cui Y, Sun S, Gong G, Zhang H, Chai Q, Wang J and Liu Z (2020) Telmisartan and Rosuvastatin Synergistically Ameliorate Dementia and Cognitive Impairment in Older Hypertensive Patients With Apolipoprotein E Genotype. *Front. Aging Neurosci.* 12:154. doi: 10.3389/fnagi.2020.00154

**Objective:** To investigate the effect of telmisartan, rosuvastatin, or their combination on dementia and to understand the impact of *apolipoprotein E* (*APOE*) genotype on the effect of the medications in older patients with hypertension.

**Methods:** This is a double-blind, randomized, and placebo-controlled trial using a 2 × 2 factorial design. Between April 2008 and November 2010, 1,244 hypertensive patients aged ≥60 years without cognitive impairment were recruited from communities in six cities in Shandong area, China. Patients were randomized into telmisartan and rosuvastatin administration after a 2-week washout period. *APOE* genotype was identified at the baseline. Possible dementia was determined using the combination of the global cognitive function and Assessment of the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE).

**Results:** Over an average follow-up of 7 [interquartile range (IQR): 6.7–7.2] years, telmisartan and rosuvastatin significantly reduced the cognitive impairment progression and the incidence of dementia. There was a synergistic interaction between telmisartan and rosuvastatin to reduce the cognitive impairment and the incidence of dementia ( $P_{\text{adjusted}} < 0.001$ ). The cognitive impairment progression and the risk of dementia were higher in the hypertensive patients with *APOE* ε4 allele than in those without *APOE* ε4 allele. Rosuvastatin medication significantly alleviated the cognitive impairment progression and the risks of dementia in patients with *APOE* ε4 allele.

**Conclusion:** The combination of telmisartan and rosuvastatin might be an effective prevention and/or treatment strategy for cognitive impairment and dementia, especially in hypertensive patients with the *APOE* ε4 allele.

## INTRODUCTION

Dementia is an age-related and progressive neurodegenerative disease characterized by a decline in cognitive function that affects the quality of life in older adults (Peng et al., 2014; Sabia et al., 2017). Epidemiological studies reported 47 million cases of dementia worldwide in 2015 and have predicted that this will triple by 2050, given the steadily increasing life expectancy (Prince et al., 2013; Sabia et al., 2017), placing a heavy burden on individuals, families, and society. Hence, preventing and delaying the progression of dementia and cognitive impairment is a global public health issue (Shah et al., 2016).

Dementia and cognitive impairment are multifactorial diseases that are most frequently caused by aging, hypertension, dyslipidemia, and genetic factors (Farao and Iadecola, 2013; Sabia et al., 2017; Van Middelaar et al., 2018). Although hypertension is often accompanied by dyslipidemia, it is debatable whether antihypertensive treatment can improve cognitive outcome in the elderly (Farao and Iadecola, 2013; Sörös et al., 2013), and there are no specific classes of antihypertensive agents that have consistently shown greater efficacy in alleviating dementia or cognitive impairment (Gorelick et al., 2011; Farao and Iadecola, 2013). Moreover, it is unclear whether lipid-lowering statin treatment is beneficial, since different studies have reported conflicting findings (Jick et al., 2000; Hajjar et al., 2002; Rodrigues et al., 2002).

Sartans are some of the widely used antihypertensive medications. This popularity of sartans is due to its superior efficacy and tolerability profiles and the long duration of action. Sartans have been demonstrated to protect against cognitive deficits in animal models of Alzheimer's disease (Kehoe et al., 2009; Ahmed et al., 2018) and in human beings (Petek et al., 2018). However, there is an argument on the beneficial effect of sartans on cognitive decline (Diener et al., 2008; Tsukuda et al., 2009; Ho and Nation, 2017).

Statins has been recommended by guidelines as the medication for primary prevention of cardiovascular disease (Bibbins-Domingo et al., 2016; Mortensen and Nordestgaard, 2018; Arnett et al., 2019). A recent meta-analysis study demonstrated that statin medications could produce significant reductions in major vascular events irrespective of age (Cholesterol Treatment Trialists' Collaboration, 2019). Studies also showed that statins possess beneficial effects on reducing stroke risks and ameliorating dementia (Power et al., 2015; Geifman et al., 2017; Zissimopoulos et al., 2017; Petek et al., 2018). However, similar to sartans, the beneficial effect of statins on cognitive decline also remains controversial (Power et al., 2015; Geifman et al., 2017; Zissimopoulos et al., 2017; Sinyavskaya et al., 2018).

Several genes have been identified as risk factors for dementia and cognitive impairment in genome-wide association studies (Dergunov, 2011; Nazarian et al., 2019). One of these, *apolipoprotein E* (*APOE*), has three common alleles ( $\epsilon 2$ ,  $\epsilon 3$ , and  $\epsilon 4$ ) encoding distinct protein isoforms (Dergunov, 2011; Ji et al., 2018). In particular, the *APOE*  $\epsilon 4$  allele is closely associated with elevated levels of total cholesterol and low-density lipoprotein cholesterol (Dergunov, 2011) with increased risk of dementia and cognitive impairment (Mahely and Huang, 1999; Reitz, 2012). However, the relationships between the *APOE* gene and blood pressure and *APOE* gene and plasma lipid-lowering treatments are not well understood. To address this issue, the present study investigated how the *APOE*  $\epsilon 4$  genotype influences the effects of sartans and statins on dementia and cognitive impairment risk in older hypertensive patients.

## METHODS

### Standard Protocol Approval, Registration, and Patient Consent

This study was conducted in compliance with the Declaration of Helsinki and adhered to good clinical practice guidelines. The study protocol was approved by the Research Ethics Committee of the Institute of Basic Medicine, Shandong Academy of Medical Sciences, and was retrospectively registered with ChiCTR.org.cn (ChiCTR-IOR-17013557). Written informed consents were obtained from all the patients.

### Study Design and Sample Size Determination

This study was a double-blind, randomized, and placebo-controlled trial using a  $2 \times 2$  factorial design. The protocol of this study is described elsewhere (Ji et al., 2018). The major objective was to investigate the interaction of sartans and low-dose statins on the incident cardio- and cerebro-vascular events including stroke and myocardial infarction. The sample size was determined using the stroke incidence, and 1,244 essential hypertensive elderly aged  $\geq 60$  years were determined (Ji et al., 2018). In this study, we mainly investigated the interaction of sartans, statins, and *APOE* genotype on dementia incidence and the trajectory of global cognitive function during the study period. So, the sample size should be determined using the incidence of dementia. Given that the incidence of dementia is 5.1% per year (Jia et al., 2014), the sample size of 1,244 patients could well provide a statistical power of 90% including taking into account a dropout rate of 10% in this study.

### Study Patients

Details of the study patients are as described in our previous study (Ji et al., 2018). Briefly, 1,244 essential hypertensive patients

aged  $\geq 60$  years were eligible and recruited from communities in six cities in Shandong, China, between April 2008 and November 2010. The exclusion criteria were patients with Alzheimer's disease, Parkinson's disease, schizophrenia, seizures, Mini-Mental State Examination (MMSE) score  $\leq 23$ , secondary hypertension, diabetes mellitus, myocardial infarction or stroke in the last 6 months, clear hypersensitivity or contraindication to the medications administered in the study, chronic liver disease or renal dysfunction, inflammatory muscle disease, connective tissue diseases or malignancy, drug or alcohol abuse, intention to leave current residence within 6 years, inability to walk to the clinic, and unwillingness to provide informed consent.

## Study Randomization, Intervention, and Follow-Up

After a 2-week washout period, the patients were randomized on a 1:1:1:1 ratio into control (telmisartan placebo and rosuvastatin placebo), telmisartan (telmisartan activator and rosuvastatin placebo), rosuvastatin (telmisartan placebo and rosuvastatin activator), and combination (telmisartan activator and rosuvastatin activator) groups. A computer-generated randomization was conducted by members who were not directly working on the study according to the order of recruitment with a block size of eight without stratification. Each patient was assigned a unique number that was used throughout the study. The investigators and patients were masked to treatment assignment until the completion of the study and until final clinical database lockdown.

Telmisartan was administered at a concentration of either 40 mg or increased to 80 mg once daily if needed and rosuvastatin at 10 mg once daily. Hydrochlorothiazide (12.5 mg increased to 25 mg once daily if needed) was used as an open-label medication and a background treatment in the four groups. Patients were visited weekly during the washout period, then at trial months 1, 3, and 6, every 6 months thereafter, and at final visit.

## Evaluation of Global Cognitive Function

Assessments of global cognitive function include the MMSE (Liu et al., 2016; Duan et al., 2017), Montreal Cognitive Assessment (MoCA; Duan et al., 2017), Mattis Dementia Rating Scale (DRS; Chan et al., 2001), and Clinical Dementia Rating (CDR; Yue et al., 2016). The scales were implemented at baseline, annual follow-up, and final visits using the Chinese versions. All tests were conducted by experienced neuropsychology research assistants who were blinded to clinical and laboratory data, genotype, and psychological outcomes. The MMSE, MoCA, DRS, and CDR are widely used standard tests for assessing, screening, and staging cognitive dysfunction and dementia with excellent test-retest and inter-rater reliability. Lower MMSE, MoCA, and DRS scores reflect more severe cognitive impairment and dementia, whereas a higher CDR score represents more severe dementia. After testing 90 patients in random, the coefficients of variation of the interobserver were 0.91 for the MMSE score, 0.89 for the MoCA score, 0.87 for DRS score, and 0.84 for CDR score.

## The Informant Questionnaire on Cognitive Decline in the Elderly

Assessment of the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) was implemented at baseline, biennial follow-up, and final visits. The IQCODE is one of the worldwide used informant (proxy)-rated complementary screening tool for dementia that rates the change in cognitive function from a previous level of 10 years earlier (Jorm and Jacomb, 1989; Jorm, 1994, 2004). It is available in various versions (Jorm and Jacomb, 1989; Jorm, 1994, 2004; Harrison et al., 2016), has demonstrated utility in multiple cultural groups (Jorm and Jacomb, 1989; Fuh et al., 1995; Morales et al., 1995; Harrison et al., 2016), and has high internal ( $\alpha = 0.95$ ) and test-retest (correlation coefficient = 0.75) reliabilities (Jorm and Jacomb, 1989; Gavett et al., 2011). Our study used a shortened version consisting of 16 items, which was demonstrated essentially to be comparable to the original version (Jorm, 1994), to measuring cognitive decline during the follow-up period. The IQCODE was independently completed by the spouses, relatives, friends, or carers who closely knew the patients for at least 10 years. Each item on the IQCODE is rated on a five-point scale, where 1 represents "Much better," 2 "A bit better," 3 "Not much change," 4 "A bit worse," and 5 "Much worse." The final score is the average of the rated 16 item scores. A higher score represents a greater cognitive impairment. The coefficient of variation of the interobserver was 0.93 after being tested in random samples of 90 patients.

## APOE Genotyping

DNA was extracted from 10 ml peripheral blood mixed with ethylenediaminetetraacetic acid (EDTA). *APOE* genotyping based on the presence of the single-nucleotide polymorphisms rs429358 and rs7412 was carried out by polymerase chain reaction using the TaqMan genotyping kit (Applied Biosystems, Foster City, CA, USA). The primers used were forward primer: 5'-TTG AAG GCC TAC AAA TCG GAA CTG-3' and reversed primer: 5'-CCG GCT GCC CAT CTC CTC CAT CCG-3' (Molinuevo et al., 2016). Patients were categorized as  $\epsilon 4$ -positive carriers (genotypes  $\epsilon 2/\epsilon 4$ ,  $\epsilon 3/\epsilon 4$ , or  $\epsilon 4/\epsilon 4$ ) or  $\epsilon 4$ -negative carriers (genotypes  $\epsilon 2/\epsilon 2$ ,  $\epsilon 2/\epsilon 3$ , or  $\epsilon 3/\epsilon 3$ ; Ji et al., 2018).

## Outcomes

Primary outcomes included changes in global cognitive function including MMSE, MoCA, DRS, and CDR scores and dementia incidence. Possible dementia was diagnosed depending on a combination of IQCODE and global cognitive function assessment according to the recommendations from the National Institute on Aging-Alzheimer's Association workgroups on diagnostic guidelines for Alzheimer's disease (Narasimhalu et al., 2008; Albert et al., 2011). The cut-off of MMSE was  $\leq 23$  points or a decline of  $\geq 3$  points between any two annual follow-up visits (Liu et al., 2016; Duan et al., 2017), MoCA was  $> 20$  points (Delgado et al., 2017), DRS was  $> 120$  points (Chan et al., 2001), CDR was  $\geq 1.0$  (Yue et al., 2016), and IQCODE was  $\geq 3.38$  (Biessels et al., 2006). The secondary

outcomes were incident stroke and all-cause mortality during the follow-up period.

## Statistical Analysis

The intention-to-treat principle was followed in the analysis of this study. Continuous data are expressed as mean with standard deviation (SD) or the median with interquartile range (IQR; the range between the 25th and 75th percentiles) depending on the normality of the data, and categorical data are expressed as a frequency with percentages. The Kolmogorov–Smirnov test was used to assess the normality of the continuous data. Comparisons of continuous data between groups were performed with the one-way analysis of variance (ANOVA) with the Bonferroni procedure or Kruskal–Wallis H test with a Wilcoxon rank-sum test depending on the normality of the data; categorical data were compared with the chi-square test. A linear mixed model was used to assess differences in the trajectory of MMSE, MoCA, CDR, and DRS scores over the follow-up period among groups. A Kaplan–Meier analysis with the log-rank test was used to evaluate differences in the risks of dementia incidence. The Cox proportional hazards model was used to assess the hazard ratio (HR) and 95% confidence interval (CI).

In this study, we tested the interactions between telmisartan and rosuvastatin; *APOE*  $\epsilon 4$  allele status and telmisartan; *APOE*  $\epsilon 4$  allele status and rosuvastatin; and among *APOE*  $\epsilon 4$  allele status, telmisartan, and rosuvastatin on the trajectory of global cognitive function and the dementia incidence. First, we classified patients into control, telmisartan, rosuvastatin, and combination groups to investigate the interaction between telmisartan and rosuvastatin. Then, we reclassified patients into telmisartan placebo \*  $\epsilon 4$  negative/positive [telmisartan(–) \*  $\epsilon 4$ (–)/(+)] and telmisartan activator \*  $\epsilon 4$  negative/positive [telmisartan(+) \*  $\epsilon 4$ (–)/(+)] groups to investigate the interaction between telmisartan and *APOE*  $\epsilon 4$  allele status. Third, we reclassified patients into rosuvastatin placebo \*  $\epsilon 4$  negative/positive [rosuvastatin(–) \*  $\epsilon 4$ (–)/(+)] and rosuvastatin activator \*  $\epsilon 4$  negative/positive [rosuvastatin(+) \*  $\epsilon 4$ (–)/(+)] groups to investigate the interaction between rosuvastatin and *APOE*  $\epsilon 4$  allele status. Finally, we subclassified the control, telmisartan, rosuvastatin, and combination groups into control \*  $\epsilon 4$ (–)/(+), telmisartan \*  $\epsilon 4$ (–)/(+), rosuvastatin \*  $\epsilon 4$ (–)/(+), and combination \*  $\epsilon 4$ (–)/(+) groups, respectively, to investigate the interaction among *APOE*  $\epsilon 4$  allele status, telmisartan, and rosuvastatin.

Models were adjusted for age, sex, education, smoking, alcohol consumption, baseline body mass index, baseline blood pressure, baseline fasting plasma glucose, baseline plasma lipids, the status of hydrochlorothiazide administration, changes in blood pressure, lipids, and fasting plasma glucose during the trial period, and the stroke incidence during the trial period. Multiple sensitivity analyses were performed using: (1) first diagnosed dementia during the trial period; (2) multiple imputation by chained equations for imputing missing data for variables; (3) stratified analysis to make sure that the associations found are robust; and (4) confounders included the changes in blood pressure, lipids, and fasting plasma glucose

and the stroke incidence during the trial period in models. Statistical analyses were performed using SPSS v.24.0 (SPSS Inc., Chicago, IL, USA). A two-sided *P*-value < 0.05 was considered statistically significant.

## RESULTS

### Baseline Characteristics

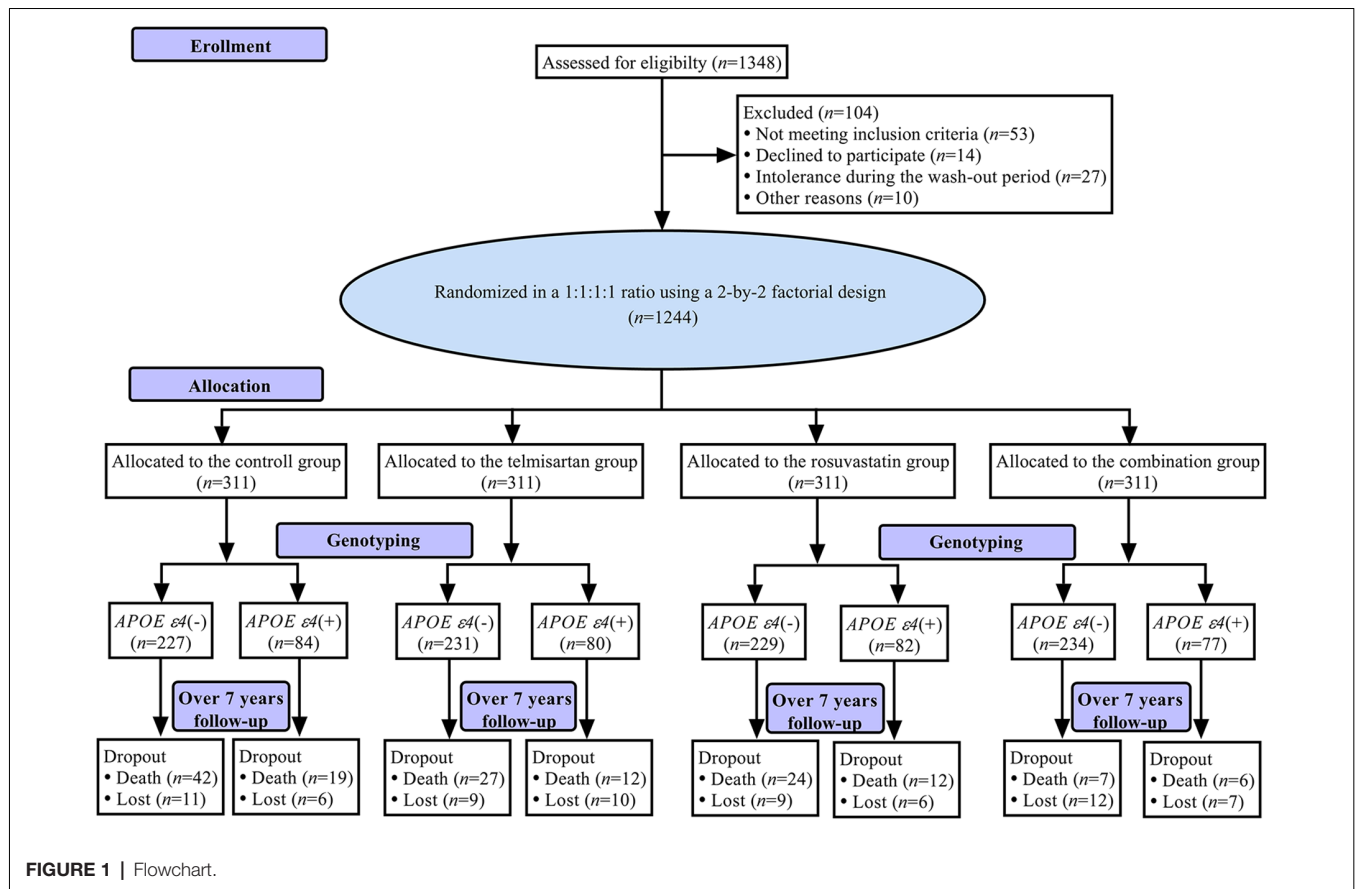

**Figure 1** shows a flowchart of this study. The first patient was recruited on April 28, 2008, and the final follow-up visit was completed on September 25, 2017. The average follow-up period was 7.0 (IQR: 6.7–7.2) years. The mean age at baseline was  $70.11 \pm 6.08$  years, 597 (48.0%) subjects were female, and 323 (26.0%) were *APOE*  $\epsilon 4$ (+). The demographic and baseline clinical characteristics of the patients in control, telmisartan, rosuvastatin, and combination groups are shown in **Table 1**. There were no significant differences in the demographic and clinical characteristics among the four groups (all *P* > 0.05).

### Outcomes

Over the follow-up period, a total of 176 patients (2.0% per year) developed dementia. The scores of MMSE, MoCA, and DRS were declined, and the scores of CDR and IQCODE were increased relative to the baseline.

### Interactions Between Telmisartan and Rosuvastatin

The trajectories of MMSE, MoCA, DRS, CDR, and IQCODE scores in the duration of follow-up are presented in **Figure 2**. There were declining trends in MMSE, MoCA, and DRS and increasing trends in CDR and IQCODE in the four groups. However, the differences in the trends were significant among the four groups after adjustment for confounders as above described (all *P*<sub>adjusted</sub> < 0.001). The declining trends in MMSE, MoCA, and DRS and the increasing trends in CDR and IQCODE were significantly lower in the combination group than in the control, telmisartan, and rosuvastatin groups (all *P*<sub>adjusted</sub> < 0.05). These trends in telmisartan and rosuvastatin groups were slower in the telmisartan and rosuvastatin groups when compared with the control group (all *P*<sub>adjusted</sub> < 0.05). Moreover, similar results were found when we further compared the changes in MMSE, MoCA, DRS, CDR, and IQCODE scores from the baseline among the four groups (all *P*<sub>adjusted</sub> < 0.05; **Supplementary Figure S1**). There were significant differences in the incidences of dementia among the four groups after adjustment for covariates (*P*<sub>adjusted</sub> < 0.001). The risks of dementia in the combination, telmisartan, and rosuvastatin groups were significantly lower when compared to the control group (all *P*<sub>adjusted</sub> < 0.001; **Figure 2, Supplementary Table S1**). Compared with the combination group, the risks of dementia were higher in the telmisartan group and the rosuvastatin group (all *P*<sub>adjusted</sub> < 0.05). There was a significant interaction between telmisartan and rosuvastatin based on the changing trends in MMSE (*P*<sub>adjusted</sub> = 0.011), MoCA (*P*<sub>adjusted</sub> = 0.007), DRS (*P*<sub>adjusted</sub> = 0.013), CDR (*P*<sub>adjusted</sub> = 0.019),

## Interactions Between Telmisartan and APOE $\epsilon 4$ Allele

Compared to the telmisartan(−) \*  $\epsilon 4$ (+) group, the declining trends in MMSE, MoCA, and DRS and the increasing trends in CDR and IQCODE were significantly lower in

the other three groups after adjustment for confounders (all  $P_{\text{adjusted}} < 0.05$ ; Figure 3). The declining trends in MMSE and MoCA in the telmisartan(+) \*  $\epsilon 4$ (−) group were lower than those in the telmisartan(−) \*  $\epsilon 4$ (−) group ( $P_{\text{adjusted}} = 0.002$  and  $= 0.023$ , respectively). The increasing

**FIGURE 3 |** Trajectory of global cognitive function and IQCODE and cumulative hazards of dementia incidence during the follow-up period in the patients grouped by telmisartan administration and APOE genotype. Panel (A) is the trajectory of MMSE; panel (B) is the trajectory of MoCA; panel (C) is the trajectory of DRS; panel (D) is the trajectory of CDR; panel (E) is the trajectory of IQCODE, and panel (F) is the cumulative hazard of dementia incidence. MMSE, Mini-Mental Scale Estimation; MoCA, Montreal Cognitive Assessment; DRS, Mattis Dementia Rating Scale; CDR, Clinical Dementia Rating; IQCODE, Informant Questionnaire on Cognitive Decline in the Elderly; APOE, apolipoprotein E.

trend in IQCODE in the telmisartan(-) \*  $\epsilon 4(-)$  group was lower than that in the telmisartan(-) \*  $\epsilon 4(+)$  group ( $P_{\text{adjusted}} = 0.017$ ). We further compared the changes in MMSE, MoCA, DRS, CDR, and IQCODE scores from the baseline among the four groups (Supplementary Figure S2). The changes in MMSE, MoCA, DRS, CDR, and IQCODE scores from

the baseline were significantly higher in the telmisartan(-) \*  $\epsilon 4(+)$  group than the other three groups (all  $P_{\text{adjusted}} < 0.05$ ). The risks of dementia in the telmisartan(+)\*  $\epsilon 4(-)$  group were lower when compared to the telmisartan(-) \*  $\epsilon 4(+)$  and telmisartan(-) \*  $\epsilon 4(-)$  groups (Figure 3, Supplementary Table S1). No statistical interaction was observed between

telmisartan and *APOE*  $\epsilon 4$  allele on the changes in MMSE, MoCA, DRS, CDR, and IQCODE and in the incidences of dementia (all  $P_{\text{adjusted}} > 0.05$ ).

### Interactions Between Rosuvastatin and *APOE* $\epsilon 4$ Allele

The declining trends in MMSE, MoCA, and DRS and the increasing trends in CDR and IQCODE and the risks of the dementia were significantly lower in the rosuvastatin(+) \*  $\epsilon 4$ (-) group than in the rosuvastatin(-) \*  $\epsilon 4$ (+) and rosuvastatin(-) \*  $\epsilon 4$ (-) groups (all  $P_{\text{adjusted}} < 0.05$ ; **Figure 4**). The declining trends in MoCA and DRS and the increasing trend in CDR were lower in the rosuvastatin(+) \*  $\epsilon 4$ (+) group than in the rosuvastatin(-) \*  $\epsilon 4$ (+) group (all  $P_{\text{adjusted}} < 0.05$ ). The increasing trend in IQCODE was lower in the rosuvastatin(+) \*  $\epsilon 4$ (-) group than in the rosuvastatin(-) \*  $\epsilon 4$ (+) and lower in the rosuvastatin(-) \*  $\epsilon 4$ (-) group than in the rosuvastatin(-) \*  $\epsilon 4$ (+) group (all  $P_{\text{adjusted}} < 0.05$ ). We further found that there were significant differences in the changes in MMSE, MoCA, DRS, CDR, and IQCODE scores from the baseline among the four groups (all  $P_{\text{adjusted}} < 0.05$ ; **Supplementary Figure S3**). However, the differences in the changes in MMSE, MoCA, DRS, CDR, and IQCODE scores from the baseline were not significant between rosuvastatin(+) \*  $\epsilon 4$ (+) and rosuvastatin(+) \*  $\epsilon 4$ (-) group (all  $P_{\text{adjusted}} > 0.05$ ). The risks of the dementia incidence were significantly lower in the rosuvastatin(+) \*  $\epsilon 4$ (-) group than in the rosuvastatin(-) \*  $\epsilon 4$ (+) and rosuvastatin(-) \*  $\epsilon 4$ (-) groups (all  $P_{\text{adjusted}} < 0.05$ ; **Figure 4**, **Supplementary Table S1**). The statistical interactions were observed between rosuvastatin and *APOE*  $\epsilon 4$  allele on the changes in MMSE ( $P_{\text{adjusted}} = 0.018$ ), MoCA ( $P_{\text{adjusted}} = 0.020$ ), DRS ( $P_{\text{adjusted}} = 0.031$ ), CDR ( $P_{\text{adjusted}} = 0.027$ ), and IQCODE ( $P_{\text{adjusted}} = 0.022$ ) and in the dementia ( $P_{\text{adjusted}} = 0.022$ ).

### Interactions Among Telmisartan, Rosuvastatin, and *APOE* $\epsilon 4$ Allele

The declining trends in MMSE, MoCA, and DRS and the increasing trends in CDR and IQCODE were the lowest in the combination \*  $\epsilon 4$ (-) group and the highest in the control \*  $\epsilon 4$ (+) group after the patients were grouped based on telmisartan, rosuvastatin, and *APOE*  $\epsilon 4$  genotype. There were significant differences in the changing trends among these groups (all  $P_{\text{adjusted}} < 0.05$ ; **Figure 5**). Considering the changes in MMSE, MoCA, DRS, CDR, and IQCODE scores from the baseline, we did not find significant differences between the rosuvastatin \*  $\epsilon 4$ (-) and rosuvastatin \*  $\epsilon 4$ (+) groups and between the combination \*  $\epsilon 4$ (-) and combination \*  $\epsilon 4$ (+) groups (all  $P_{\text{adjusted}} > 0.05$ ; **Supplementary Figure S4**). The cumulative hazards of the incidences of dementia were the lowest in the combination \*  $\epsilon 4$ (-) group and the highest in the control \*  $\epsilon 4$ (+) group (**Figure 5**, **Supplementary Table S1**). There were interactions among telmisartan, rosuvastatin, and *APOE*  $\epsilon 4$  genotype on the changing trends in MMSE ( $P_{\text{adjusted}} = 0.029$ ), MoCA ( $P_{\text{adjusted}} = 0.033$ ), DRS ( $P_{\text{adjusted}} = 0.040$ ), CDR ( $P_{\text{adjusted}} = 0.036$ ), and IQCODE ( $P_{\text{adjusted}} = 0.031$ ) and in the

incidences of dementia ( $P_{\text{adjusted}} = 0.028$ ) after adjustment for confounders.

### Changes in Blood Pressure, Lipids, and Fasting Plasma Glucose and Cumulative Hazards of Stroke Incidence

**Supplementary Figures S5–S8** summarized the changes in blood pressure, lipids, and fasting plasma glucose and the cumulative hazards of stroke during the follow-up period in the patients after being grouped by different classification methods.

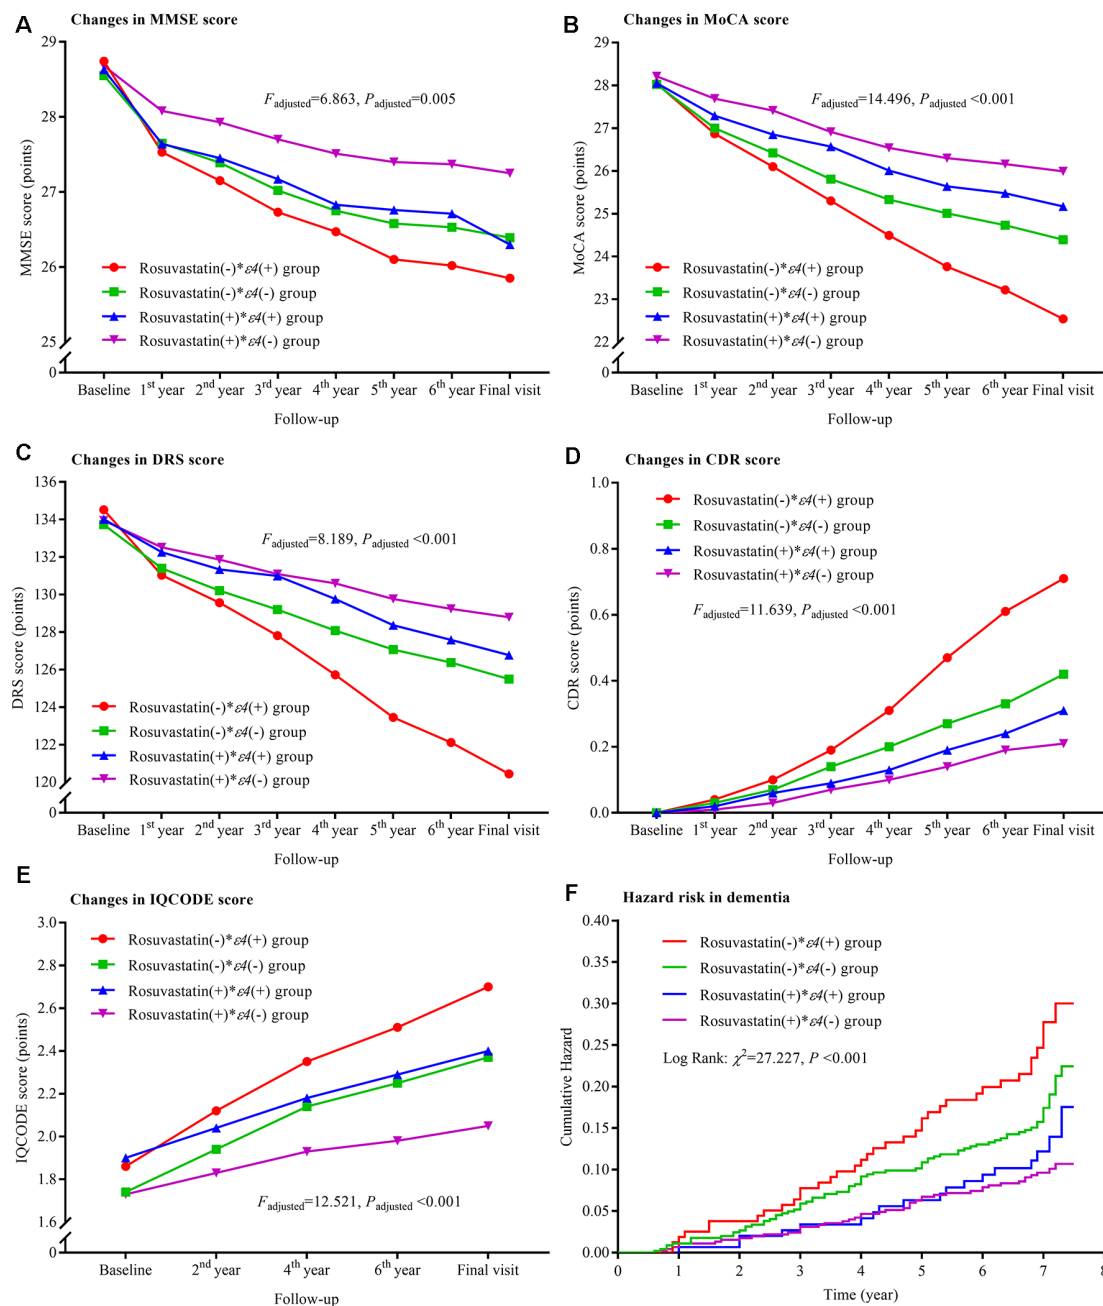

## DISCUSSION

In this randomized clinical trial, we investigated the effects of antihypertensive and anti-lipidemic treatment on dementia, stroke incidence, and all-cause mortality in older hypertensive patients. Furthermore, the impact of *APOE* genotypes on the treatment was investigated in this study. The main findings were as follows: (1) both telmisartan and rosuvastatin alleviated the progression of cognitive impairment and reduced the risk of dementia; (2) telmisartan synergistically interacts with rosuvastatin to reduce the progression of cognitive impairment and the risk of dementia; (3) the hypertensive patients with *APOE*  $\epsilon 4$  allele had a higher risk of cognitive impairment progression and the dementia incidence than those without *APOE*  $\epsilon 4$  allele; and (4) rosuvastatin significantly alleviated the progression of cognitive impairment and the risks of dementia in patients with *APOE*  $\epsilon 4$  allele.

Although the argument on the effects of sartans and statins alleviating the progression of cognitive impairment and reducing the risk of dementia remains (Diener et al., 2008; Kehoe et al., 2009; Tsukuda et al., 2009; Power et al., 2015; Geifman et al., 2017; Ho and Nation, 2017; Zissimopoulos et al., 2017; Ahmed et al., 2018; Petek et al., 2018; Sinyavskaya et al., 2018), we found that both telmisartan and rosuvastatin significantly alleviated the progression of cognitive impairment and reduced the risk of dementia even after adjustment for confounders including the level of education and the status of hydrochlorothiazide administration. A previous study indicated that telmisartan performed slightly better than placebo on attenuating the progression of cognitive impairment and the risk of dementia (Zhang et al., 2019).

In a case-control and retrospective cohort study, the use of statins was associated with a lower prevalence of dementia and improved MMSE scores compared to patients who did not receive statin treatment (Hajjar et al., 2002). A previous study (Ji et al., 2018) showed that the risk of white matter hyperintensity progression was lower in the rosuvastatin than in the placebo group, which could underlie the lower risk of dementia and cognitive impairment progression in the former patients.

In this study, we observed that telmisartan synergistically interacted with rosuvastatin to reduce the progression of cognitive impairment and the risks of dementia. This result may be due to the fact that telmisartan mainly lowers blood pressure whereas rosuvastatin mainly lowers plasma lipid. As is known, hypertension is often

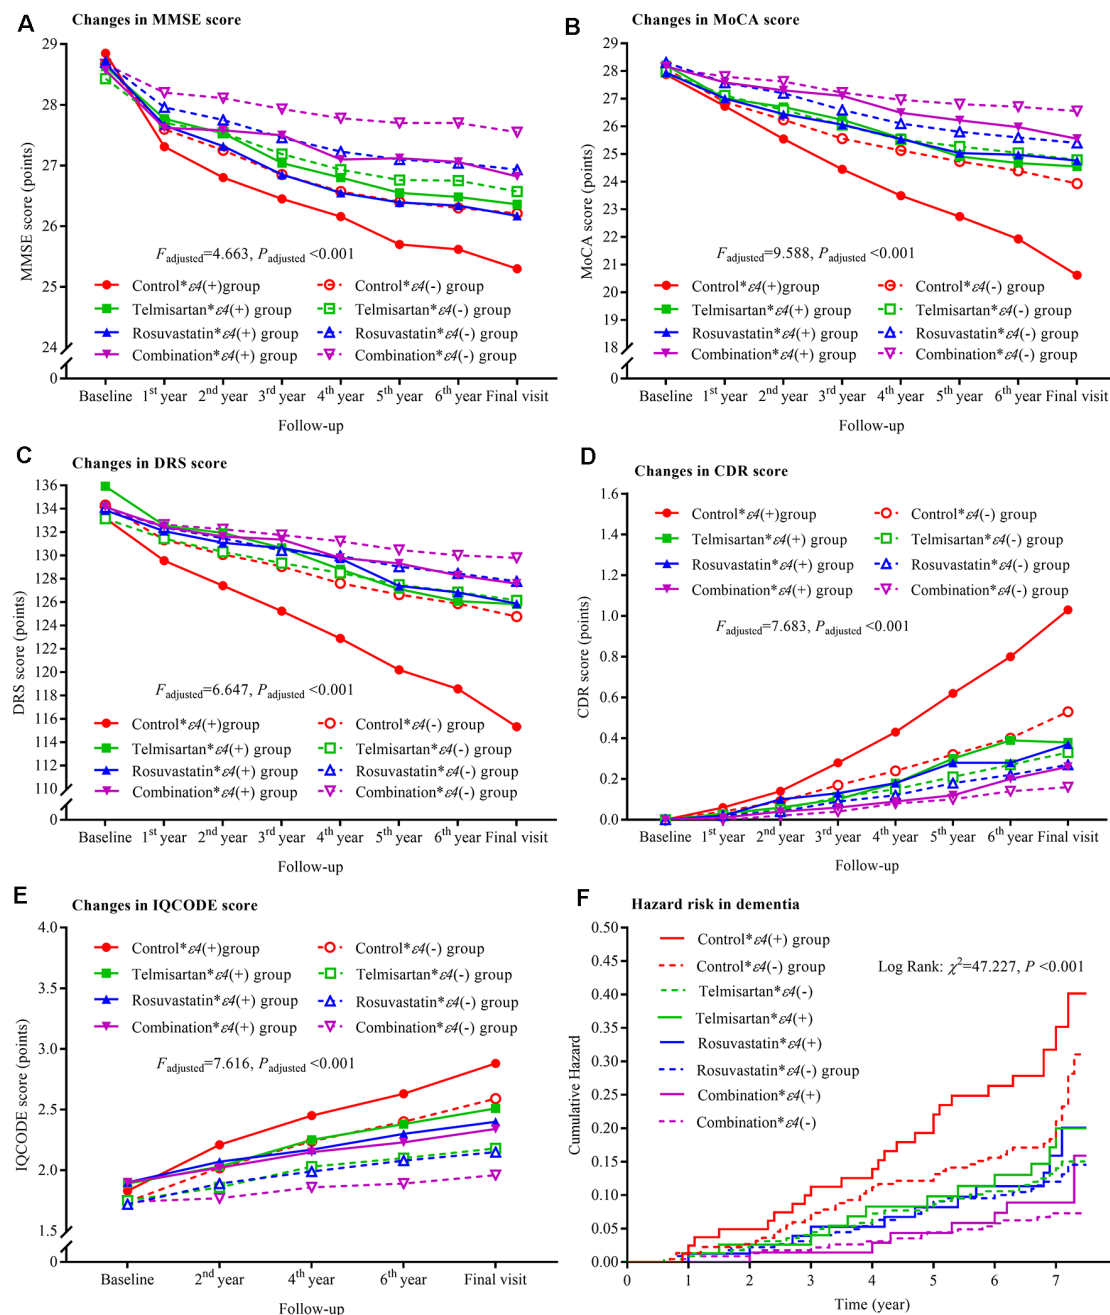

**FIGURE 4 |** Trajectory of global cognitive function and IQCODE and cumulative hazards of dementia incidence during the follow-up period in the patients grouped by rosuvastatin administration and APOE genotype. Panel (A) is the trajectory of MMSE; panel (B) is the trajectory of MoCA; panel (C) is the trajectory of DRS; panel (D) is the trajectory of CDR; panel (E) is the trajectory of IQCODE, and panel (F) is the cumulative hazard of dementia incidence. MMSE, Mini-Mental Scale Estimation; MoCA, Montreal Cognitive Assessment; DRS, Mattis Dementia Rating Scale; CDR, Clinical Dementia Rating; IQCODE, Informant Questionnaire on Cognitive Decline in the Elderly; APOE, apolipoprotein E.

accompanied by dyslipidemia. Another reason might be that telmisartan and rosuvastatin exhibit pleiotropic and protective effects on the cardio- and cerebrovascular systems including anti-inflammatory and antioxidant effects (Rizos et al., 2013; Liu et al., 2014), which is significant since inflammation and oxidative stress play important roles in

dementia and cognitive impairment (Bulzacka et al., 2016; Liu et al., 2018).

Genotype frequencies can be used to evaluate the efficacy of health care practices. In this study, we observed that the risk of dementia in the patients with APOE  $\epsilon 4$  allele was higher than those without APOE  $\epsilon 4$  allele irrespective of treatment they

**FIGURE 5 |** Trajectory of global cognitive function and IQCODE and cumulative hazards of dementia incidence during the follow-up period in the patients grouped by telmisartan, rosuvastatin, and APOE genotype. Panel (A) is the trajectory of MMSE; panel (B) is the trajectory of MoCA; panel (C) is the trajectory of DRS; panel (D) is the trajectory of CDR; panel (E) is the trajectory of IQCODE, and panel (F) is the cumulative hazard of dementia incidence. MMSE, Mini-Mental Scale Estimation; MoCA, Montreal Cognitive Assessment; DRS, Mattis Dementia Rating Scale; CDR, Clinical Dementia Rating; IQCODE, Informant Questionnaire on Cognitive Decline in the Elderly; APOE, apolipoprotein E.

received. We did not find any interaction between telmisartan and APOE  $\epsilon 4$  allele. However, as expected, a significant interaction was found between rosuvastatin and APOE  $\epsilon 4$  allele. The differences in the changes in global cognitive function from baseline were not significant between rosuvastatin \*  $\epsilon 4(-)$  and rosuvastatin \*  $\epsilon 4(+)$  groups and between combination \*  $\epsilon 4(-)$

and combination \*  $\epsilon 4(+)$  groups. A previous study showed that the risk factors for the incidence of small cerebral vessel diseases including white matter hyperintensities, lacunes, and microbleeds that were strongly associated with dementia and cognitive impairment in subjects with APOE  $\epsilon 4$  allele were markedly mitigated by rosuvastatin (Ji et al., 2018). Meanwhile,

*APOE*  $\epsilon 4$  allele is closely associated with elevated levels of plasma lipids and has been demonstrated to increase the risk of dementia and cognitive impairment (Mahely and Huang, 1999; Reitz, 2012). Thus, the risks of dementia might be reduced by rosuvastatin in subjects with *APOE*  $\epsilon 4$  allele that has been regarded as a statin treatment threshold in clinical practice (Davies et al., 2011).

One of the major strengths of our study is that dementia was diagnosed using the combination of global cognitive function scale testing the patients themselves and based on the informant interview on cognitive decline. Second, the changes in blood pressure and lipids and the stroke incidence were included as confounders in analysis models. Third, the impact of *APOE* genotype on the treatment of telmisartan, rosuvastatin, and their combination was examined. The randomized, double-blind, placebo-controlled design and long-term follow-up might also be an advantage in this study.

On the other hand, our study also had several limitations. Firstly, hydrochlorothiazide was used as a basic medication in all patients. It is difficult to distinguish between these two groups in terms of differences in the incidence of dementia and cognitive impairment, although the status of hydrochlorothiazide administration was adjusted in the analysis models. Second, we did not consider the effects of ethnicity and gender. A previous meta-analysis showed that these factors do not alter the influence of the *APOE*  $\epsilon 4$  allele in dementia (Farrer et al., 1997), whereas others have reported that the effects of statins on Alzheimer's disease patients varied according to race (Zissimopoulos et al., 2017). The differences in gender may affect the treatments of statins and sartans on cognitive impairment (Zissimopoulos et al., 2017; Ji et al., 2018). Third, a lower socioeconomic status was found to be closely associated with an increased risk of dementia and cognitive decline (Russ et al., 2013; Rusmaully et al., 2017). Socioeconomic background could bias the results of this study. Fourth, dementia was not subclassified into Alzheimer's disease, senile dementia, and vascular dementia in this study. Lastly, we did not assess the effect of antiplatelet agents and antihyperglycemic medications as potential confounders on cognitive impairment and dementia in this study.

In conclusion, after over an average of 7 years' follow-up, our findings indicate that the combination of telmisartan and rosuvastatin might be an effective prevention and/or treatment strategy for cognitive impairment and dementia in hypertensive patients, especially in those with *APOE*  $\epsilon 4$  allele. However, our results should be validated by additional studies which take into account the differences in ethnicity, socioeconomic background, and statin agents.

Parkinson's disease (PD) is a neurodegenerative disease characterized by progressive degeneration of dopaminergic neurons, and at the cellular level by the formation of Lewy bodies in the central nervous system (CNS). However, the onset of the disease is believed to be localized to peripheral organs, particularly the gastrointestinal tract (GIT) and the olfactory bulb sooner before neuropathological changes occur in the CNS. Patients already in the pre-motor stage of PD suffer from various digestive problems and/or due to significant changes in the composition of the intestinal microbiome in this early stage of the disease. Detailed analyses of patient biopsies and autopsies as well as animal models of neuropathological changes characteristic of PD provided important information on the pathology or treatment of PD symptoms. However, presently is not clarified (i) *the specific tissue in the GIT* where the pathological processes associated with PD is initiated; (ii) *the mechanism* by which these processes are disseminated to the CNS or other tissues within the GIT; and (iii) which neuropathological changes could also serve as a *reliable diagnostic marker of the premotor stages of PD*, or (iv) *which type of GIT tissue* would be the most appropriate choice for routine examination of patient biopsies.

**Keywords:** Parkinson's disease, alpha-synuclein, gastrointestinal tract, enteric nervous system, animal models, wholemount tissue staining

## INTRODUCTION

Parkinson's disease (PD) with the prevalence of approximately 2%, is the second most common neurodegenerative disease in the world after Alzheimer's disease (AD) (de Lau and Breteler, 2006), in which the incidence increases rapidly with age (Dauer and Przedborski, 2003). Most cases of PD, approximately 90%, represent the idiopathic forms of the disease (Hansen and Li, 2012). The disease is characterized by progressive degeneration of dopaminergic neurons in the central nervous system (CNS), namely, the *substantia nigra pars compacta* (SNpc), and dopamine (DA) deficiency in the striatum, which is associated with the occurrence of many motor and non-motor symptoms (Dauer and Przedborski, 2003; Jankovic, 2008; Santos et al., 2019). In addition to the characteristic clinical motor symptoms such as tremor, bradykinesia, stiffness and postural instability, the disease is also manifested by non-motor symptoms, most commonly by dysfunction of the gastrointestinal tract (GIT) and olfaction (Braak et al., 2003).

The neuropathological feature of PD is the formation of intraneuronal cytoplasmic eosinophilic protein inclusions, Lewy bodies (LB) and Lewy neurites (LNs) in neurons of both the central and

enteric nervous systems (ENS). The major component of LB and LNs, among other proteins, is pathologically aggregated alpha-synuclein ( $\alpha$ S) (Braak et al., 2006; Caputi and Giron, 2018). The  $\alpha$ S is a presynaptic protein whose exact physiological function is currently not fully understood, but its localization in the presynaptic nerve terminals may indicate an influence on the regulation of synaptic vesicle transduction (Cabin et al., 2002; Trancikova et al., 2011). Physiologically,  $\alpha$ S most commonly occurs in the form of stable unfolded monomers (Eliezer et al., 2001) or folded tetramers (Bartels et al., 2011). Oligomers, protofibrils, and fibrils (Lashuel et al., 2013), typically phosphorylated at serine 129 (S129) (Okochi et al., 2000; Fujiwara et al., 2002) are considered to be pathological conformers associated with the  $\alpha$ S pathogenesis in neurodegenerative diseases (Figure 1).

As early as the beginning of the 21st century, Braak et al. (2003, 2006) suggested that the development of PD initiates in the ENS based on the effect of an unknown toxin and/or pathogen, and progresses to the CNS through anatomical connections of these systems or that ENS may be affected by PD pathology in the initial stage of the disease. However, the exact GIT localization of initial PD pathology and specific mechanisms of disease spreading to the CNS are still not fully understood.

The aim of this article is to: (i) summarize experimental possibilities of early PD diagnosis based on biopsies and autopsies of PD patients and animal models; (ii) on the basis of current knowledge, delineate possible mechanisms by which the disease can develop and spread in the CNS, and (iii) finally, we focused on the complexity and lack of information in the studies and attempted to explore the possibilities for improving the detection of PD-related pathological processes in GIT tissues.

## IMPACT OF PD-ASSOCIATED PATHOLOGICAL PROCESSES ON THE ENTERIC NERVOUS SYSTEM

The enteric nervous system (“second brain”) is a complex neural network made up of about 100 million neurons (Furness, 2008) consisting of two plexuses: myenteric (Auerbach's) and submucosal (Meissner's). These innervate both the proximal part of GIT, the oral cavity, the salivary glands, the esophagus, and the stomach; as well as the distal GIT, the small intestine, colon and rectum (Lebouvier et al., 2009; Visanji et al., 2014). The myenteric plexus is located between the longitudinal and circular muscle layers throughout the entire GIT, where it controls mainly smooth muscle activity and motility. The submucosal plexus is mainly present in the small and large intestine, to a lesser extent in the stomach, while in the esophagus it is not present at all (Visanji et al., 2014). Enteric neurons are unevenly distributed in both plexuses, ENS along the entire GIT consists of intrinsic innervation located in the gastrointestinal wall and extrinsic innervation derived from sympathetic and parasympathetic nervous systems. Regulation of GIT function, such as motility and secretion by the ENS is independent of the CNS. However, ENS is bidirectionally connected to the CNS and together they form the so-called gut–brain axis (GBA) at the

level of the autonomic nervous system (Lebouvier et al., 2009; Carabotti et al., 2015). Despite the fact that the ENS controls the physiological processes taking place in GIT independently of the CNS, the link between the two systems mediates their mutual influence (Rao and Gershon, 2016). Because of this connection, a healthy organism maintains intestinal homeostasis, and vice versa, neurodegenerative CNS diseases are reflected in ENS disorders and thus in gastrointestinal problems of patients. This causality is also seen in other neurodegenerative diseases such as AD, transmissible spongiform encephalopathies, or amyotrophic lateral sclerosis (Spielman et al., 2018), while GIT disorders often result in CNS-related symptoms (Caputi and Giron, 2018). The ENS, similar to the CNS, also contains a small proportion of dopaminergic neurons present at higher concentrations in both plexuses of the proximal parts of the GIT, with a decreasing tendency in its distal parts (Anlauf et al., 2003). However, the correlation between PD and the loss of dopaminergic neurons in GIT has only been demonstrated by Singaram in the analysis of colon tissues from patients with developed PD (Singaram et al., 1995). The study of the presence of LBs and LNs is still receiving a great deal of attention. We will deal with this issue in more detail in the following sections.

We must not forget the effect of the intestinal microbiome on the gut–brain relationship and their crosstalk. The intestinal microbiome constantly interacts with the ENS, either through bacterial metabolites or components of the bacterial walls and thus influences neural transmission in the ENS (Thomas et al., 2012; Forsythe and Kunze, 2013; Elfil et al., 2020). The intestinal epithelium forms a barrier that prevents the passage of harmful content and at the same time allows the absorption and secretion of nutrients (Marchiando et al., 2010; Chapelet et al., 2019) or drugs (Jin et al., 2019). The composition of the intestinal microbiota affects the proper function of this barrier, by regulating the expression of the tight junction proteins such as occludin, claudins, and zonula occludens-1 (ZO-1) (Bhattarai, 2018; Chapelet et al., 2019). Increased bowel permeability, called “leaky gut,” is typical for patients with early PD (Forsyth et al., 2011), when the function of the intestinal barrier is disrupted with subsequent inflammatory processes and increased oxidative stress. This environment further promotes  $\alpha$ S accumulation and aggregation in the ENS (Sampson et al., 2016). Consistent with these findings, decreased expression of some tight junction proteins has been found in animal PD models (Gorecki et al., 2019; Dodiya et al., 2020) or in PD patients (Maes and Leunis, 2008; Clairembault et al., 2015a). In addition, increased expression of inflammatory cytokines and glial markers, also detected in GIT biopsies of PD patients, was positively correlated with disease progression and severity (Devos et al., 2013; Lin et al., 2019; Elfil et al., 2020).

An even higher incidence of peptic ulcer and *Helicobacter pylori* infections has been found in patients with PD up to 8–10 years before the onset of motor symptoms (Alvarez-Arellano and Maldonado-Bernal, 2014; Elfil et al., 2020). PD-associated neurodegeneration is likely to occur through the *Helicobacter pylori*-induced autoimmune and inflammatory response with increased production of pro-inflammatory cytokines and leukocyte activation. These can cross the disrupted blood–brain

barrier (BBB), causing neurotoxicity and neurodegeneration (Dobbs et al., 2008; Elfil et al., 2020). In addition, *Helicobacter pylori* infection is associated with decreased L-DOPA absorption, whether due to *Helicobacter pylori*-induced inflammatory response in the gut of PD patients or increased gastric acid secretion. In these patients, eradication of *Helicobacter pylori* led to an improvement in L-DOPA responsive motor problems (Pierantozzi et al., 2006; Lee et al., 2008; Elfil et al., 2020). Several studies have confirmed reproducible and significant changes in the intestinal microbiome composition that correlate with PD-related motor symptoms (Scheperjans et al., 2015; Sampson et al., 2016; Perez-Pardo et al., 2017; Elfil et al., 2020). These changes are summarized in detail by several authors (Sun and Shen, 2018; Chapelet et al., 2019; Elfil et al., 2020; Shen, 2020).

These authors agree that the intestinal microbiome is also important for the development of the “parkinsonian intestine” phenotype. For example, a significantly increased concentration of *Enterobacteriaceae* in PD patients, which correlates with the severity of postural instability and gait difficulty. Conversely, reduced level of *Prevotellaceae* family correlates with increased intestinal permeability and vitamin B1 and B9 deficiency in these patients (Scheperjans et al., 2015). In addition, significantly reduced levels of the *Lactobacillaceae* family (Mukherjee et al., 2016) in patients with PD are mainly associated with the development of inflammatory processes, since anti-inflammatory effects are attributed to this bacterial family (Borre et al., 2014; Scheperjans et al., 2015; Unger et al., 2016). Decreased levels of some bacterial families (such as *Prevotellaceae*, *Lactobacillaceae*, *Lachnospiraceae*) in PD patients are interesting in terms of their ability to reduce short-chain fatty acid (SCFA) levels (Scher et al., 2013; Zmora et al., 2019) or ghrelin (Song et al., 2017; Yanagi et al., 2017). Both SCFA and ghrelin have a neuroprotective function, so their reduced levels observed in patients with PD can be considered not only as one of the critical factors of PD but also potentially reflect disease severity (Hill-Burns et al., 2017; Song et al., 2017; Elfil et al., 2020).

Intestinal microbiota may also affect drug metabolism and uptake, as confirmed by a negative correlation in the case of

*Prevotellaceae* or, conversely, a positive correlation in the case of *Turicibacteraceae* (Lin et al., 2019). In this context, the positive effect of probiotic supportive treatment on the motor as well as non-motor symptoms of the disease was confirmed not only in PD patients (Tamtaji et al., 2019) but also in experimental animal models of PD (Srivastav et al., 2019; Hsieh et al., 2020).

## LOCALIZATION OF PATHOLOGICAL FORMS OF $\alpha$ -SYNUCLEIN IN THE ENS OF PD PATIENTS

Since Qualman et al. (1984) published the presence of LBs in the esophagus in 1 PD patient and 1 PD patient in the colon in 1984, an increasing number of post-mortem and *in vivo* studies have focused on finding or developing a suitable method for reliable detection of neuropathological changes in peripheral organs that would be suitable for taking biopsies. Pathologically aggregated  $\alpha$ S in GIT has been identified to date in biopsies of PD patients from different parts of GIT (summarized in Table 1). However, the number of studies provided, the size of the individual groups used in these studies and controversy in obtained results (see below) does not make it possible to clearly determine the primary initiation site of the disease pathology onset within GIT and where or to which organs the pathology subsequently spreads (Cersosimo, 2015).

### Salivary Glands and Pharynx

Salivary glands as a tissue with a relatively high number of  $\alpha$ S aggregates have been studied in autopsies (Beach et al., 2010) as well as in biopsies of PD patients (Cersosimo et al., 2011). The presence of  $\alpha$ S inclusions in minor salivary glands biopsies was confirmed in all PD ( $n = 3$ ) patients, whereas control biopsies ( $n = 3$ ) did not show this pathology (Cersosimo, 2015).

A needle core biopsy of the submandibular gland of PD revealed the presence of LBs was confirmed in 75% of cases but the study did not include control patients or patients with another type of neurodegenerative disease. However, due to minimal

**TABLE 1** | Summary of studies focused on the presence of pathological forms of  $\alpha$ S in various peripheral tissues.

The only direct evidence of PD-related neuropathological changes in the ENS seems to be the confirmation of the presence of pathological forms of  $\alpha$ S and protein inclusions in the peripheral tissues of PD patients. The table summarizes the numbers of patients and controls in each study, broken down by the peripheral tissue of interest. Detected forms of  $\alpha$ S and the study outcomes are indicated. PD, Parkinson's disease;  $\alpha$ S,  $\alpha$  Synuclein; ND, not defined; T, total; P, phosphorylated at S129; AGG, aggregated; LBs, Lewy bodies; LN<sub>s</sub>, Lewy neurites; LTS, Lewy type synucleinopathy; A, autopsy; B, biopsy.

invasiveness, the possibility of using only local anesthesia, and the overall simplicity and reproducibility, this method presents a suitable method for monitoring Lewy body pathology in patients with PD (Adler et al., 2014).

Dysphagia is one of the many clinical problems of PD patients but often leads to more serious clinical complications, such as aspiration pneumonia, the most common cause of death in PD patients (Mu et al., 2013). Analysis of the pharynx autopsies of patients with confirmed PD ( $n = 10$ ) and control samples ( $n = 4$ ) confirmed the presence of phosphorylated  $\alpha$ S (P- $\alpha$ S) aggregates in the sensory nerve axons of all PD patients with PD, compared to control samples. Patients with dysphagia even exhibited more  $\alpha$ S-positive fibers than PD patients without diagnosed dysphagia. These results, therefore, suggest that pharyngeal sensory nerves are primarily affected by PD pathology, which may be related to subsequent sensitization of pharyngeal tissue, presence of oedema and further development of dysphagia in PD patients (Mu et al., 2013).

## Esophagus

At about the same time as Qualman published the first mention of LBs in ENS, Wakabayashi et al. (1988) focused on autopsies of GIT tissues in patients with histologically confirmed PD ( $n = 7$ ). The presence of LBs was observed across the entire GIT with the highest concentration in the myenteric plexus at

the lower part of the esophagus. However, healthy individuals (8/24) also showed LB-positivity (Wakabayashi et al., 1988). Extensive analysis of the presence of P- $\alpha$ S in autopsies of various tissues of patients not only with PD ( $n = 17$ ) but also AD ( $n = 19$ ), dementia with LBs (DLB,  $n = 9$ ) and incidental Lewy body disease ( $n = 7$ ) in comparison with healthy individuals ( $n = 23$ ), confirmed the rostrocaudal P- $\alpha$ S distribution in the GIT of PD patients. The highest incidence was detected in the submandibular gland and lower part of the esophagus, while the concentration of aggregates decreased in the stomach, small intestine, colon, and rectum and even no presence of P- $\alpha$ S positive inclusions has been reported in the upper 2/3 of the esophagus (Beach et al., 2010).

Similarly, in a post-mortem histopathological study of tissues derived from the CNS and autonomous nervous system from PD patients PD ( $n = 10$ ), DLB ( $n = 5$ ) and others ( $n = 13$ ) including atypical parkinsonism and dementia without LBs ( $n = 13$ ), the presence of  $\alpha$ S aggregates was confirmed in all PD and DLB case, in contrast to the atypical form of parkinsonism and dementia without LBs. These aggregates have been confirmed not only in GIT tissues, but also in the adrenal gland, heart, sympathetic ganglia, vagus nerve, and genitourinary tract, with the typical rostrocaudal distribution. Distal esophagus and stomach contained the most observed  $\alpha$ S aggregates, while the rectum contained the least (Gelpi et al., 2014).

## Stomach and Small Intestine

Analysis of the gastric mucosa in PD patients, control subjects, including cases with premotor symptoms, confirmed  $\alpha$ S inclusions in the gastric mucosa were found in (17/28) patients with PD, in control biopsies (1/23) and patients with premotor symptoms (1/6) (Sanchez-Ferro et al., 2015). Besides that, the intraneuronal  $\alpha$ S-positive inclusions have also been observed across the entire gastric ENS (cardia, fundus, pylorus), in the myenteric and submucosal plexus, as well as in the peripheral nerves found in the adventitia, in autopsies obtained from the brain and stomach of patients with sporadic PD (Braak et al., 2006). Also, the presence of  $\alpha$ S-positive LNs was determined in fundic, antral and duodenal submucosa biopsies from one PD patient (Poucllet et al., 2012).

## Colon

To date, the colon has been the most studied part of the GIT in relation to PD (Schneider et al., 2016). Several studies have confirmed the occurrence of P- $\alpha$ S-positive LNs in colon biopsies from PD patients suggesting that conventional colon biopsies can be used to study the submucosal plexus of the ENS (Lebouvier et al., 2009, 2010; Shannon et al., 2012a,b; Gold et al., 2013; Visanji et al., 2014; Clairembault et al., 2015a).

In colon biopsies from PD patients (21/29) but not in healthy individuals (0/10), Lebouvier observed  $\alpha$ S-positive LNs along with the loss of neurofilament-positive neurons in the ganglia. This increased number of LNs correlated with PD symptoms (Lebouvier et al., 2010). Similarly, Clairembault et al. (2015a) detected P- $\alpha$ S-positive LNs in the submucosal plexus of the colon (23/31). In all cases, control samples were negative for P- $\alpha$ S.

Several studies have focused on early PD symptoms in the GIT, and thus on pre-motor PD patients (Shannon et al., 2012a,b; Hilton et al., 2014; Visanji et al., 2014). Shannon et al. (2012a) confirmed the presence of  $\alpha$ S in colon biopsies confirmed in all premotor PD patients (9/9) but not in healthy individuals (0/23), supporting the hypothesis of the incidence of pathological  $\alpha$ S in GIT tissues in the pre-motor stages of the disease. In addition, increased oxidative stress was present in PD patients as well as in both control groups, suggesting that the pathological occurrence of  $\alpha$ S is not the result of an inflammatory process or oxidative stress (Shannon et al., 2012b). Visanji et al. (2015) compared the presence of  $\alpha$ S and P- $\alpha$ S in colon biopsies from patients at various stages of the disease (early PD  $n = 15$ ; late PD  $n = 7$ ) and healthy individuals ( $n = 11$ ). However, the analysis did not confirm the difference in the presence of  $\alpha$ S and P- $\alpha$ S within the studies groups, mainly due to the high positivity for  $\alpha$ S and P- $\alpha$ S in control samples (Visanji et al., 2015). To date, the largest study has focused on analyzing the accumulation of pathological P- $\alpha$ S in various types of GIT tissues in patients with a very early pre-motor phase of the disease, at least 8 years before the first motor symptoms of PD. Together, they studied 117 biopsies from 62 PD patients and 161 samples from healthy subjects. Accumulation of P- $\alpha$ S was confirmed in mucosal and submucosal neurites in only seven PD patients, with all control biopsies without positive findings. Regarding GIT tissues, P- $\alpha$ S positivity was detected in gastric, duodenal and colon biopsies. However, in contrast to the

abovementioned studies by Qualman et al. (1984), Wakabayashi et al. (1988), and Gelpi et al., 2014, esophageal samples did not confirm this positivity (Hilton et al., 2014).

In colon mucosa biopsies of idiopathic PD patients,  $\alpha$ S positivity was present in most PD subjects studied (18/19), but P- $\alpha$ S was found in all PD patients (19/19) and all healthy individuals (8/8) (Antunes et al., 2016). When comparing colon biopsy samples of PD patients with AD and healthy individuals, up to 53% of all study subjects being positive for  $\alpha$ S in an age-independent manner. While all samples from PD patients (10/10) were positive for  $\alpha$ S, with significantly higher prevalence and expression compared to the control group, AD patients were in most cases negative for the presence of  $\alpha$ S or did not exceed the control group (Gold et al., 2013).

A recent study focused not only on the detection of pathological forms of  $\alpha$ S in the GIT, but the results have been correlated with non-motor symptoms of the disease (Lee et al., 2018). However, the presence of  $\alpha$ S in gastric and colonic biopsies of PD patients ( $n = 35$ ) and healthy individuals ( $n = 52$ ) did not significantly correlate with complex GI dysfunction such as constipation, dyspepsia, abdominal pain or with the deterioration of a specific intestinal segment (Lee et al., 2018). Despite the relatively large sample of subjects studied, this study has several limitations: (i) analysis of deeper intestinal layers (especially ENS of submucosal and myenteric plexuses) and other GIT tissue types, (ii) immunohistochemical staining for pathological  $\alpha$ S, (iii) the use of conventional histological approach only, (iv) lack of other experimental methods (e.g., biochemical) and (v) the low sample quality.

In general, the results agree that immunohistochemical confirmation of colorectal  $\alpha$ S pathology in PD patients may be a suitable pre-mortem diagnosis of the disease. However, due to the slight inconsistency of the results in relation to healthy individuals, it is necessary to extend the standard immunological analysis to other types of analysis. Corbille et al. (2016) evaluated and compared four different immunohistochemical methods for optimal detection of Lewy-type synucleinopathy from submucosal colon biopsies of PD patients ( $n = 9$ ) and healthy individuals ( $n = 3$ ). However, none of the compared  $\alpha$ S detection methods, granular staining in the *lamina propria*, perivascular/vascular wall submucosal staining, lacy-granular pattern in the submucosa and epithelial cell nuclear staining, showed specificity and sensitivity of more than 80%, which evaluates these methods as inadequate for routine PD diagnostics (Corbille et al., 2016). Similarly, biochemical analysis by one-dimensional or two-dimensional electrophoresis of colon biopsy samples from 17 PD patients ( $n = 17$ ) and healthy individuals ( $n = 13$ ) did not confirm a difference in  $\alpha$ S expression levels, phosphorylation and aggregation between the groups in the study (Corbille et al., 2017). These findings reflect the limitations of individual methods suggesting the need for new and more sensitive methods, as well as the necessity to combine several methodologies for an accurate diagnosis.

Furthermore, Fenyi et al. (2019) recently studied GIT biopsies from the antrum, sigmoid colon and rectum from 18 PD patients and 11 healthy individuals. However,

the classical immunohistochemical detection has been extended by the protein misfolding cyclic amplification (PMCA) assay. Interestingly, control subject with positive PMCA test subsequently developed PD symptoms. The immunohistochemical detection revealed the presence of P- $\alpha$ S in 5/15 PD samples, with four of these samples also being PMCA positive, indicating the diagnostic potential of the PMCA method. Control samples did not show any positivity for P- $\alpha$ S. Rectal biopsy does not represent a possibility of obtaining material in the case of PMCA due to insufficient number of  $\alpha$ S aggregates (Fenyi et al., 2019).

## Appendix

It is now well documented that the vermiform appendix is part of the immune tissues associated with GIT, and also serves as a reservoir of the intestinal microbiome (Killinger and Labrie, 2019). Nevertheless, the mechanisms by which the appendix affects intestinal immunity and microbiome are still unknown today. In relation to PD, epidemiological studies have found that early appendectomy correlates with a reduction in the risk of developing PD (Killinger et al., 2018). This is probably due to the presence of aggregated  $\alpha$ S also in healthy individuals in the mucosa and enteric plexuses of the appendix (Killinger et al., 2018). The fact, that a higher density of  $\alpha$ S aggregates in the appendix was detected in PD patients as well as asymptomatic patients (Stokholm et al., 2016) suggest, that misfolded  $\alpha$ S accumulates in the appendix, from where the pathology may have spread to other organs. Therefore, early removal of lymphoid organs with accumulated misfolded  $\alpha$ S could potentially represent a therapeutic tool for patients in the early stages of PD or with familiar form (Gray et al., 2014; Killinger et al., 2018).

## ANIMAL MODELS

Animal models in PD research represent an irreplaceable source of new knowledge, whether in connection with the understanding of the pathomechanisms that of PD initiation and progression, but also as preclinical models of PD (Metzger and Emborg, 2019). They can also help to elucidate whether intestinal dysbiosis is a cause or a consequence of PD-related pathology. However, no animal model can recapitulate all the symptoms and processes associated with the pathogenesis and progression of PD (summarized in **Table 2**) (Klingelhoefer and Reichmann, 2015). Just in an effort to address these shortcomings, a new generation of PD models is constantly being developed (Metzger and Emborg, 2019).

## Toxin-Induced Models

Toxin-induced models are widely used models mainly due to the relatively simple use of the toxin, clear phenotype, the rapid onset of motor or non-motor symptoms of the disease and the ability to reflect motor complications of antiparkinsonian drugs, such as L-DOPA-induced dyskinesia (Morin et al., 2014; Taguchi et al., 2020b). The disadvantage is the exposure of experimenters to toxins, the frequent criticism that the concentrations used

to induce PD-related symptoms do not commonly occur in the natural environment, but in particular that robust motor phenotypes may interfere with the analysis of non-motor symptoms (Taguchi et al., 2020b).

## Rotenone Models

Rotenone is a highly lipophilic pesticide that readily crosses the BBB, spreads to neurons, and accumulates in mitochondria, where it acts as an inhibitor of mitochondrial complex I (Duty and Jenner, 2011). Rotenone-induced rodent models of PD are able to reproduce the neuropathological, anatomical as well as behavioral properties of the disease (Betarbet et al., 2000). In addition to the neurodegeneration of the nigrostriatal dopaminergic system and the presence of cytoplasmic inclusions in these neurons, accompanied by motor problems (Tieu, 2011), non-motor symptoms at the GIT level were also observed (Drolet et al., 2009; Greene et al., 2009; Tieu, 2011). However, Tasselli et al. (2013) did not confirm the delay in gastric emptying after oral application of rotenone to mice, despite the present neurodegeneration in *SNpc*. Similarly, the presence or absence of LB or pathological  $\alpha$ S in the GIT or ENS depends on the route of rotenone administration, the dose used, and the length of exposure (Drolet et al., 2009; Greene et al., 2009; Pan-Montojo et al., 2010; Metzger and Emborg, 2019).

Regarding microbiota changes in the GIT, a significant decrease in the beneficial *Bifidobacterium* bacteria (Perez-Pardo et al., 2018) or, conversely, an increase in Gram-negative mucin-degrading bacteria (*Akkermansia*) (Dodiya et al., 2020) were observed in the rotenone-induced PD model. Chronic stress is another factor leading to an increase in intestinal hyperpermeability and a reduction of anti-inflammatory bacteria (*Lactobacillus*) in experimental animals. In combination with rotenone, chronic stress even promoted its potential to induce CNS pathology, manifested by a significant increase in the number of dystrophic microglia, increased reactivity of lipopolysaccharides (LPS) in *SNpc* and decreased DA in the striatum compared to control mice (Dodiya et al., 2020).

## MPTP Models

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is a potent neurotoxin with high affinity for the DA transporter, as a result of which the metabolite MPTP (MPP<sup>+</sup>) accumulates in the mitochondria and acts as an inhibitor of mitochondrial complex I (Cleeter et al., 1992). MPTP is used to induce a parkinsonian-like phenotype in a number of mammalian animal models, e.g., in monkeys, mice, rats, swine, cats and sheep (Tieu, 2011). The mouse and monkey model are most commonly used, as the sensitivity to MPTP is comparatively lower in other mammals (e.g., rats) (Hisahara and Shimohama, 2010). The neuropathological effect of MPTP on the nigrostriatal DA pathway in animal models is similar to that observed in PD patients (Langston et al., 1999).

In ENS, an MPTP-induced significant decrease in dopaminergic neurons, tyrosine hydroxylase-positive (TH<sup>+</sup>), in the myenteric plexus has been described in monkeys (Chaumette et al., 2009) as well as in a mouse model of PD (Anderson et al., 2007). Other GIT dysfunctions have been described in a mouse

**TABLE 2 |** Overview of the most used animal models of PD, their associated phenotypes and AS pathology.

Model	Type	Motor phenotype	Non-motor phenotype	Animal	$\alpha$ S/Lewy pathology

$\alpha$ S,  $\alpha$  Synuclein; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, 6-OHDA, 6-hydroxydopamine, PFF, recombinant  $\alpha$ S preformed fibrils.

model, but the information is controversial in some cases. While Anderson et al., 2007 reported increased MPTP-induced colon motility as well as unchanged emptying time compared to control animals, several other authors observed a significant reduction in colonic motility and constipation (Natale et al., 2010; Ellett et al., 2016). Selective loss of TH+ neurons was observed in the myenteric and submucosal plexuses of the colon, but not in the esophagus and stomach. The decrease in DA was accompanied by an increase in  $\alpha$ S levels (Natale et al., 2010). Furthermore, in mice, MPTP-induced loss of TH+ neurons in ENS led to a strong immune response in the GIT (Cote et al., 2015; Ellett et al., 2016). Interestingly, partial depletion of pro-inflammatory M1 monocytes had a positive effect in terms of protecting ENS from TH+ neuronal loss, but this effect was not manifested in the CNS (Cote et al., 2015). On the other hand, therapeutics (CuII) with a neuroprotective effect on the CNS improve not only motor functions but also intestinal functions defined by improved stool frequency, reduced enteric glial cell reactivity and markers of inflammation, as well as restoration of neuronal subpopulations in myenteric plexus damaged by MPTP exposure. These results suggest the existence of similar pathomechanisms in the CNS and ENS (Ellett et al., 2016).

## 6-OHDA Models

6-OHDA is a hydroxylated DA analog acting as a selective catecholaminergic neurotoxin that inhibits mitochondrial complex I and IV (Glinka and Youdim, 1995) and produces reactive oxygen species in cells (Cohen and Heikkila, 1974). Since 6-OHDA cannot effectively cross the BBB, direct injection of this toxin into a specific site in the brain is required (Perese et al., 1989; Przedborski et al., 1995; Hisahara and Shimohama, 2010; Duty and Jenner, 2011). As early as 1968 (Ungerstedt, 1968), complete anterograde degeneration of the nigrostriatal dopaminergic neural system associated with motor problems was described in rats after administration of 6-OHDA into the SNpc. In addition to the ability to recapitulate the motor symptoms of the disease (Hisahara and Shimohama, 2010; Tieu, 2011), the 6-OHDA rat model mimics many of the biochemical features of PD, such as a reduction in DA and TH levels in the striatum (Duty and Jenner, 2011). However, like many other animal models of PD, the 6-OHDA model fails to induce the formation of LBs, an important pathological feature of PD.

Regarding pre-motor symptoms, several authors reported PD-like constipation in 6-OHDA animal models (Blandini et al., 2009; Zhu et al., 2012; Levandis et al., 2015; Zhang et al., 2015; Fornai et al., 2016). Unilateral (Zhu et al., 2012) or bilateral (Zheng et al., 2011) injection of 6-OHDA to SNpc of rats leads to a general decrease of central DA as well as delayed gastric emptying, suggesting that central DA may regulate GIT function (Zheng et al., 2011; Zhu et al., 2012; Metzger and Emborg, 2019).

## Paraquat Models

The herbicide Paraquat, (1,1'-dimethyl-4,4'-bipyridine) is the inducer of  $\alpha$ S aggregation and the oxidative stress in dopaminergic neurons (Kuter et al., 2007, 2010). Anselmi et al. (2017, 2018) reported a paraquat-induced decrease in gastric motility, and gastric tone, followed by increased  $\alpha$ S immunoreactivity in dorsal motor nucleus of the vagus (DMV) in a rat model of PD (Anselmi et al., 2017, 2018). Co-administration of subthreshold doses of paraquat with lectin directly into the stomach of rats leads to a progressive PD-like phenotype, represented by the decrease in TH+ neurons in SNpc, the presence of misfolded  $\alpha$ S in the SNpc and DMV, and L-DOPA responsive motor deficits. These symptoms were preceded by gastric dysmotility. Interestingly, vagotomy was able to block the spread of misfolded  $\alpha$ S outside the myenteric neurons and even prevented the development of PD-related symptoms in these rats (Anselmi et al., 2018).

## Genetic Models

Since the number of patients with the familial form of PD is significantly lower than the incidence of an idiopathic form of the disease, genetic research of affected families is very demanding (Hisahara and Shimohama, 2010). Particularly because of this fact, it is extremely important to develop appropriate genetic animal models for research to investigate the etiopathology of PD. In these models, we must not forget that the choice of promoter fully influences the observed phenotype, whether in terms of the level of expression or the regions in which this gene will be expressed. A disadvantage compared to toxic models is the slower onset of the phenotype, and also that only a few models show loss of DA neurons and an associated motor phenotype (Taguchi et al., 2020b). Nevertheless, these models can significantly contribute not only to the understanding of PD-related pathomechanisms

but also in the development of symptomatic or disease-modifying therapies that target non-motor symptoms associated with the disease. Therefore, efforts are constantly increasing to develop a PD model that would reproduce several PD-specific premotor symptoms at the same time, followed by slowly progressive DA neurodegeneration (Taguchi et al., 2020b).

## $\alpha$ S Overexpressing Models

In the case of  $\alpha$ S, it is known that quantitative, as well as qualitative changes in  $\alpha$ S, contribute to the development of PD. Several models have been developed, either based on overexpression of the wt  $\alpha$ S gene (SNCA) or with the insertion of pathological mutations (A53T, A30P) (Singleton et al., 2003; Chartier-Harlin et al., 2004; Ibanez et al., 2004; Taguchi et al., 2020b). As mentioned above, the choice of strong exogenous promoters used in these models affects not only the phenotype but also the spatial and temporal distribution of the pathology, which may not always reflect the real human PD pathology. However, in general, we can say that  $\alpha$ S transgenic models are able to recapitulate  $\alpha$ S aggregation, similar to PD patients (Taguchi et al., 2020b).

Overexpression of  $\alpha$ S (Thy1- $\alpha$ S) results in decreased basal stool, slower colonic transit time with significantly higher stool content (Wang et al., 2008). This manifestation was preceded by increased  $\alpha$ S in myenteric plexuses with numerous varicose terminals surrounding specifically immunoreactive pChAT neurons (Wang et al., 2012). Sampson et al. (2016) revealed that in Thy1- $\alpha$ S mice, microbial depletion reduces the CNS pathology, characterized by reduced accumulation of pathological  $\alpha$ S in the brain, as well as motor and GIT dysfunction. Microbiota transplants from PD patients lead to a significant deterioration of intestinal dysfunction as well as overall PD symptoms in these mice (Sampson et al., 2016). Similarly, colonization of curli (amyloid protein)-producing *Escherichia coli*, in Thy1- $\alpha$ S mice induces the  $\alpha$ S pathology in both the gut and brain, along with classical intestinal and motor dysfunctions. Interestingly, treatment of these mice with a gut-restricted amyloid inhibitor blocks the progression of curli-induced pathology (Sampson et al., 2020). These results confirm the role of intestinal microbiota and bacteria-produced amyloids in the progression of PD-related CNS pathology, presumably through microglial activation and neuroinflammation, suggesting a potential positive effect of antibiotic treatment on ameliorating GIT as well as CNS symptoms in PD patients (Sampson et al., 2016, 2020).

Several studies have addressed the induction of the PD phenotype by lipopolysaccharide (LPS). LPS is a pro-inflammatory bowel-derived bacterial endotoxin that has been shown to induce progressive nigrostriatal pathology (Qin et al., 2007; Liu et al., 2008; Kelly et al., 2014). In addition, an increased amount of LPS-producing *Gammaproteobacteria* or mucin-degrading bacteria *Verrucomicrobiaceae* has been confirmed in patients with PD (Gorecki et al., 2019). In Thy1- $\alpha$ S mice, low dose oral administration of LPS induces the early onset of motor symptoms along with increased  $\alpha$ S in the CNS. However, microbiota analysis did not confirm a higher rate of *Gammaproteobacteria* or the amount of

*Verrucomicrobiaceae*, which were even reduced. These results confirm that elevated central levels of  $\alpha$ S alone may not lead to early intestinal manifestations in PD (Gorecki et al., 2019). In contrast, induction of PD-related pathology by IP application of LPS in a wt mice led to increased  $\alpha$ S expression and accumulation of pathological P- $\alpha$ S specifically in the colon, accompanied by a temporary increased colon permeability. However, nigrostriatal degeneration or other significant pathological changes in the CNS have not been confirmed (Kelly et al., 2014).

## $\alpha$ S-A53T Transgenic Models

Previous studies using experimental animals have confirmed the role of the pathological A53T mutation of  $\alpha$ S in the development of PD-related motor and non-motor dysfunctions, such as age-related anxiety and loss of olfaction associated with  $\alpha$ S aggregation in the olfactory bulb as well as myenteric plexus and adrenal neurons (Farrell et al., 2014; Kujawska and Jodynis-Liebert, 2018; Taguchi et al., 2020b). Similarly, in PrP-A53T- $\alpha$ S (M83 tg) mice, the age-related significant accumulation of P- $\alpha$ S was detected first in the intestinal nervous system and later in the brain, but in both cases, it preceded the onset of motor symptoms of the disease (Bencsik et al., 2014). The combination of oral paraquat application in M83 tg mice accelerated the onset of  $\alpha$ S-associated pathology, with motor dysfunction as well as the presence of P- $\alpha$ S and neuroinflammation in ENS already present in young mice (Naudet et al., 2017). In the context of GIT symptoms, already young M83 tg mice show remarkable signs of gastrointestinal dysfunction, which precede motor abnormalities and CNS pathology. The presence of aggregated forms of  $\alpha$ S has been detected in neurons in both myenteric and submucosal plexuses but specifically only in the colon. The problems with intestinal peristalsis are indicated by a slowed transit time through the colon and an abnormal stool. This assertion was supported by electrically evoked contractions of the colon, which showed a reduced motor response in these mice (Rota et al., 2019).

Recently, a new BAC-A53T- $\alpha$ S mouse model with the insertion of two single nucleotide polymorphisms associated with familial PD or with an increased risk of sporadic PD has been published. The expression of pathological forms of  $\alpha$ S (truncated, oligomeric and phosphorylated) has been confirmed in areas consistent with clinical findings, including the olfactory bulb, cerebral cortex, striatum and SNpc. Among the first symptoms, the authors observed REM sleep disorders, with P- $\alpha$ S present in areas regulating neuronal populations in the lower brainstem such as the sublaterodorsal tegmental nucleus, nuclei in the ventromedial medullary reticular formation, and pedunculopontine nuclei. With the delay, the present hyposmia correlated with the accumulation of P- $\alpha$ S in the olfactory bulb. These manifestations appeared long before the degeneration of dopaminergic neurons in the SNpc. However, the authors did not observe any associated motor dysfunction (Taguchi et al., 2020a). Together, these results support the hypothesis that GIT dysfunction and other

non-motor symptoms represent an early symptom of  $\alpha$ S-mediated pathology without parallel involvement of the CNS (Farrell et al., 2014; Naudet et al., 2017; Rota et al., 2019; Taguchi et al., 2020a).

## Other Genetic Models

Mutations in *phosphatase and tensin homolog- (PTEN-) induced novel kinase 1* (PINK1) are associated with early-onset PD. In addition to its role in mitophagy (Narendra et al., 2008), it also plays an important role in adaptive immunity (Matheoud et al., 2016), supporting the hypothesis that autoimmune mechanisms are involved in the etiology of Parkinson's disease (Matheoud et al., 2019). The deletion of the *pink1* gene in mouse alone does not reflect the characteristic features of the disease, suggesting that the development of the disease symptoms is likely to occur in conjunction with other factors. In this respect, in a recent interesting study, the authors described that intestinal infection of PINK<sup>-/-</sup> mice with Gram-negative bacteria induces autoimmune mechanisms not only in the periphery but also in the CNS, which are presented by a decrease in the density of dopaminergic axonal varicosities in the striatum or L-DOPA responsive motor functions. The authors suggest that PINK1 also plays a role in immune system repression and support the gut-brain axis hypothesis of PD-related pathomechanisms (Matheoud et al., 2019).

MitoPark is a chronic, progressive mouse model that recapitulates several key motor (Ekstrand et al., 2007; Li et al., 2013; Ay et al., 2017; Langley et al., 2018) as well as non-motor (Ekstrand and Galter, 2009; Li et al., 2013; Ghaisas et al., 2019) aspects of PD. From the point of view of the GIT itself, among the first non-motor symptoms of PD, decreased motility of the GIT was observed with gradual progression of colon transit times, reduced fecal water content and intestinal inflammation characterized by activation of glial cells in the myenteric plexus. Later, a loss of TH<sup>+</sup> neurons was also observed, as well as reduced levels of DA in midbrain as well as in the intestine. Metabolomics analysis also showed slight changes in the composition of the intestinal microbiota or bacterial metabolites (Ghaisas et al., 2019). In this context, Hsieh et al. (2020) observed that long-term administration of probiotics has neuroprotective effects on dopamine neurons and significantly reduced motor dysfunction in MitoPark PD mice (Hsieh et al., 2020). These results suggest the neuroprotective potential of probiotics, probably due to their inhibition of glial cell activation and neuroinflammation, increased butyrate levels, and increased levels of some neurotrophic factors (Fang, 2019; Srivastav et al., 2019). However, the effects and basic mechanisms of such probiotic treatment in PD are unclear (Ghaisas et al., 2019).

## $\alpha$ S Propagation Models

Although  $\alpha$ S propagation models are still in development, but due to the shorter onset of the phenotype, their widespread use in terms of experimental models, they represent a promising model in the study of prodromal PD (Kim et al., 2019; Taguchi et al., 2020b). However, it should be borne in mind that different

approaches to the purification of  $\alpha$ S fibrils, as well as application in different models, can significantly affect the degree of their spread in cells as well as the observed phenotype (Uemura et al., 2018; Kim et al., 2019).

One possibility is the purification of pathological forms of  $\alpha$ S from extracts of human brain tissue from patients with dementia with LB (DLB) (Lee et al., 2011) or PD (Holmqvist et al., 2014). Injection of human brain tissue extracts from DLB patients containing stable  $\alpha$ S aggregates into the gastric walls of transgenic M83 tg mice resulted in increased deposition and aggregation of  $\alpha$ S in myenteric neurons, accompanied by a transiently increased inflammatory response in the GIT. These results indicate that pathological  $\alpha$ S aggregates may induce aggregation of endogenous  $\alpha$ S in myenteric neurons in M83 tg mice, suggesting the transmission of  $\alpha$ S-associated pathology within the ENS (Lee et al., 2011). Application of human brain tissue extracts from PD patients containing various physiological as well as pathological forms of  $\alpha$ S to the intestinal wall of rats confirmed retrograde transport of aggregated  $\alpha$ S through vagal nerves from the intestine to the brain and that slow and fast components of axonal transport are involved in this process (Holmqvist et al., 2014).

The second, frequently used, the possibility is the preparation of recombinant  $\alpha$ S preformed fibrils (PFF). Intramuscular administration of PFF in M83 tg transgenic mice resulted in motor disorders accompanied by the presence of CNS protein inclusions and neuroinflammation. Transection of the sciatic nerve in these mice significantly delayed the onset of CNS pathology as well as motor symptoms themselves, suggesting the involvement of retrograde transport in the induction of  $\alpha$ S pathology in the CNS (Sacino et al., 2014). Intraperitoneal or intraglossal application of PFF in M83 tg led to the development of paralysis and the presence of aggregated as well as P- $\alpha$ S in the CNS and spinal cord (Breid et al., 2016). In another study, the authors focused on the propagation of PFFs applied to the olfactory bulb of wild-type (WT) mice. They observed the progression of  $\alpha$ S-associated pathology initially manifested by the olfactory disorders, and gradually spread to distant areas of the brain (Rey et al., 2018). Uemura et al. (2018) focused on the propagation of  $\alpha$ S-associated pathology mediated by the injection of PFF into the gastric wall of WT or  $\alpha$ S-A53T BAC transgenic mice (Uemura et al., 2020). In the case of WT mice, the presence of aggregates of P- $\alpha$ S was observed in the DMV, which, however, did not progress further. Performed vagotomy resulted in a gradual reduction of P- $\alpha$ S aggregates in DMV but did not affect the P- $\alpha$ S-positive aggregates in the myenteric plexus (Uemura et al., 2018). When  $\alpha$ S PFF were applied to the gastric wall of  $\alpha$ S A53T BAC transgenic mice, they observed a significant increase in  $\alpha$ S levels in the brain as well as in stomach compared to WT mice, along with an increased amount of P- $\alpha$ S in DMV. These results indicate, that BAC transgenic expression of  $\alpha$ S promoted the propagation of  $\alpha$ S-associated pathology in the brainstem, but not subsequent caudo-rostral spread in line with Braak's hypothesis (Uemura et al., 2020).

## POSSIBLE PATHWAYS OF PD PATHOLOGY PROPAGATION FROM ENS TO CNS

According to Braak's model, neuropathological changes from GIT are transmitted through anatomical connections between ENS and CNS (Braak et al., 2003, 2006), with the initiation of PD pathogenesis in the ENS and DMV much earlier than *SNpc* pathology. This hypothesis is also supported by the results of biopsies, experimental animals but also with the use of cellular models. For example, in cellular models, the oligomeric  $\alpha$ S can be endocytosed by neurons and induce  $\alpha$ S aggregation in primary neuronal cultures (Lee et al., 2008; Desplats et al., 2009; Liu et al., 2009). Several either toxin-induced (Pan-Montojo et al., 2012) or PFF-propagation (Holmqvist et al., 2014; Uemura et al., 2018; Kim et al., 2019) mouse models demonstrated vagus-dependent transmission of  $\alpha$ S-pathology from peripheral tissues to the CNS followed by the development of motor symptoms. Slight differences in observations in these studies, such as the degree of  $\alpha$ S-pathology in the CNS, in some cases its gradual decrease with the inability to lead to the loss of dopaminergic neurons, may also be the result of various PFF purification as well as application protocols used in experiments (Kim et al., 2019). However, important findings were that the hemivagotomy or sympathectomy blocked (Pan-Montojo et al., 2012; Kim et al., 2019), reduced or at least delayed the observed CNS pathology. Similarly, in patients who underwent truncal vagotomy, the risk of PD was significantly reduced (Svensson et al., 2015; Tysnes et al., 2015). All these data suggest that transmission via nervus vagus is one of the possible ways of spreading  $\alpha$ S-related PD pathology.

On the other hand, in mice with PFF-induced pathology in the duodenum, the presence of  $\alpha$ S inclusion, has been observed in the ENS, intermediolateral spinal cord but also stomach, the dorsal motor nucleus of the vagus nerve, locus coeruleus and even heart. In control animals, these pathological features were not observed. These results open new possibilities for bidirectional  $\alpha$ S propagation through the *nervus vagus*: duodenum-brainstem-stomach, which means the possibility of secondary transmission of  $\alpha$ S pathology through the anterograde pathway after initial retrograde transmission (Van Den Berge et al., 2019).

An interesting view of the origin and development of PD-associated pathology is provided by the so-called "the threshold hypothesis," which is based on the parallel degeneration of PNS and CNS (Engelender and Isacson, 2017). According to this theory, almost non-motor symptoms in PD are the result of a "lower functional threshold of enteric neurons," due to their less-developed network with a smaller number of compensatory mechanisms and connections in the ENS compared to the CNS. As PD-associated motor symptoms occur with the loss of approximately 70% of dopaminergic neurons in the *SNpc*, multiple compensatory mechanisms are thought to exist in the CNS (Marsden, 1982; Hantraye et al., 1992; Wullner et al., 1994; Brownell et al., 1998; Cooper et al., 2009; Mou et al., 2020).

The authors claim that this principle reflects current knowledge of the neurobiology of PD better compared to Braak's

hypothesis. The main counter-arguments are that the only presumed mechanism of selective sensitivity of certain enteric neurons is the less developed compensatory mechanisms in the ENS and also that it does not explain experimental data on  $\alpha$ S-associated pathology between ENS and CNS (Mou et al., 2020).

Finally, we must not forget the observed changes in the composition of the intestinal microbiota in PD patients as well as in experimental animals. These changes may affect the local immune response, which leads to disruption of the mucosal barrier of the GIT and subsequent inflammatory reactions. Systemic inflammation as a result of migrated gut bacteria and cytokines may result in an impairment of BBB, progressively to neuroinflammation and through the over-response of the CNS immune system or CNS inflammatory response to neurodegeneration (Maes and Leunis, 2008; Clairembault et al., 2015b; Yang et al., 2017; Morais et al., 2018; Perez-Pardo et al., 2018; Dodiya et al., 2020). However, the role of the intestinal microbiota in the initiation and progression of PD-related pathology is currently unclear, as well as whether these changes in the intestinal microbiome are the cause or consequence of  $\alpha$ S-related pathology. In any case, changes in the composition of the intestinal microbiome, as well as gut inflammation, are considered a risk factor in the development of PD (Chapelet et al., 2019).

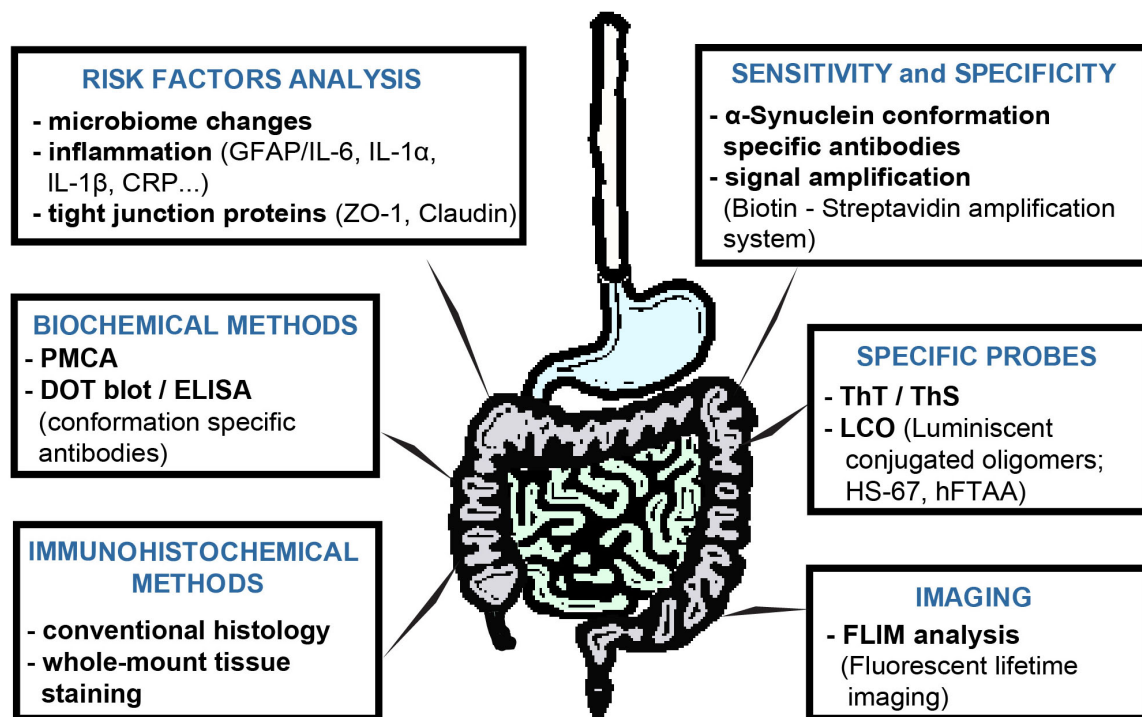

## CONCLUDING REMARKS AND PERSPECTIVES

The finding that primary PD pathogenesis occurs in peripheral tissues already several years prior the onset of typical motor symptoms suggests that it is extremely important to focus further PD research on early detection of disease, which could bring new treatment options to patients in early stages of PD and improvement of the life quality.

However, despite the incredible efforts and progress in this area, a number of principal questions remain unanswered. One of them poses the question of why, despite the presence of pathological  $\alpha$ S forms in peripheral tissues, for example in the appendix (Killinger et al., 2018), there is no pathogenesis of PD in all humans (Mazursky and Howitt, 2019).

Moreover, it is currently unknown which GIT tissue would be most suitable for early detection of neuropathological PD changes with respect to minimal invasiveness and patient safety. Therefore, further research into the pathogenesis of PD would need to focus on a more comprehensive examination of tissues, whether obtained from appropriate animal models or biopsy patients obtained both in the pre-motor stage of PD and after the onset of neuropathological changes in the CNS and the development of motor symptoms. These more detailed and, in particular, more comprehensive studies would help several questions to be answered:

- (i) in which part of the GIT the pathogenesis of PD occurs
- (ii) whether the pathology from that particular tissue progressively spreads to the CNS
- (iii) or is first disseminated within the GIT itself

**FIGURE 2 |** Possibilities to extend of  $\alpha$ S-detection methods in GIT tissues of PD patients or animal models. Each method has its limits, so in order to find a reliable method of PD diagnosis, a more comprehensive approach to the analysis of studied tissues is necessary. In contrast to conventional immunohistochemistry, immunohistochemical analysis of whole-mount tissues provides a more comprehensive view of the processes taking place in the studied tissue under. The conformation-specific antibody may significantly improve the ability to detect pathological  $\alpha$ S, as the detection of total  $\alpha$ S, or its phosphorylated form, does not appear to be sufficient at present. These can be used not only for immunohistochemical or biochemical analyzes and, together with various currently widely available signal amplification systems, they can increase not only the specificity but also the sensitivity of the given methods. PMCA appears to be very versatile and specific in detecting  $\alpha$ S pathological forms, as well as in distinguishing individual pathological  $\alpha$ S strains. Imaging methods may rely on the continuous development of either fluorescent probes or the development of the methodologies themselves. Luminescent-conjugated oligothiophenes (LCO) represent a new generation of probes with the ability to detect a broader spectrum of protein aggregate proteins, compared to conventional probes. In addition, based on changes in emission spectra, they also provide information on the conformation of the studied aggregated proteins. Fluorescent lifetime imaging (FLIM) reflects the qualitative changes near fluorophore, and therefore with higher sensitivity can detect very small, such as conformational, changes. Although the role of the intestinal microbiome in the PD pathogenesis is currently unclear, analysis of the intestinal microbiota, inflammatory response or permeability of the intestinal barrier can provide a more comprehensive view of the processes taking place in the GIT.

(iv) or the onset is localized across the entire GIT.

The next limiting step in such studies is the methodology itself. Each method, as we all know very well, has its limitations, advantages, and disadvantages, therefore, it is necessary not only to continually improve and optimize these methods but also to confirm the obtained results with other methodologies. Recent studies suggest that a combination of several methodologies could provide answers to the questions asked (Fenyl et al., 2019) (Figure 2). A large number of studies that we summarized in this review are based on immunohistochemical detection of neuropathological changes in the peripheral tissues of PD patients. In these types of experiments, however, very few studies are concerned with comprehensive research into PD neuropathology, often lacking appropriate control subjects, colocalization of several types of pathological forms of  $\alpha$ S, or confirmation of results by biochemical methods. Animal experiments can provide a more comprehensive

view, but in these cases, conventional immunohistochemical analysis is often combined only with behavioral tests or basic biochemical methods.

Detection of pathological changes by classical histology with analysis and staining of microsections obtained from patient biopsies has, similar to other methods, its limitations. These arise mainly from the nature of the methodology where the tissue is not analyzed as a whole, which can lead to the loss of important information within individual micro-sections. A significant advantage of this methodology, however, is the minimal invasiveness in the removal of biological material from a living patient. Unlike micro-section analysis, the wholemount tissue analysis approach can visualize and analyze innervation from a larger area of the GIT, at a greater depth that can provide a more comprehensive view of the processes taking place in a given tissue (Wang et al., 2012; Harsanyiiova et al., 2019). Increasing the sensitivity of immunohistochemical staining, for example by the amplification method (Harsanyiiova et al., 2019), could help detect even minimal levels of various pathological forms

of  $\alpha$ S. The availability of antibodies against a wider spectrum of pathological forms of  $\alpha$ S makes it possible to extend the possibilities of immunohistochemical staining and may suggest a time course of the disease.

It is believed that the toxicity of oligomeric forms of  $\alpha$ S is higher than insoluble fibrils. Therefore, it is the oligomeric forms that are considered to be initiators of neurodegeneration not only in PD but also in other neurodegenerative diseases (Glabe and Kaye, 2006; Benilova et al., 2012; Mou et al., 2020). Conformational-specific antibodies may be useful in detecting the initiation stages of  $\alpha$ S-associated pathology in GIT tissues, not only by immunohistochemical staining of tissues but in some cases also in biochemical analyzes such as, e.g., dot blot or ELISA. The PMCA assay utilizes the functional properties of oligomers to inoculate polymerization of monomeric protein. Its versatility and high specificity are confirmed by studies where PMCA has been used to detect the pathological forms of  $\alpha$ S in colony biopsies (Fenyl et al., 2019), or cerebrospinal fluid (Shahnawaz et al., 2017; Kang et al., 2019). PMCA is also able to distinguish different conformational strains of  $\alpha$ S that are involved in the development of various synucleinopathies, as confirmed by analysis of samples from patients with PD multiple systemic atrophy (MSA), with an overall sensitivity of up to 95.4% (Shahnawaz et al., 2020).

Furthermore, using more sophisticated FLIM-based detection methods that analyze the lifetime of fluorescence emitted by endogenous or exogenous fluorophores can help resolve the onset and progression of PD pathogenesis at the very early stages of the disease. The lifetime of fluorescence emitted by a fluorophore is affected by the environment of a given fluorophore, which allows the detection of even very small changes (e.g., conformational changes of  $\alpha$ S) with higher sensitivity compared to immunohistochemical or biochemical methods.

Several fluorescent probes used as a “gold standard” (Thioflavin S and Thioflavin T) in the detection of aggregated proteins associated with neurodegenerative diseases have been successfully used in FLIM analysis not only in recombinant

systems (Plotegher et al., 2015) but also in cellular models (Pokusa and Kralova Trancikova, 2018). Furthermore, FLIM analysis using luminescent conjugated oligothiophenes (LCOs) was able to distinguish  $\alpha$ S-positive inclusions in the brain sections of the brain of PD patients and patients with MSA (Klingstedt et al., 2019 #174). LCOs are, in comparison with classical fluorescent probes, such as Thioflavins or Congo red, able to detect a wider range of protein aggregates. Due to their flexible thiophene backbone, the emitted light depends on their binding to proteins in different conformations. In addition, differences in the emission spectra of these LCOs reveals different conformations of  $\alpha$ S strains in patients with PD and MSA (Klingstedt et al., 2011, 2019).

## AUTHOR CONTRIBUTIONS

JH focused on the detection of pathological processes in the tissues of the GIT in animal models. She also specializes in the optimization of detection methods such as classical histology, immunostaining of wholemount tissues, amplification of the detection signal and further analysis by confocal and multiphoton microscopy. TB focused on the clinical part of the manuscript, where he can best use his MD education and experience. AK focused on animal and genetic models of Parkinson's disease, where she can best use her long-term experience in this field. Also, she focused on the possibilities of improving the detection of PD-related pathological changes in the tissues of the GIT, in particular confocal microscopy and FLIM analysis. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by the Research and Development Grant of Ministry of Health of the Slovak Republic No. 2018/10-UKMT-6.

Steroid receptor coactivator 1 (SRC-1) is the key coactivator because of its transcriptional activity. Previous studies have shown that SRC-1 is abundant in the hippocampus and has been implicated in cognition. SRC-1 is also related to some major risk factors for Alzheimer's disease (AD), such as a decline in estrogen and aging, however, whether SRC-1 is involved in the pathogenesis of AD remains unclear. In this study, we established SRC-1 knockout in AD mice by cross breeding SRC-1<sup>-/-</sup> mutant mice with APP/PS1 transgenic mice, and investigated the expression of some synaptic proteins, the amyloid  $\beta$  (A $\beta$ ) deposition, and activation of astrocytes and microglia in the hippocampus of APP/PS1  $\times$  SRC-1<sup>-/-</sup> mice. The results showed that SRC-1 knockout neither affects the A $\beta$  plaque and activation of glia, nor changes the expression of synaptic proteins in AD model mice. The above results suggest that the complete deletion of SRC-1 in the embryo exerts no effect on the pathogenesis of APP/PS1 mice. Nevertheless, this study could not eliminate the possible role of SRC-1 in the development of AD due to the lack of observation of other events in AD such as tau hyperphosphorylation and the limitation of the animal model employed.

**Keywords:** steroid receptor coactivator 1, Alzheimer's disease, amyloid- $\beta$ , synapse, glia

## INTRODUCTION

Alzheimer's disease (AD), the most prevalent cause of dementia, is characterized by progressive cognitive impairment (Fernandez et al., 2019; Lu et al., 2019). The mechanisms of sporadic AD (representing more than 95% of AD cases) are uncertain, but some major risk factors have been identified. The incidence of AD rises exponentially with age (Villemagne et al., 2013; Wattmo and Wallin, 2017). The sex hormone offers protective effects on the brain and the deprivation during menopause or andropause triggers neurodysfunction, neurodegeneration, and cognitive disease

(Meng et al., 2010; Ross et al., 2017) and disproportionately increases the risk of AD (Zhao et al., 2015; Tang et al., 2018).

Steroids, such as estrogen and androgen, have profound roles in the hippocampal function and may causally be involved in cognitive deficits in AD (Hasanpour et al., 2018). Steroid receptor coactivator 1 (SRC-1) is the key coactivator to the nuclear receptors (NRs) of the steroids and is important to their effect on transcriptional activities (Bayele, 2019; Heck et al., 2020). It has been reported that SRC-1 is abundantly expressed in specific brain regions such as the hippocampus and cortex, which are recognized as the crucial brain structures in cognition (Charlier et al., 2005, 2013; Qiu et al., 2016; Zalachoras et al., 2016). Previous studies have shown that SRC-1 is involved in the estrogen receptor (ER) or androgen receptor (AR) induced memory formulation and synaptic plasticity in the hippocampus (Bian et al., 2012; Liu et al., 2015; Qiu et al., 2016; Zhao et al., 2017). The aged-related decrease of SRC-1 expression is also observed, especially in the hippocampus region (Zhang et al., 2011; Zhao et al., 2017). Taken together, these studies indicate that SRC-1 might be implicated in the interaction of these risk factors and the development of AD, which leads to the question of whether SRC-1 is involved in the pathogenesis of AD or not.

In this study, we first evaluated the SRC-1 level in APP/PS1 transgenic mice, and then investigated the effect of SRC-1 in the pathogenesis of AD mice by cross breeding the SRC-1 knockout (SRC-1<sup>-/-</sup>) mice with the APP/PS1 mice. Our results showed that SRC-1 expression in the APP/PS1 mice was not different from the wild type (WT) mice and SRC-1 deletion had no effect on A $\beta$  deposition, activation of microglia and astrocytes, and synaptic protein expression in APP/PS1 mice. These negative results suggest that SRC-1 does not interfere with AD progression, at least in the current experimental condition.

## MATERIALS AND METHODS

### Animals

SRC-1<sup>+/-</sup> mice (with a C57BL/6J background) were kindly provided by Dr. Jianming Xu from Baylor College of Medicine, TX, USA. APP<sup>swe</sup>/PS1 $\Delta$ e9 (APP/PS1) mice (with a C57BL/6J background) were purchased from Jackson Laboratory. C57BL/6J were provided by the Animal Center of Dalian Medical University (DMU).

Male SRC-1<sup>+/-</sup> were bred with SRC-1<sup>+/-</sup> females. Offspring males homozygous for the SRC-1<sup>-/-</sup> (SRC-1 knockout, KO) and the WT littermates (SRC-1<sup>+/+</sup>) were used in the experiments at 3–4 months of age.

APP/PS1 mice were bred with WT C57BL/6J. Male offspring heterozygous for the APP/PS1 transgenic construct and the WT littermates (not expressing any transgene) were used as the control. APP/PS1 mice develop plaque deposition by 6 months of age, while the plaque would be clearly visible when the mice are more than 7-months old. Male APP/PS1 and the WT littermates used in the experiments were at 8–9 months old.

All the animals were raised and bred in the Animal Center of DMU and allowed access to food and water *ad libitum*. Animals were maintained on a 12:12 light–dark

cycle (lights on at 08:00, lights off at 20:00), within a temperature-controlled room (T: 24°C  $\pm$  1°C). All tests were performed during the light cycle. All experiments were carried out under the guidelines of the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

### Generation of APP/PS1 $\times$ SRC-1<sup>-/-</sup> Mice

SRC-1 knockout in APP/PS1 (APP/PS1  $\times$  SRC-1<sup>-/-</sup>) mice were obtained by breeding SRC-1<sup>-/-</sup> mice with APP/PS1 mice, using a three-generation breeding scheme (**Supplementary Figure S1**). APP/PS1 mice were crossed with SRC-1<sup>-/-</sup> mice to introduce the SRC-1 knockout allele into the F1 generation (APP/PS1  $\times$  SRC-1<sup>+/+</sup>). APP/PS1  $\times$  SRC-1<sup>+/-</sup> mice were then crossed with SRC-1<sup>+/-</sup> mice to obtain the F2 generation which could comprise APP/PS1  $\times$  SRC-1<sup>+/+</sup> (APP/PS1), APP/PS1  $\times$  SRC-1<sup>+/-</sup>, APP/PS1  $\times$  SRC-1<sup>-/-</sup>, SRC-1<sup>+/+</sup> (WT), SRC-1<sup>+/-</sup> and SRC-1<sup>-/-</sup>. The proportions of each genotype of the mice are shown in **Supplementary Figure S1**.

APP/PS1  $\times$  SRC-1<sup>-/-</sup> mice were then age-matched with APP/PS1  $\times$  SRC-1<sup>+/+</sup> mice, which were used as the control. The SRC-1<sup>+/+</sup> littermates express neither the APP/PS1 gene nor SRC-1 mutants and could be considered as wildtype (WT). Female mice were only used for the breeding. All the male mice used in the experiment were 8–9 months old.

### Western Blot

The proteins were extracted using an extraction kit (Keygen Biotech, China), and the protein content was measured by a BCA protein assay (Keygen Biotech, China). For Western Blotting, the proteins (10–30  $\mu$ g) for each sample were loaded into a 10% SDS PAGE gel for electrophoresis, then the protein components were transferred to polyvinylidene difluoride (PVDF) membranes. Later, the PVDF membranes were blocked with 5% bull serum albumin (BSA) in TBST (TBS + 0.1% Tween-20) for 1 h, and immunoblotted overnight at 4°C with the primary antibodies: SRC-1 (180 KD, 1:1,000, Cell signaling technology, Millipore, 2191S); PSD95 (1:1,000, Abcam, ab2723); Synapsin (70 KD, 1:1,000, Abcam, ab64581); GluR1 (100 KD, 1:1,000, Abcam, ab31232); APP (87 KD, 1:1,000, Abcam, ab15272); beta-site APP-cleaving enzyme 1 (BACE-1; 70 KD, 1:1,000, Abcam, ab2077);  $\beta$ -actin (1:2,000, Abcam, ab6276). The following day, the membranes were washed in TBST three times, then incubated with a horseradish peroxidase-labeled secondary antibody (anti-mouse or anti-rabbit, 1:5,000; ZSJBIO Company, Beijing, China) for 1 h at room temperature. The infrared band signals were detected using BIO-RAD gel analysis software (Hercules, CA, USA). The densitometric analysis of immunoreactivity was conducted using the NIH ImageJ software (Li et al., 2019).

### Immunohistochemistry (IHC) and Immunofluorescence (IF)

IHC and IF were carried out according to our previous work (Wang et al., 2018). The primary antibodies: SRC-1 (1:100–200); 6E10 (for A $\beta$ ; 1:100, Covance, S39320260); GFAP (1:200, DAKO, 20334); Iba-1 (1:200, WAKO, 019-19741) were

used. The mice were anesthetized with pentobarbital (50 mg/kg, 0.05 ml/10 g body weight, i.p.) and perfused with 0.1% phosphate buffer (PB), followed by 4% paraformaldehyde (PFA) dissolved in 0.1% PB. Afterward, the brains were removed and left in 4% PFA at 4°C for 24 h, and then transferred to 30% sucrose dissolved in 0.1% PB. Following saturation of the brains in sucrose, serial 16  $\mu$ m coronal sections were made with a cryostat (Leica CM 3050 S, Leica Microsystems AG, Wetzlar, Germany) after OCT embedding. The slices that contained cortex and ventral hippocampus were used for the staining. For the IHC staining procedure, the slices were thoroughly rinsed in 0.3% PBS-T for 15 min, then quenched by 3% H<sub>2</sub>O<sub>2</sub> in 0.01 M PBS for 15 min. Subsequently, they were rinsed again and pre-incubated in 2% BSA and 0.3% Triton X-100 in 0.01 M PBS at room temperature for 1 h, and then incubated at 4°C with the primary antibody in 0.01 M PBS containing 2% BSA and 0.3% Triton X-100 overnight. After incubation with a biotinylated goat anti-rabbit or anti-mouse IgG secondary antibody (1:200; Vector Laboratories, Burlingame, CA, USA) for 2 h, the bound antibodies were visualized using an avidin–biotin–peroxidase complex system (Vectastain ABC Elite Kit, Vector Laboratories, Burlingame, CA, USA) and then stained with diaminobenzidine (DAB; Vectro Laboratories) as a chromogen. The slides were visualized with a microscope and digitally photographed (Pannoramic Digital Slide Scanners, 3DHISTECH, Budapest, Hungary).

For the IF staining procedure, the sections were washed with 0.3% PBST (three times, 10 min each time). After that, the sections were blocked with 5% BSA in PBS containing 0.3% Triton X-100 at room temperature for 1 h, and then incubated with primary antibody overnight at 4°C. On the second day, the sections were incubated with secondary antibody for 2 h at room temperature after being washed with 0.3% PBST three times. Images were captured under a microscope (Pannoramic Digital Slide Scanners, 3DHISTECH, Budapest, Hungary). The analysis of mean integrated optical density (MIOD) was performed using ImageJ software from the National Institutes of Health.

## Statistical Analysis

All statistical analyses were performed using SPSS22.0 and the figures were created using GraphPad Prism (GraphPad Software Inc.). Data were presented as the mean  $\pm$  SEM. Comparisons between two groups were made by student 2-tailed unpaired *t*-test. Comparisons between three or four groups were made by one-way ANOVA. *p* value < 0.05 was considered statistically significant (\**p* < 0.05, \*\**p* < 0.01, \*\*\**p* < 0.001).

## RESULTS

### SRC-1 Expression in APP/PS1 Mice

APP/PS1 mice, which express human mutant APP and PS1 (Garcia-Alloza et al., 2006), are commonly used as an A $\beta$ -induced AD model. We first examined the expression of SRC-1 in the hippocampus (Figure 1A) and cortex (Figure 1F) of APP/PS1 mice. Both IHC (Figures 1A,B) and western (Figures 1C,D) results showed that SRC-1 is

abundant in the region of the hippocampus but no changed expression was observed in the APP/PS1 mice compared to the littermate WT mice.

### SRC-1 Knockout Shows No Effect on Synaptic Protein Expression in APP/PS1 Mice

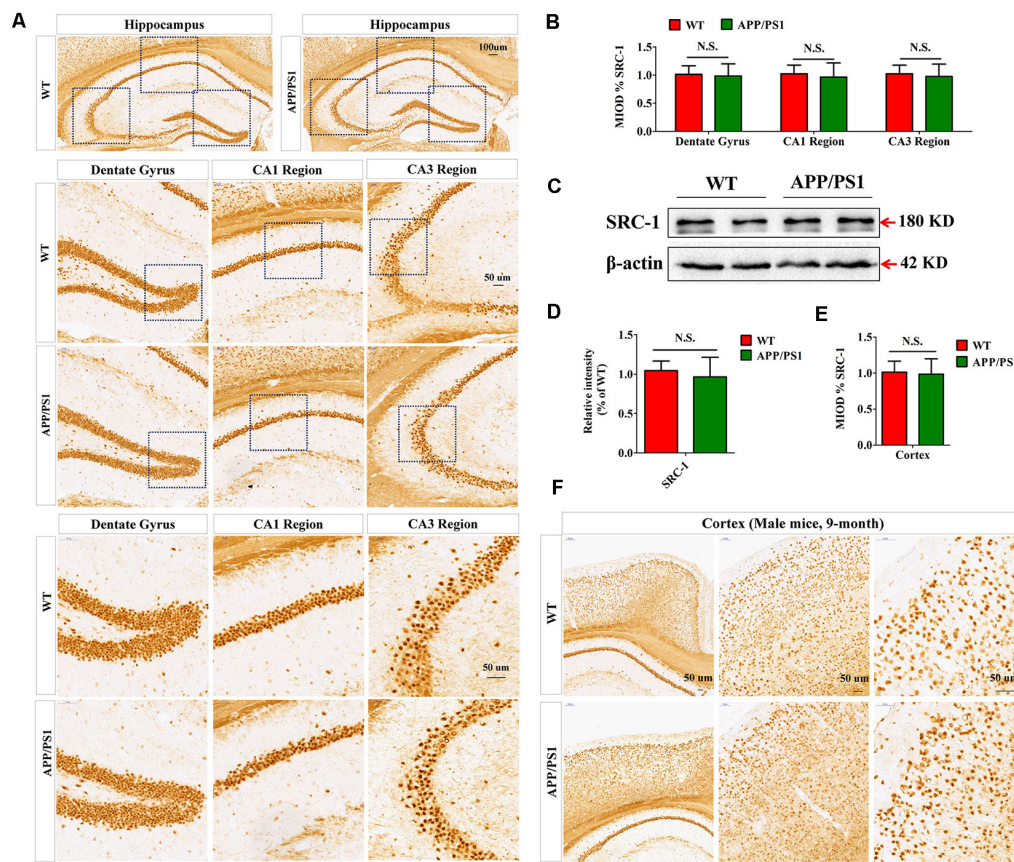

In order to observe the possible role of SRC-1 in the AD model, we bred SRC-1<sup>-/-</sup> mice with APP/PS1 mice and obtained APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice at the F2 generation, with the control APP/PS1 $\times$ SRC-1<sup>+/+</sup> (Supplementary Figure S1). The immunofluorescent staining of SRC-1 in WT (SRC-1<sup>+/+</sup>), APP/PS1 $\times$ SRC-1<sup>+/+</sup> and APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice (Supplementary Figure S2) showed no positive staining of SRC-1 in APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice, and non-changed SRC-1 expression between the WT and APP/PS1 $\times$ SRC-1<sup>+/+</sup> mice, which is consistent with the result in Figure 1.

Synaptic loss is the main reason of the cause cognitive deficiency in AD. Postsynaptic density (PSD) 95, Synapsin and glutamate receptor 1 (GluR1) are the important proteins in synapse and their level shows a positive correlation to synaptic function. The expression of the three selected proteins was detected in the hippocampus of APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice (Figure 2). The results showed, compared to the WT mice, that the APP/PS1 (shown as APP/PS1 $\times$ SRC-1<sup>+/+</sup>) mice exhibited a notable decrease in the expression of PSD95, Synapsin, and GluR1 (Figure 2). However, none of the three synaptic proteins showed any changed expression in the hippocampus of APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice, compared to the APP/PS1 $\times$ SRC-1<sup>+/+</sup> mice. These findings indicates that the deletion of SRC-1 has no effect on synaptic protein expression in the AD mouse model. Similarly, in the non-AD model (as shown in Supplementary Figure S3), PSD95, Synapsin, and GluR1 expression remain constant in the SRC-1 knockout (SRC-1<sup>-/-</sup>) mice compared to their WT littermates.

### SRC-1 Knockout Exerts No Effect on A $\beta$ Deposition in APP/PS1 Mice

The A $\beta$  senile plaque is the major pathological hallmark of AD. To further determine the effects of SRC-1 knockout on AD, we detected the A $\beta$  plaque in both APP/PS1 $\times$ SRC-1<sup>+/+</sup> and APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice (Figures 3A,C). The IHC results demonstrated that the number and area of the A $\beta$  plaque in APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice was comparable to those in APP/PS1 $\times$ SRC-1<sup>+/+</sup> mice (Figures 3A,B). It is known that A $\beta$  production is affected by protein levels of APP and APP processing enzymes such as BACE-1. We discovered that APP/PS1 $\times$ SRC-1<sup>+/+</sup> mice showed an increased expression of both APP and BACE-1 compared to WT mice (Figures 3D–F); but APP/PS1 $\times$ SRC-1<sup>-/-</sup> mice showed an expression change of neither APP nor BACE-1 compared to APP/PS1 $\times$ SRC-1<sup>+/+</sup> mice (Figures 3D–F). In addition, we also detected an APP and BACE-1 level in the non-transgenic AD mice and the result showed no expression difference of APP or BACE-1 between SRC-1<sup>-/-</sup> mice and their WT littermates (Supplementary Figure S4).

**FIGURE 1 |** The expression of Steroid receptor coactivator 1 (SRC-1) protein in APP/PS1 mice. **(A,B)** SRC-1 expression in the coronal sections of the hippocampus (10 $\times$ ) in APP/PS1 mice at 8–9 months of age. Dentate gyrus (20 $\times$  and 40 $\times$ ), CA1 region (20 $\times$  and 40 $\times$ ), and CA3 region (20 $\times$  and 40 $\times$ ). **(C,D)** Representative immuno-blot and densitometry analysis of SRC-1 expression in the hippocampus of APP/PS1 mice. **(E,F)** SRC-1 expression in the coronal sections of the cortex (10 $\times$ , 20 $\times$  and 40 $\times$ ). Data are presented as the mean  $\pm$  SEM of six mice in each group. N.S., no significance.

## SRC-1 Knockout Exerts No Effect on the Activation of Microglia and Astrocytes in APP/PS1 Mice

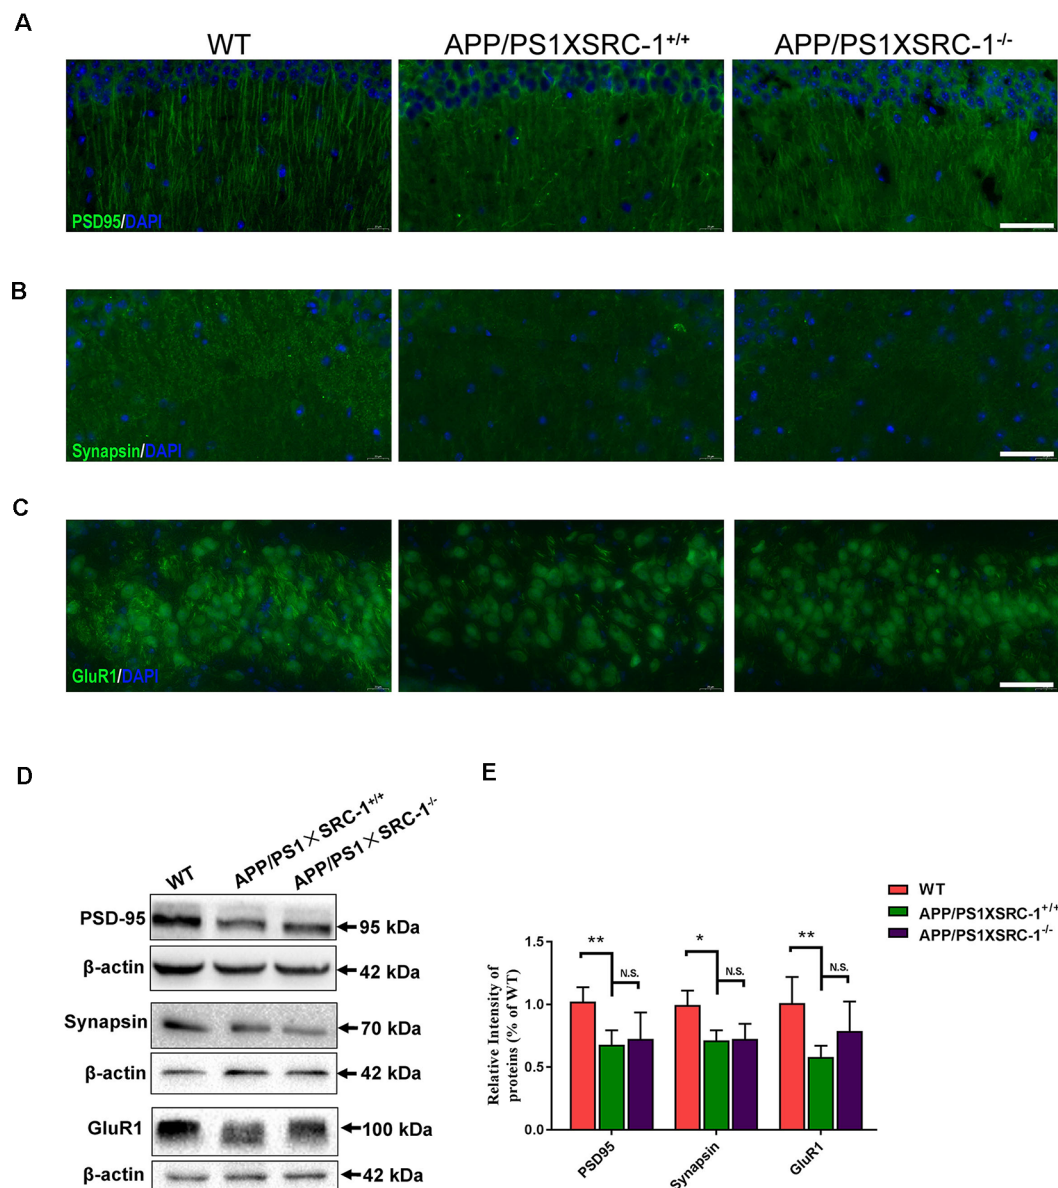

Neuroinflammation characterized by the activation of astrocytes and microglia is also a significant contributor to the pathological progression of AD (Zheng et al., 2018). To investigate whether SRC-1 is involved in the neuroinflammation of APP/PS1 mice, we then stained the coronal sections of the hippocampus of each group of mice with antibodies against GFAP (a marker for astrocytes) or Iba-1 (a marker for microglia; **Figures 4A,C**). Over activation of glial cells was shown in APP/PS1  $\times$  SRC-1<sup>+/+</sup> mice in contrast to WT mice, however, the volume of both astrocytes and microglia in the hippocampus of APP/PS1  $\times$  SRC-1<sup>-/-</sup> is similar to that of APP/PS1  $\times$  SRC-1<sup>+/+</sup> mice (**Figures 4B,D**). This result showed that SRC-1 deletion would not affect the over activation status of microglia and astrocytes in the APP/PS1 mice.

## DISCUSSION

Steroids modulate the structure and function of the brain by binding to the NRs (Bayele, 2019; Heck et al., 2020), then the

activated NRs recruit the steroid receptor coactivators (SRCs, also named nuclear receptor coactivators) to enhance their transcriptional activities (McEwen and Milner, 2017). SRC-1 is the key coactivator for the transcriptional regulation of NRs (Bayele, 2019; Heck et al., 2020). There are studies that have reported that SRC-1 is widely expressed in the brain (Chen et al., 2015; Kerver and Wade, 2015) and modulates many brain functions, such as motor, energy homeostasis, and reproductive behavior (Charlier et al., 2005; Yang et al., 2019) through the effect on cerebellar Purkinje cells (Eijun et al., 2003), hypothalamic neurons (Yang et al., 2019; Heck et al., 2020), and so on. Furthermore, a recent study has shown that SRC-1 is highly expressed in the hippocampus, and hippocampal SRC-1 knockdown mediated by the lentivirus could cause decreased synaptic protein expression and memory impairment (Bian et al., 2018; Chen et al., 2020). On the other hand, the ER regulates the synaptic protein expression, such as PSD95 and Synapsin, and the cognitive function through the SRC-1-dependent pathway (Liu et al., 2015; Zhao et al., 2017, 2018). This evidence suggests that SRC-1 is implicated in the cognitive function under the physiological condition and might even play a role in brain disorders with defects of cognition.

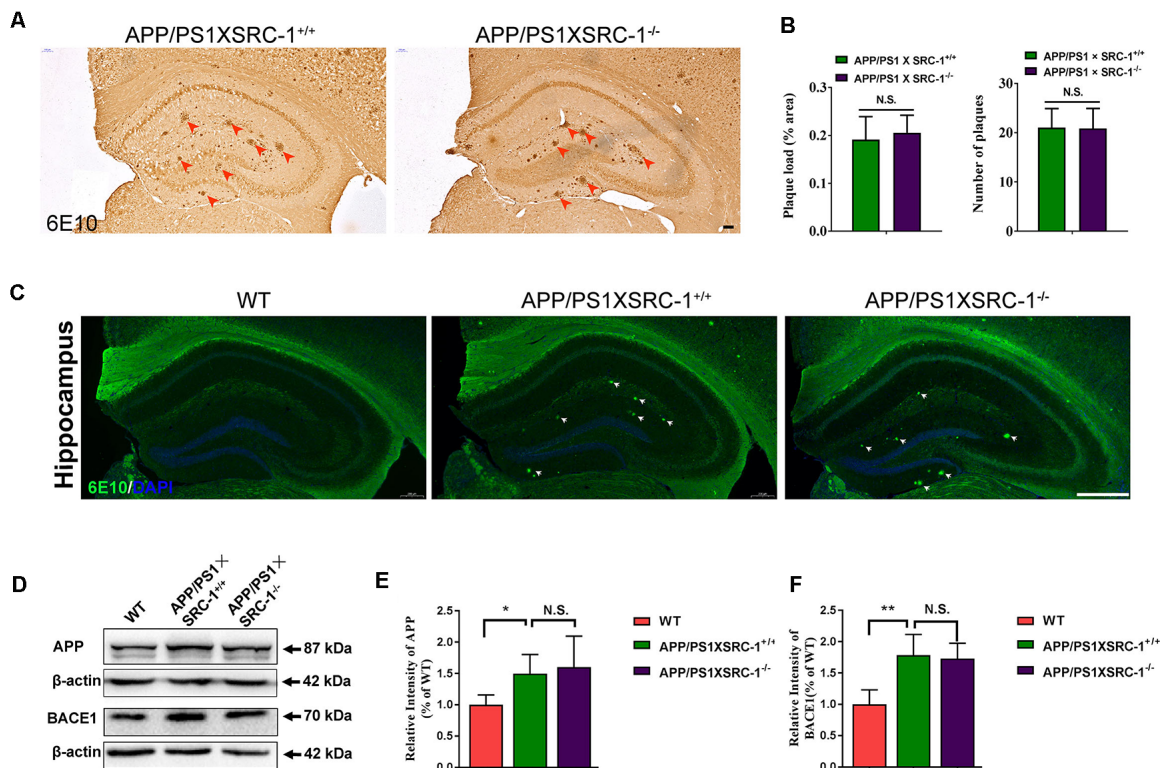

**FIGURE 2 |** Expression of PSD95, Synapsin and GluR1 in the hippocampus of APP/PS1×SRC-1<sup>-/-</sup> mice. **(A–C)** The coronal sections of the hippocampus were stained for PSD95 **(A)**, Synapsin **(B)**, GluR1 **(C)**, and 4',6-diamidino-2-phenylindole (DAPI) in APP/PS1×SRC-1<sup>-/-</sup>, APP/PS1×SRC-1<sup>+/+</sup> control and wildtype (WT) mice (8–9 months age). Scale bars: 50  $\mu$ m. **(D,E)** Representative immunoblots and densitometry analysis of PSD95, Synapsin and GluR1 expressions in each group. Data are presented as the mean  $\pm$  SEM of six mice in each group. \* $p < 0.05$ , \*\* $p < 0.01$  and N.S., no significance.

AD is a neurodegenerative disease and its major symptom is impaired cognitive function. It is of interest to see whether the SRC-1 protein level correlates with AD. In the present study, we first examined the SRC-1 protein level in the hippocampus and cortex of APP/PS1 mice, and the result showed no difference in SRC-1 expression between AD mice and the WT littermates. This result indicates that the transgene of APP/PS1 and the consequent pathology, have no effect on SRC-1 expression. Furthermore, we investigated whether SRC-1 knockout affected the expression of the synaptic protein in AD mice. Our results demonstrated that SRC-1 deficiency (APP/PS1×SRC-1<sup>-/-</sup>) had

no effect on the expression of PSD95, Synapsin, and the GluR1 protein in AD. Consistently, the level of the three synaptic proteins in the SRC-1 KO mice was comparable to those in the WT mice.

However, a previous study has reported that SRC-1 knockdown in the hippocampus of mice during adulthood leads to the decreased expression of PSD95 and other synaptic proteins for weeks (Bian et al., 2018; Chen et al., 2020). The discrepancies between their studies and ours might be explained by the different gene manipulations of SRC-1. SRC-1 knockout is the complete deletion of SRC-1 from the embryo period, so

**FIGURE 3 |** The A $\beta$  plaque in the hippocampus of APP/PS1  $\times$  SRC-1<sup>-/-</sup> mice. **(A,C)** The coronal sections of the hippocampus in APP/PS1 with (APP/PS1  $\times$  SRC-1<sup>+/+</sup>) or without SRC-1 APP/PS1  $\times$  SRC-1<sup>-/-</sup> mice of 8–9 months age were stained for A $\beta$  (6E10). Scale bars: 100  $\mu$ m. **(B)** The mean A $\beta$  plaque load (% area) and number were quantified. **(D–F)** Representative immunoblot and densitometry analysis of APP and BACE-1 expression in the APP/PS1  $\times$  SRC-1<sup>-/-</sup>, APP/PS1  $\times$  SRC-1<sup>+/+</sup> control and WT. Data are presented as the mean  $\pm$  SEM of six mice in each group. \* $p$  < 0.05, \*\* $p$  < 0.01 and N.S., no significance.

**FIGURE 4 |** The activation of microglia and astrocyte in the hippocampus of APP/PS1  $\times$  SRC-1<sup>-/-</sup> mice. **(A,C)** The coronal sections of the hippocampus in each group were stained for GFAP **(A)**, Iba-1 **(C)** and DAPI. Scale bars: 50  $\mu$ m. **(B,D)** The volume of astrocyte **(B)** and microglia **(D)** in APP/PS1  $\times$  SRC-1<sup>-/-</sup> mice, respectively. Data are presented as the mean  $\pm$  SEM of six mice in each group. \*\* $p$  < 0.01 and N.S., no significance.

its function might be compensated by other coactivators, such as SRC-2 or SRC-3. Another study has actually revealed that knockout of both SRC-1 and SRC-3 during the embryo stage would cause a cardiomyopathy phenotype, however, the heart morphology and tissue structures in mice with either SRC-1

or SRC-3 knockout were very similar to those of WT mice (Chen et al., 2015). Similarly, the same reason might be used to explain that SRC-1 knockdown in adulthood caused the memory loss (Bian et al., 2018) but the SRC-1 knockout did not (Eijun et al., 2003).

The A $\beta$  plaque is the major pathological feature in AD (Masters and Beyreuther, 2006). A decrease of synaptic protein expression in the APP/PS1 mice is probably the result of the overproduction of A $\beta$  (Evin and Weidemann, 2002). A $\beta$  peptides are generated from APP sequentially cleaving by  $\beta$ - and then  $\gamma$ -secretase (Maia and Sousa, 2019; Zhang et al., 2020). In our study, SRC-1 deletion has not affected the A $\beta$  plaque in the APP/PS1 mice, in neither the number nor the area of the plaque load. We also demonstrated that APP/PS1 $\times$ SRC-1 $^{-/-}$  mice showed no change of the expression of the APP and BACE-1 protein. Furthermore, SRC-1 $^{-/-}$  mice also exhibited the non-changed expression of APP or BACE-1, similar to that in the AD model. As the source of A $\beta$ , APP and BACE-1 expression was not affected by SRC-1 deletion, which would sustain the result of the invariable A $\beta$  plaque in APP/PS1 $\times$ SRC-1 $^{-/-}$  mice, at least to some extent. A $\beta$  deposition is often accompanied by activation of microglia and astrocytes, an important event in AD brain, which produces proinflammatory cytokines and chemokines causing neuronal dysfunction and further neurodegeneration (Galea et al., 2015). Here, the cell number of astrocytes and microglia increased in the hippocampus of APP/PS1 mice compared to the WT, consistent with previous reports (Lu et al., 2019); but in the APP/PS1 $\times$ SRC-1 $^{-/-}$  group, no clear changes of astrocytes and microglia were observed compared to the APP/PS1 $\times$ SRC-1 $^{+/+}$  group.

Altogether, our results suggest that the SRC-1 knockout would neither change the synaptic protein expression, nor affect the A $\beta$  plaque or activation of astrocytes and microglia in APP/PS1 mice. But this outcome could not completely eliminate the possible role of SRC-1 in AD. First, as we have discussed, SRC-1 knockout and knockdown shows different consequences. SRC-1 knockdown during the adulthood of APP/PS1 mice might possibly exhibit quite different results from this present study. Second, our experiments only detected the effect of SRC-1 deletion, but not the effects of SRC-1 over-expression or activation. Wang et al. (2015) has reported that MCB613 could be a potent small molecule “stimulator” for SRC-1, which could be used to enhance the activity of SRC-1 in APP/PS1 mice for further investigation of the role of SRC-1. Finally, we could not completely exclude the possible connection between SRC-1 and tau hyperphosphorylation, and more experiments are required to further address this question. In summary, our study confirms

that SRC-1 knockout has no effect on some of the pathologic features of APP/PS1 mice.

Calcium-sensing receptor (CaSR) is a G protein-coupled receptor (GPCRs). Soluble  $\beta$ -amyloid peptide (A $\beta$ ) is one of the orthosteric modulators of CaSR, while, the role and underlying mechanism of CaSR in cognitive decline in Alzheimer's disease (AD) is unclear. In this study, molecular technology such as live-cell imaging combined with behavioral tests were used to explore the role and the underlying mechanism of CaSR in the cognitive deficits in AD mice. The expression levels of CaSR were increased both in AD mice and A $\beta$ <sub>1-42</sub> ( $\beta$ -amyloid protein)-treated primary cultured neurons. Pharmacological inhibition of CaSR ameliorated cognitive and spatial memory deficits of A $\beta$ <sub>1-42</sub>-oligomer-treated mice in a dose-dependent manner. Pharmacological inhibition of CaSR or down-regulation of the expression of CaSR by CaSR-shRNA-lentivirus prevented the impairment of filopodia, and the synapse induced by oligomeric A $\beta$ <sub>1-42</sub>. The contents of cytosolic phospholipase A2 (cPLA2) and prostaglandin E2 (PGE2) in hippocampal neurons and tissue were increased after treatment with A $\beta$ <sub>1-42</sub> oligomers. Inhibition or down-regulation of CaSR mediates A $\beta$ -induced synapse formation and cognitive deficits partially, through the activation of the cPLA2/PGE2 pathway. This study provides novel insights on CaSR, which is a promising therapeutic target for AD.

**Keywords:** Alzheimer's disease (AD),  $\beta$ -amyloid peptide (A $\beta$ ), calcium-sensing receptor (CaSR), synapse formation, cytosolic phospholipase A2, prostaglandin E2

## INTRODUCTION

Alzheimer's disease (AD) is one of the most common neurodegenerative diseases with a slow and gradual deterioration of the memory that affects language, personality, and cognitive control (Wyss-Coray and Rogers, 2012; Mhatre et al., 2014; Dos Santos Picanco et al., 2018). AD is a severe threat for human health, along with an aging population, however, the pathogenesis of it is still unclear. Mounting evidence shows that the accumulation of  $\beta$ -amyloid peptide ( $A\beta$ ) is an important contributing factor in the pathology of AD (Baek et al., 2017; Choi et al., 2017).  $A\beta$  has different aggregated forms, including monomers, oligomers, protofibrils, and mature fibrils (Ahmed et al., 2010). It is well demonstrated that soluble oligomers of  $A\beta$  is the pertinent toxic form of  $A\beta$  (Wang H. C. et al., 2016; Wang T. et al., 2016). Both others, and our previous studies have shown that soluble  $A\beta$  oligomers could decrease the number of dendritic spines and inhibit the long-term potentiation (LTP), leading to the decline of cognitive function in AD mice (Price et al., 2014; Jiang et al., 2016). Disrupting synapse function plays an important role in the memory deficits of AD, which stands out in early AD pathological changes (Price et al., 2014; Teich et al., 2015; Wang X. et al., 2018). Therefore, it is a promising strategy to consider amelioration of synaptic impairment induced by  $A\beta$  oligomers as the target of prevention or treatment of AD.

$A\beta$  is also one of the allosteric agonists of calcium-sensing receptor (CaSR).  $A\beta$  has been shown to interact directly with CaSR *via* a proximity ligation assay (Diez-Fraile et al., 2013; Leach et al., 2015). CaSR, a member of the G protein-coupled receptor (GPCRs) C family, is a seven-transmembrane protein (Brauner-Osborne et al., 2007; Conigrave and Ward, 2013; Summers, 2016). CaSR has been detected in the hippocampus which is an important brain structure that is essential for spatial memory, language learning, and episodic memory (Ferry et al., 2000). CaSR is mainly localized in nerve endings in the neurons and is involved in regulating brain excitability (Chen et al., 2010). CaSR activation depends on the persistent interaction with its agonists. At physiological conditions, CaSR is partially activated (Ruat and Traiffort, 2013; Díaz-Soto et al., 2016). In cultured cells,  $A\beta$ -activated CaSR could cause excessive release of  $A\beta$  (Armato et al., 2013; Dal Prà et al., 2014). The expression of CaSR was significantly increased in AD transgenic mice (Leach et al., 2015; Gardenal et al., 2017). The role of CaSR in AD is unclear and the cellular mechanisms have not been well characterized. As a promising therapeutic target, we therefore evaluated the role of CaSR in cognitive deficits in the mouse model of AD and its underlying cellular mechanisms. The effects of CaSR on oligomeric  $A\beta$ -induced synaptic injury are unknown. In the current study, we have also evaluated the role and the underlying mechanisms of CaSR in  $A\beta$ -mediated synaptic impairment.

## MATERIALS AND METHODS

### $A\beta_{1-42}$ Oligomers Preparation

Preparation of soluble  $A\beta_{1-42}$  oligomers was done according to the protocol previously described (Jiang et al., 2016;

Ding et al., 2019). One milligram of  $A\beta_{1-42}$  (Bachem, Cat# H-1368.1000) powder was dissolved in 400  $\mu$ l ice-cold 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP; Aladdin, Cat# K1625063), and incubated at room temperature for 20 min. Hundred microliter of this complete solution was diluted into 900  $\mu$ l of deionized water to a final concentration of 0.25 g/l. After centrifugation at 14,000 g for 15 min, the supernatant was collected and the HFIP was completely evaporated. Then the collected supernatant was kept stirring for 48 h at room temperature. A 50  $\mu$ M  $A\beta_{1-42}$  solution was obtained and stored at 4°C. The preparation is the combination of low molecular weight forms of soluble  $A\beta$  (Chunhui et al., 2018).

### Animals

ICR mice (RRID:IMSR\_CRL:22) or B6C3-Tg (APPswe/PSEN1dE9) mice were used in our experiments. Breeding pairs of APPswe/PSEN1dE9 transgenic mice were originally purchased from Jackson Laboratories, USA. A breeding colony of APPswe/PSEN1dE9 mice was established at the Medical School of Ningbo University. All experimental animals were housed in a temperature and humidity-controlled animal facility ( $22 \pm 3^\circ\text{C}$ ,  $60\% \pm 5\%$ ) with a 12 h light and dark cycle and free access to standard chow and water. Experiments were carried out in accordance with the National Institute of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No. 80-23, revised 1996) and approved by the Institutional Animal Care and Use Committee of the Ningbo University. The approval number for the animal experiments is SYXK (ZHE) 2013-0191. Genotypes of APPswe/PSEN1dE9 mice were analyzed as follows: DNA was isolated from the tail tip of each mouse and PCR was performed using the following primer pairs: APP, forward primer 5'-GACTGCCACTCGACCAGGTTCTG-3', reverse primer 5'-CTTGTAAGTTGGATTCTCATATCCG-3'; PS1, forward primer 5'-GTGGATAACCCCTCCCCCAGCCTAGACC-3', reverse primer 5'-AATAGAGAACGGCAGGAGCA-3'. APPswe/PSEN1dE9 transgenic mice and wild type mice were identified by agarose gel electrophoresis. In each identification experiment, both positive and negative controls were designed.

### Animal Surgery

Two-month-old healthy male ICR mice (25–30 g) were pseudo-randomly assigned to the experimental groups using a random number generated from Excel, and all mice were marked by staining in different parts of the back. A pre-test open field experiment was first performed on all mice to determine the locomotor activity before the formal experiments and to exclude those with an obvious movement disorder. No obvious movement disorder was found among the mice. Thus, no mice were excluded. ICR mice were anesthetized by intraperitoneal administration of sodium pentobarbital (50 mg/kg) before they were placed in a stereotaxic apparatus (Stoelting, Wood Dale, IL, USA). Cannulas (RWD Life Science, Shenzhen, China) were surgically implanted into bilateral hippocampal regions of the mice using the following coordinates: AP  $-1.7$  mm from Bregma; ML  $\pm 1.0$  mm from the midline; DV  $-1.5$  mm from pia

mater. After 7 days of post-operative recovery, the minipump needle tips were inserted into the ventricle through cannulas to inject pharmaceuticals. Experimental mice were given three consecutive infusions of  $A\beta_{1-42}$  (4  $\mu\text{mol/kg}$ ) and/or NPS 2143 (Sigma, Cat# SML0360, 0.08 or 0.16  $\mu\text{mol/kg}$ ), while the control mice received saline injections instead of the drugs.

## Behavior Tests

The novel object recognition (NOR) task, consisting of a familiarization phase and a test phase, was carried out in an open-field arena (60 × 60 × 15 cm) on the 11th to 12th day after the first injection. On the first day, they were familiarized with two identical objects for 5 min. On the second day, one of the objects was replaced by a novel one with a different shape and color, and the mice were allowed to explore the arena for 5 min. To ensure the absence of olfactory cues, the open-field arena and the objects were cleaned thoroughly. Exploration was defined as sniffing or touching the objects. The distance between the nose and object was no more than 2 cm. If the mice traveled around or sat on the objects, this was not defined as object recognition. The discrimination index, the ratio of the amount of time spent exploring any one of the two objects (training session) or the novel object (retention session), over the total time spent exploring both objects, was used to measure the cognitive function of animals.

A Morris water maze (MWM) was performed as described (Jiang et al., 2016). Briefly, the equipment included a pool with a diameter of 110 cm that was filled with opaque water at approximately  $22 \pm 1^\circ\text{C}$ . Spatial memory was assessed by recording the latency time for the animal to escape from the water onto an escape platform during the place navigation phase. At the learning phase, mice were given 90 s to find the hidden platform that was 1 cm below the water surface. The place navigation test of the MWM, which consisted of four trials (interval 20–30 min) each day, took place during the 14th day to the 17th day and the latency time was recorded. On the 18th day, the platform was removed from the maze. A probe trial was conducted to measure the trajectories and entries of mice to the target quadrant with a video tracking system (Ethovision XT). The assessor was blinded to the experimental conditions for analysis of the behavioral tests.

## Primary Hippocampal Neuronal Cultures

Neurons were derived from the dissociating hippocampus of newborn ICR mice (RRID:IMSR\_CRL:22). To achieve dissociated and single cells, the tissue was cut into tiny pieces, and the cells within released by a mild treatment with 0.125% (v/v) trypsin (Gibco, Cat# 11668–019) for 15 min at  $37^\circ\text{C}$ . Isolated neurons were then planted on coverslips (Fisherbrand, Cat# 12–545–83), pre-coated with poly-D-lysine (Sigma, Cat# P0899–10MG) in Dulbecco's modified Eagle media (Gibco, Cat# 11995065) containing 10% (v/v) FBS (Gibco, Cat# 10099141), 10% (v/v) F-12 (Gibco, Cat# 11765054), and 1% (v/v) of penicillin-streptomycin solution (Solarbio, Cat# P1400). After the cells were incubated at  $37^\circ\text{C}$ , 5% (v/v)  $\text{CO}_2$  for 24 h, the medium was changed to Neurobasal medium supplemented with 2% (v/v) B27 (Gibco, Cat# 17504044) and 1% (v/v) L-glutamine (Gibco, Cat# 25030–081). The medium

was half-replaced every 3 days. At the 5th day *in vitro* (DIV 5), cytosine arabinofuranoside (Sigma, Cat# 147–94–4) was added at a final concentration of 2  $\mu\text{M}$  to decrease glial cell growth. The neurons were transfected with farnesylated enhanced green fluorescent protein (F-GFP) and GFP-actin using Lipofectamine 2000 (Invitrogen, Cat# 11668–019). At DIV 7 or DIV 14 of culture, NPS 2143 was added to cultures of hippocampal neurons at a final concentration of 0.1  $\mu\text{M}$  for 2 h. After the treatment of NPS 2143, neurons were incubated with  $A\beta_{1-42}$  (final concentration 0.5  $\mu\text{M}$ ) for 3 h. For the effect of  $A\beta_{1-42}$  on the expression of CaSR, primary hippocampal neurons (DIV 7) were incubated with  $A\beta_{1-42}$  for 36 h.

## Immunohistochemistry and Immunocytochemistry

Mice were decapitated and their brains were removed after perfusion. After fixation with 4% paraformaldehyde (Solarbio, Cat# P1110), dehydration with 30% sucrose solution and after being embedded with an optimum cutting temperature compound (Solarbio, Cat# 4583), the brains were cut into 30  $\mu\text{m}$  frozen brain slices. Cultured cells were also fixed with 4% paraformaldehyde at room temperature. After being washed with phosphate-buffered saline (PBS) three times, the brain slices or cultured cells were blocked with sheep serum at room temperature for 1 h, to saturate unspecific binding sites, and then permeabilized in PBS containing 0.01% (V/V) triton (Solarbio, Cat# T8200). The sections or coverslips were incubated overnight ( $4^\circ\text{C}$ ) with anti-postsynaptic density 95 antibody (PSD 95, 1:200, Abcam, Cat# ab2723), anti-synaptotagmin-1 antibody (1:200, Millipore, Cat# AB5600–50UL), anti-MAP2 antibody (1:200, CST, Cat# 8707), anti-CaSR antibody (1:200, Santa Cruz Biotechnology, Cat# sc-47741), or DAPI (1:5000, Beyotime, Cat# C1002). After thorough washing, sections or coverslips were incubated with Alexa-488 anti-mouse secondary antibodies (1:1,000, Invitrogen, Cat# A-10680) or Cyanine 5 anti-mouse secondary antibody (1:1,000, Invitrogen, Cat# A10524) and Alexa-546 anti-rabbit secondary antibodies (1:1,000, Invitrogen, Cat# A11010) for 1 h at room temperature. Images of distal neuronal dendrites were captured by a confocal microscope (Olympus, Tokyo, Japan).

## Lentivirus Construction

The Lentivirus was purchased from Shanghai Genechem Company, Limited (China). The company used the following procedures: The coding sequence of the CaSR was from GenBank: NM\_013803.3. For small hairpin RNA (shRNA) against mouse CaSR, vectors were constructed from the original plasmid GV lentiviral vector, and the GV118 serotype was selected; the reaction element sequence of which is U6-MCS-Ubi-EGFP. The target gene was inserted into the MCS element by HpaI and XhoI, two restriction endonucleases. The optimal target sequence (TCTTCATCAAGTTCCGAAA) was selected for small hairpin RNA (shRNA) against mouse CaSR, and a scrambled shRNA (TTCTCCGAACGTGTCACGT) served as a control. For viral packaging, the respective recombinant plasmids were cotransfected into 293T cells (ATCC, RRID:CVCL\_0063). The GV stocks were titered by quantitative PCR, stored at  $-80^\circ\text{C}$

of a titer of  $10^9$  particles/ml and shipped with 20  $\mu$ l in every tube. We then used a total of  $5 \times 10^5$  TU/ml of the virus to transfect the hippocampal neurons. All procedures were performed under a biosafety cabinet in a biosafety level 2 facility.

## Confocal Imaging and Analysis

At DIV 7 or DIV 14 of culture, living neurons were captured by a Fluoview-1000 confocal microscope. After drug treatments, the neurons were maintained in a recording chamber with extracellular solution (148.00 mM NaCl, 3.00 mM KCl, 3.00 mM  $\text{CaCl}_2$ , 10.00 mM HEPES, and 8.00 mM glucose, pH 7.3) at room temperature. Digital images of GFP were collected on a Fluoview-1000 confocal microscope (Olympus) using a 60 $\times$  oil objective lens without optical zoom at an excitation wavelength of 488 nm. They were analyzed using Fluoview-1000 software. All lengths of the secondary dendritic branches were measured by tracing their extension, and the filopodia and spines were counted. For all analyses, images were analyzed blind to treatments and data were collected from at least three independent experiments.

## Cytosolic Phospholipase A2 (cPLA2) and Prostaglandin E2 (PGE2) Assay

Cytosolic phospholipase A2 (cPLA2) or prostaglandin E2 (PGE2) levels in cultured hippocampal neurons and tissues were assayed using a commercial mouse cPLA2 (Qiaodu-Bio, Cat# CK-E92479M) or PGE2 ELISA Kit (Qiaodu-Bio, Cat# CK-E90213M), respectively. The hippocampal neurons and tissues were homogenized in ice-cold 70  $\mu$ l RIPA (Solarbio, Cat# R0010) buffer. The samples were centrifuged at 13,000 g (4°C for 10 min). Ten micro-liter of the supernatant from the hippocampal homogenate was used to assay cPLA2 or PGE2 level, according to the manufacturer's protocols. The content of cPLA2 was based on measures of absorbance at 450 nm/well in a 96 well plate reader (Thermo Scientific, USA).

## Western Blot Assay

The hippocampus was collected after the behavioral assessments. Tissues were homogenized in RIPA lysis buffer (Beyotime, Cat# P0013C) containing a Protease Inhibitor Cocktail (one tablet for every 50 ml RIPA lysis buffer, Roche, Cat# 11697498001) and a Phosphoprotease Inhibitor Cocktail (one tablet for every 50 ml RIPA lysis buffer, Roche, Cat# 4906845001), then, crushed by ultrasound for 10 min by an ultrasonic cell disruptor (Banoelin, Germany). After 30 min of being adequately crushed, the lysates were centrifuged at 12,000 rpm, for 30 min at 4°C and the supernatant fraction was used for the Western blot assay. The protein concentration in the supernatant fraction was determined using the BCA protein assay kit (Beyotime, Cat# P0012). Equal amounts of soluble protein (25  $\mu$ g) were separated by 10% SDS-PAGE (Beyotime, Cat# P0456) and transferred onto poly-vinylidene fluoride (PVDF) membranes (0.45  $\mu$ m, Millipore, Cat# IPVH08100). After blocking with 5% fat-free milk; Beyotime, Cat# P0216) for 1 h, membranes were incubated with rabbit anti-PSD 95 (1:1,000, Cell Signaling, Cat# 3409), mouse anti-synaptotagmine-1 (1:1,000, Abcam, Cat# 13259), and rabbit anti- $\beta$ -actin (1:1,000, Cell Signaling, Cat# 4970) at 4°C

overnight. Membranes were then incubated with HRP linked anti-rabbit Antibody (1:5,000, Cell Signaling, Cat# 7074) or HRP linked anti-mouse antibody (1:5,000, Cell Signaling, Cat# 7076), respectively. Target bands were detected and quantified with BeyoECL Plus (1:1, Beyotime, Cat# P0018) by Amersham imager 600 (GE Healthcare Life Sciences, USA).

## Quantitative RT-PCR

Total RNA was extracted from primary cultured hippocampal neurons and reverse transcribed into cDNA following standard experimental procedures. The relative transcript level of CaSR was measured by quantitative PCR using LightCycle 480VR II PCR (Roche, Switzerland) with specific primers (CaSR, forward primer 5'-TTGCAAGGGCCAATGGTGG-3', reverse primer 5'-GCTTCCTGGGAAGACCCAT-3'; mouse-actin, forward primer 5'-AACAGTCCGCCTAGAAGCAC-3', reverse primer 5'-CGTTGACATCCGTAAAGACC-3').

## Statistical Analyses

Statistical analyses were performed with GraphPad PRISM software (GraphPad Software Inc., La Jolla, CA, USA, RRID:SCR\_00298). Data were presented as mean  $\pm$  SEM. Two-group comparisons were analyzed by a two-tailed student's *t*-test. Multiple group data were analyzed using a one-way analysis of variance (ANOVA) followed by a Tukey *post hoc* test, with the exception of the data of the place navigation test of the MWM tests, which were analyzed by two-way repeated-measures ANOVA with Tukey *post hoc* comparisons.  $P < 0.05$  was considered statistically significant. A test for outliers was not performed on the data.

## RESULTS

### The Expression Levels of CaSR Are Increased in AD Mice and $\text{A}\beta_{1-42}$ -Treated Primary Hippocampal Neurons

The expression levels of CaSR in APPswe/PSEN1dE9 transgenic mice and wild type mice were detected (Figures 1A,B). The expression levels of CaSR were significantly increased in the 9-month-old AD mice ( $P < 0.01$ , Figure 1G). The expression levels of CaSR in the control and  $\text{A}\beta_{1-42}$ -treated primary hippocampal neurons were also detected (Figures 1C–F). Both the mRNA and protein levels were increased by  $\text{A}\beta_{1-42}$  treatment ( $P < 0.05$ , Figure 1H;  $P < 0.01$ , Figure 1I). The results demonstrated that  $\text{A}\beta_{1-42}$  treatment upregulates the expression level of CaSR.

### Pharmacological Inhibition of CaSR Prevents Dendritic Filopodium Loss Caused by Oligomeric $\text{A}\beta_{1-42}$ in Hippocampal Neurons

To find out whether CaSR mediates  $\text{A}\beta_{1-42}$ -induced early synapse formation impairment, we measured the density of dendritic filopodium of hippocampal neurons at DIV 7 treated with  $\text{A}\beta_{1-42}$  oligomers, in the presence or the absence of CaSR antagonist NPS 2143 the density of dendrite filopodium of the  $\text{A}\beta_{1-42}$ -treated group was significantly reduced compared to the

**FIGURE 1 |** The expression levels of calcium-sensing receptor (CaSR) were increased in Alzheimer's disease (AD) mice and  $\beta$ -amyloid peptide ( $A\beta_{1-42}$ )-treated primary hippocampal neurons. **(A,B)** Immunostaining of CaSR (red) and DAPI (blue) in the hippocampus of wild type and APPswe/PSEN1dE9 transgenic mice. Scale bar 20  $\mu$ m. **(C-F)** Immunostaining of CaSR (red) and neuronal marker MAP2 (green) in primary cultured neurons in the control and 0.5  $\mu$ M  $A\beta_{1-42}$ -treated group. **(G)** Quantitative comparison of the mean density of CaSR in the hippocampus of wild type and APPswe/PSEN1dE9 transgenic mice. \*\* $P < 0.01$  vs. wild type group. Values represent mean  $\pm$  SEM,  $n = 6$  animals for each group. **(H)** Quantitative comparison of the mRNA levels of CaSR in control and  $A\beta_{1-42}$ -treated neurons. \* $P < 0.05$  vs. control group.  $n = 9$  repeats from three independent primary cell culture preparations. **(I)** Quantitative comparison of the mean density of CaSR in control and  $A\beta_{1-42}$ -treated neurons. \*\* $P < 0.01$  vs. control group,  $n = 48$ –51 neurons from three independent primary cell culture preparations.

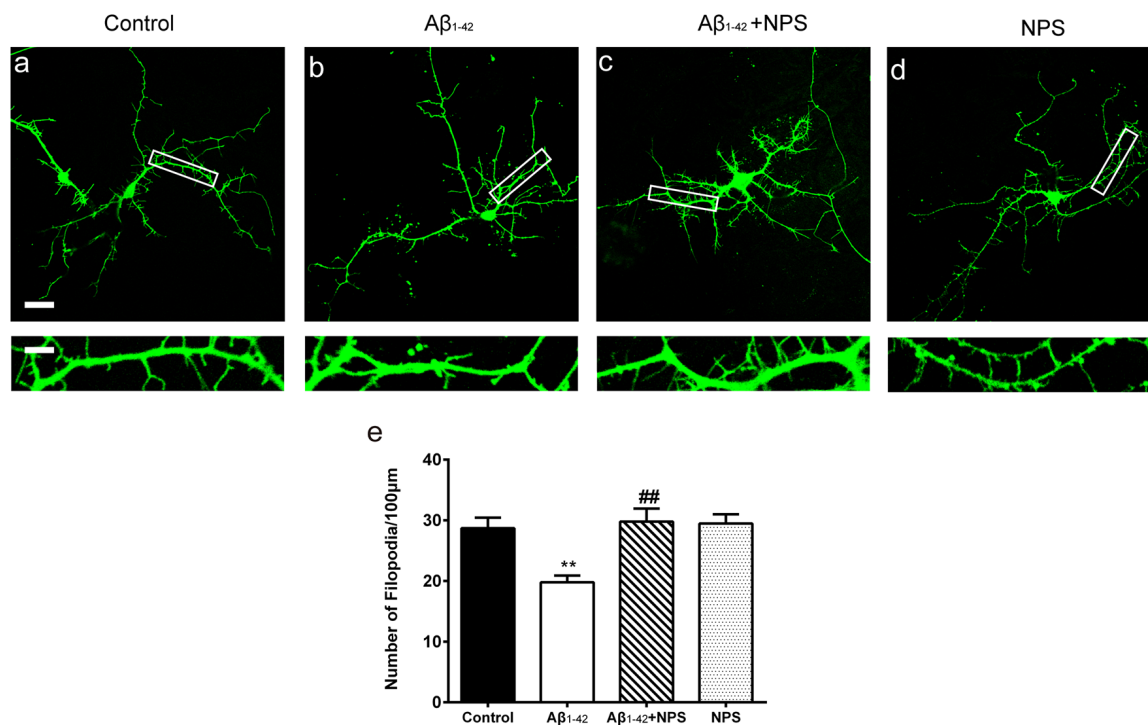

control group ( $P < 0.01$ , **Figure 2**). Treatment with NPS 2143 (0.1  $\mu$ M) significantly ameliorated the reduction of filopodium density induced by  $A\beta_{1-42}$  oligomers ( $P < 0.01$ ), while, NPS 2143 treatment alone did not alter the density of dendrite filopodium ( $P > 0.05$ , **Figure 2**).

### NPS 2143 Prevents Spine Loss and Synaptic Impairment Caused by Oligomeric $A\beta_{1-42}$ in Hippocampal Neurons

To further analyze the role of CaSR in synapse formation, the dendritic spine densities at DIV 14 were quantified in the control group, oligomeric  $A\beta_{1-42}$ -treated group, oligomeric  $A\beta_{1-42}$  + NPS 2143 group and the NPS 2143 alone group. The oligomeric  $A\beta_{1-42}$ -treated group prominently decreased the spine density ( $P < 0.01$ , **Figure 3**). Treatment with NPS 2143

(0.1  $\mu$ M) significantly prevented the decreased spine density induced by  $A\beta_{1-42}$  oligomers ( $P < 0.01$ , **Figure 3**), while, NPS 2143 treatment alone did not alter the density of the spine ( $P > 0.05$ , **Figure 3**). These results suggest that CaSR is involved in dendritic spine loss caused by  $A\beta_{1-42}$  oligomers in hippocampal neurons.

To confirm the effects of CaSR on synaptic impairment induced by  $A\beta_{1-42}$ , the synapse density was captured by immunocytochemistry (**Figures 4A–L**). At DIV 14, anti-presynaptic marker synaptotagmine-1 and anti-postsynaptic marker PSD 95 specific antibodies were used, and puncta per 100  $\mu$ m dendrite from secondary dendritic branches were analyzed. Compared with the control group, the numbers of synaptotagmine-1-positive puncta and PSD 95-positive puncta were significantly decreased after treatment with  $A\beta_{1-42}$  oligomers ( $P < 0.01$ , **Figures 4M,N**). The NPS

**FIGURE 2 |** Pharmacological inhibition of CaSR protected hippocampal neurons from soluble Aβ<sub>1-42</sub> oligomer-induced filopodium loss at day *in vitro* (DIV) 7. Structural morphology of filopodium of hippocampal neurons was displayed by co-transfection of F-GFP and GFP-actin. Fluorescent figures were displayed with the control group (A), the 0.5 μM Aβ<sub>1-42</sub> group (B), the 0.5 μM Aβ<sub>1-42</sub> + 0.1 μM NPS 2143 group (C) and the 0.1 μM NPS 2143 group (D). Scale bar 20 μm and 5 μm. (E) Quantitative comparison of the density of dendritic filopodia of the four groups. \*\**P* < 0.01 vs. control group, ##*P* < 0.01 vs. Aβ<sub>1-42</sub> oligomer-treated group. Values represent mean ± SEM, *n* = 21–25 neurons from three independent primary cell culture preparations.

2143 (0.1 μM) treatment significantly prevented the decreased puncta numbers of synaptotagmine-1 and PSD 95 induced by Aβ<sub>1-42</sub> oligomers (*P* < 0.01, **Figures 4M,N**), while, NPS 2143 treatment alone (0.1 μM) did not alter the numbers of synaptotagmine-1-positive puncta and PSD 95-positive puncta (*P* > 0.05, **Figures 4M,N**). The synaptic density of the Aβ<sub>1-42</sub> group was also significantly declined (*P* < 0.01, **Figure 4O**). The NPS 2143 (0.1 μM) treatment significantly ameliorated the reduction of synaptic density induced by Aβ<sub>1-42</sub> oligomers (*P* < 0.01), while, NPS 2143 treatment alone (0.1 μM) had no effect on the synaptic density (*P* > 0.05, **Figure 4O**).

### Down-Regulation of CaSR Expression Prevents Synaptic Impairment Induced by Oligomeric Aβ<sub>1-42</sub> in Hippocampal Neurons

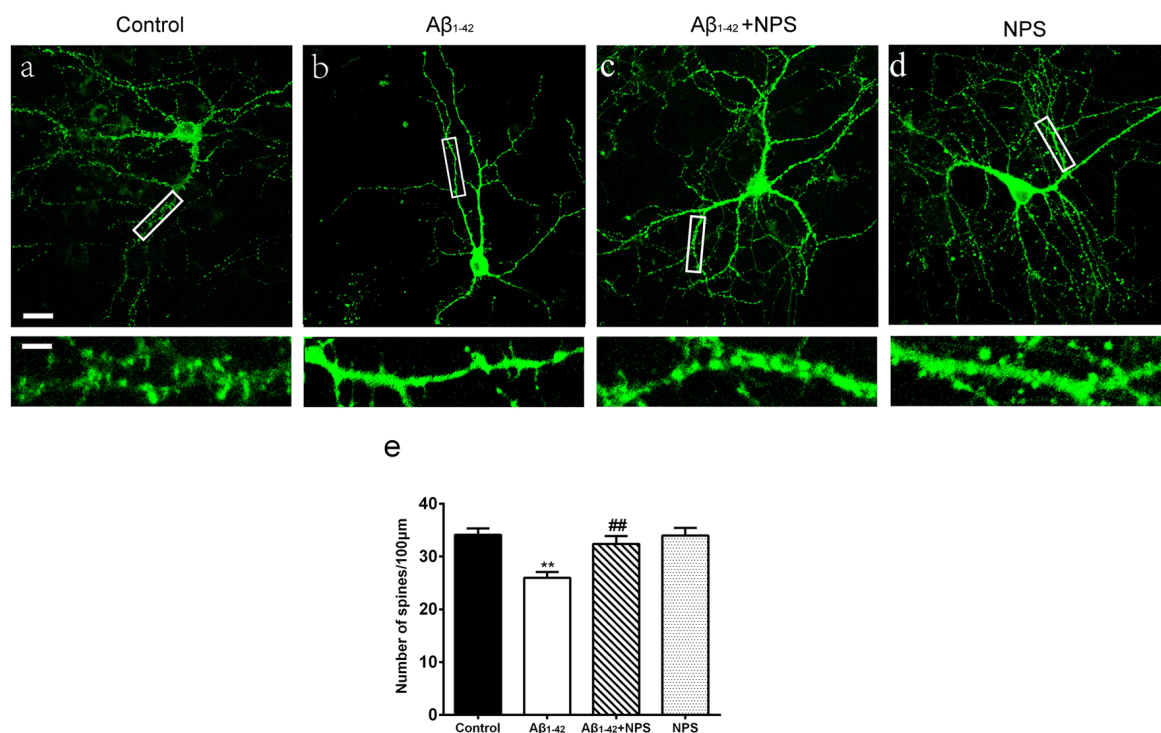

To further verify that CaSR mediates the synaptic impairment induced by Aβ<sub>1-42</sub>, the synaptic densities of neurons treated by the CaSR-shRNA-lentivirus or NC shRNA were analyzed by immunocytochemistry (**Figures 5A–P**). The expression level of CaSR was down regulated by the CaSR-shRNA-lentivirus (*P* < 0.01, **Figure 5Q**). Compared with the control group, the numbers of synaptotagmine-1-positive puncta and PSD 95-positive puncta were significantly decreased (*P* < 0.01, **Figures 5R,S**) in the oligomeric Aβ<sub>1-42</sub>-treated cells.

Down-regulation of the CaSR expression significantly prevented the decreased puncta numbers of synaptotagmine-1 and PSD 95 (*P* < 0.01, **Figures 5R,S**). The synapse number was also measured, and down-regulation of CaSR significantly protected hippocampal neurons from synapse loss induced by oligomeric Aβ<sub>1-42</sub> (*P* < 0.01, **Figure 5T**).

### NPS 2143 Prevents the Decreased Expression Levels of Synaptotagmine-1 and PSD 95 in AD Model Mice

Collective evidence shows that oligomeric Aβ<sub>1-42</sub> is regarded as the pertinent toxic form of Aβ (Baek et al., 2017; Choi et al., 2017). In order to study the single factor of Aβ and the underlying mechanism of CaSR in Aβ-mediated synaptic and cognitive impairment, the AD mouse model, made by microinjection with Aβ<sub>1-42</sub> oligomers, were used in the rest of our study.

To investigate whether CaSR also mediates the synaptic impairment in the AD mouse model, the expression levels of the presynaptic marker synaptotagmine-1 and postsynaptic mark PSD 95 were measured in the hippocampus of the mice which were microinjected with Aβ<sub>1-42</sub> (4 μmol/kg) and/or (0.08 or 0.16 μmol/kg) NPS 2143 (**Figures 6A,C**). The expression levels of synaptotagmine-1 and PSD 95 were significantly decreased in the hippocampus of the Aβ<sub>1-42</sub>-treated mice (*P* < 0.01, **Figure 6B**;

**FIGURE 3 |** NPS 2143 protected hippocampal neurons from soluble  $A\beta_{1-42}$  oligomer-induced spine loss at DIV 14. Structural morphology of the spine of hippocampal neurons was displayed by co-transfection of F-GFP and GFP-actin. Fluorescent figures captured by confocal were displayed with the control group (A), the 0.5  $\mu\text{M}$   $A\beta_{1-42}$  group (B), the 0.5  $\mu\text{M}$   $A\beta_{1-42}$  + 0.1  $\mu\text{M}$  NPS 2143 group (C) and the 0.1  $\mu\text{M}$  NPS 2143 group (D). Scale bar 20  $\mu\text{m}$  and 5  $\mu\text{m}$ . (E) Quantitative comparison of the density of the dendritic spine of the four groups. \*\* $P < 0.01$  vs. control group, ## $P < 0.01$  vs.  $A\beta_{1-42}$  oligomer-treated group. Values represent mean  $\pm$  SEM,  $n = 21$ –25 neurons from three independent primary cell culture preparations.

$P < 0.01$ , **Figure 6D**). The NPS 2143 (0.16  $\mu\text{mol/kg}$ ) treatment significantly prevented the decreased expression levels of PSD 95 and synaptotagmine-1 ( $P < 0.01$ , **Figure 6B**;  $P < 0.01$ , **Figure 6D**).

### Pharmacological Inhibition of CaSR Prevents Cognitive Deficits of $A\beta_{1-42}$ Oligomer-Treated Mice

Normal synapse formation is considered to be the structure basis of cognitive function. To find out whether the impairment of synapse formation mediated by CaSR was also involved in the cognitive deficits of the AD mouse model, NOR tests and MWM tests were used to estimate the role of CaSR in soluble  $A\beta_{1-42}$  oligomer induced recognitive and spatial memory deficits (**Figure 7**), respectively.

The discrimination indexes were used to evaluate the recognitive memory of animals in NOR tests. There was no significant difference in discrimination indexes among these groups in the training session ( $P > 0.05$ , **Figure 7B**). In the retention session, discrimination indexes were decreased in the mice injected with soluble  $A\beta_{1-42}$  oligomers ( $P < 0.05$ , **Figure 7C**). Inhibition of CaSR with NPS 2143 (0.16  $\mu\text{mol/kg}$ ) had no effect on discrimination indexes, but it significantly attenuated the  $A\beta_{1-42}$  oligomer-induced reduction of

discrimination indexes ( $P < 0.05$ , **Figure 7C**). The NPS 2143 (0.08  $\mu\text{mol/kg}$ ) treatment had no effect on  $A\beta_{1-42}$ -induced change in the discrimination indexes ( $P > 0.05$ , **Figure 7C**). These results indicated that NPS 2143 rescues  $A\beta_{1-42}$ -induced recognitive deficits in a dose dependent manner.

To further investigate whether CaSR is involved in  $A\beta_{1-42}$  oligomer-mediated spatial memory impairment, we examined memory performance with MWM tests in mice treated with  $A\beta_{1-42}$  oligomers in presence or absence of CaSR antagonist NPS 2143. Two-way ANOVA for repeated-measures revealed significant changes in drug effects ( $P < 0.01$ , **Figure 7D**) and time effects ( $P < 0.01$ , **Figure 7D**), but no interaction was found ( $P > 0.05$ , **Figure 7D**). The escape latency of  $A\beta_{1-42}$ -treated mice on day 3 and 4 was significantly longer compared with the control mice ( $P < 0.05$  and  $P < 0.01$  for day 3 and 4 respectively, **Figure 7D**). The escape latency of NPS 2143-treated mice (0.08 or 0.16  $\mu\text{mol/kg}$ ) was stable compared to that of the control mice. The NPS 2143 (0.08  $\mu\text{mol/kg}$ ) did not prevent the increase escape latency of  $A\beta_{1-42}$ -treated mice, however, the NPS 2143 (0.16  $\mu\text{mol/kg}$ ) treatment prevented the prolongation of latency induced by  $A\beta_{1-42}$  on day 3 and 4 ( $P < 0.05$ , **Figure 7D**). In the probe test, after the hidden platform was removed from the target quadrant, the  $A\beta_{1-42}$ -treated mice spent a shorter time in the target quadrant compared with the control mice ( $P < 0.01$ , **Figure 7E**). A 0.16  $\mu\text{mol/kg}$  NPS 2143 treatment reversed the

**FIGURE 4 |** NPS 2143 prevented hippocampal neurons from soluble Aβ<sub>1-42</sub> oligomer-induced synapse loss at DIV 14. Synapse was labeled through the co-localization of presynaptic marker synaptotagmine-1 (red) and postsynaptic marker PSD 95 (green). Sample figures of the control group (A,E,I), the 0.5 μM Aβ<sub>1-42</sub> group (B,F,J), the 0.5 μM Aβ<sub>1-42</sub> + 0.1 μM NPS 2143 group (C,G,K), and the 0.1 μM NPS 2143 group (D,H,L). Scale bar 20 μm and 5 μm. (M) Quantitative comparison of the numbers of synaptotagmine-1-positive puncta of the four groups. (N) Quantitative comparison of the numbers of PSD 95-positive puncta of different groups. (O) Quantitative comparison of the density of dendritic synapse of the four groups. \*\**P* < 0.01 vs. control group, ##*P* < 0.01 vs. Aβ<sub>1-42</sub> oligomer-treated group. Values represent mean ± SEM, *n* = 24–34 neurons from three independent primary cell culture preparations.

decrease of time in the target quadrant of the Aβ<sub>1-42</sub>-treated mice (*P* < 0.01, **Figure 7E**). However, treatment of NPS 2143 alone, at the dose of 0.08 or 0.16 μmol/kg, had no effect on the time

spent in the target quadrant (**Figure 7E**). Moreover, we measured the numbers of times the mice swam cross the place where the original platform was. The numbers of the target platform crosses

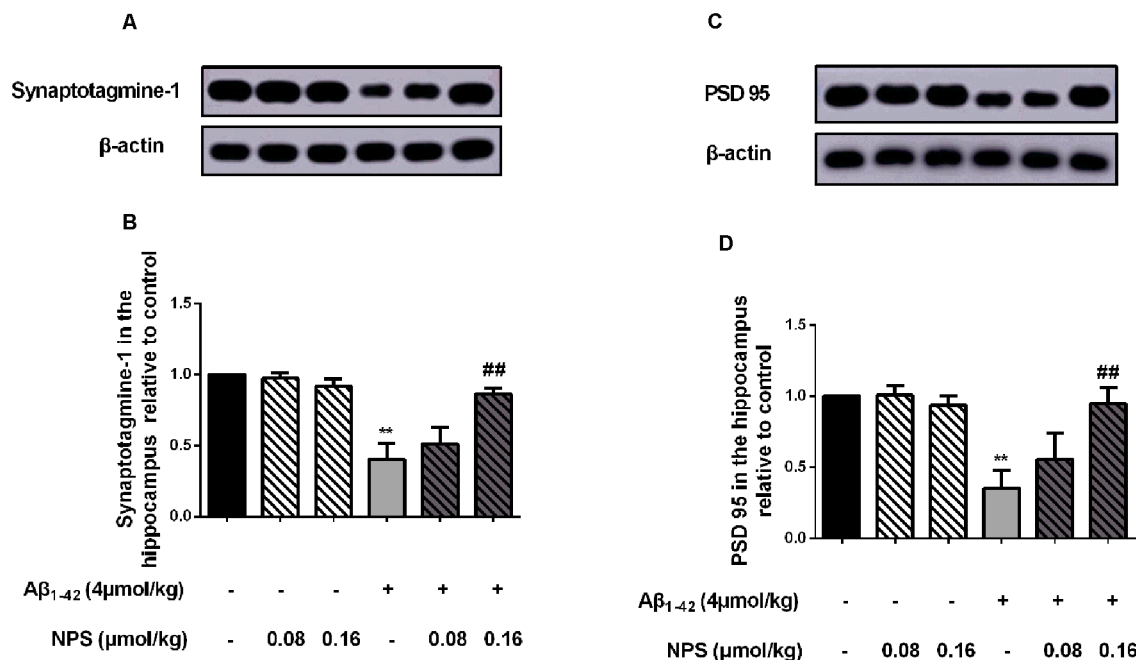

**FIGURE 5 |** Down-regulation of CaSR expression prevented synaptic impairment induced by oligomeric Aβ<sub>1-42</sub> in hippocampal neurons. Sample figures of the NC shRNA (**A,E,I,M**), the 0.5 μM Aβ<sub>1-42</sub> + NC shRNA group (**B,F,J,N**), the 0.5 μM Aβ<sub>1-42</sub> + CaSR-shRNA group (**C,G,K,O**), and the CaSR-shRNA group (**D,H,L,P**). Scale bar 20 μm and 5 μm. **(Q)** The expression level of CaSR was significantly down-regulated by CaSR-shRNA. \*\**P* < 0.01 vs. NC shRNA group. **(R,S)** Quantitative comparison of the number of synaptotagmin-1-positive puncta and PSD 95-positive puncta of the four groups. **(T)** Down-regulation of CaSR protected hippocampal neurons from synapse loss induced by oligomeric Aβ<sub>1-42</sub>. \*\**P* < 0.01 vs. NC shRNA group, #*P* < 0.05 vs. Aβ<sub>1-42</sub> + NC shRNA group, ##*P* < 0.01 vs. Aβ<sub>1-42</sub> + NC shRNA group. were decreased in the Aβ<sub>1-42</sub>-treated mice (*P* < 0.01, **Figure 7F**). Injection of NPS 2143 (0.16 μmol/kg) reversed the decreased crosses over the target platform of Aβ<sub>1-42</sub>-treated mice (*P* < 0.01, **Figure 7F**). However, treatment of NPS 2143 alone had no effect on the numbers of the target platform crosses (**Figure 7F**). We

did not observe a significant difference in velocity among the six groups in the MWM tests (**Figure 7G**), indicating that the differences in latency, time and number of crosses over the target platform among the groups were not caused by the differences in velocity. Altogether, these data suggested that pharmacological

**FIGURE 6 |** Pharmacological inhibition of CaSR prevented the decreased expression levels of synaptotagmine-1 and PSD 95 induced by oligomeric Aβ<sub>1-42</sub>. **(A)** Sample western-blot plot of synaptotagmine-1 and β-actin in the control, the oligomeric Aβ<sub>1-42</sub>-treated group (4 μmol/kg), and/or the NPS 2143-treated group (0.08 or 0.16 μmol/kg). **(B)** Quantitative comparison of hippocampal synaptotagmine-1 level in different groups. **(C)** Sample western-blot plot of PSD 95 and β-actin in six groups. **(D)** Quantitative comparison of hippocampal PSD 95 level in different groups. \*\**P* < 0.01 vs. control group, ##*P* < 0.01 vs. Aβ<sub>1-42</sub> oligomer-treated group. inhibition of CaSR prevents mice from Aβ<sub>1-42</sub> oligomer- induced spatial learning and memory deficits in MWM tests.

### CaSR Participates in Aβ<sub>1-42</sub>-Induced Increase in the Levels of cPLA2 and PGE2

To explore the downstream pathways mediated by CaSR and soluble Aβ<sub>1-42</sub> oligomers, the contents of cPLA2 and PGE2 were measured in hippocampal neurons. Aβ<sub>1-42</sub> treatment increased the content of cPLA2 (*P* < 0.01, **Figure 8A**). NPS 2143 (0.1 μM) treatment significantly prevented the increased level of cPLA2 induced by Aβ<sub>1-42</sub> oligomers (*P* < 0.01), while the level of cPLA2 remained stable under NPS 2143 (0.1 μM) alone treated neurons, compared with that of the control neurons. The expression level of CaSR was reduced by the CaSR-shRNA-lentivirus, and knocking down CaSR also prevented the increased cPLA2 content induced by Aβ<sub>1-42</sub> oligomers (*P* < 0.01, **Figure 8C**). Aβ<sub>1-42</sub> treatment also increased the content of PGE2 (*P* < 0.01, **Figure 8B**). The NPS 2143 (0.1 μM) treatment significantly prevented Aβ<sub>1-42</sub> oligomer-induced increase of the level of PGE2 (*P* < 0.01), while, the level of PGE2 remained stable under NPS 2143 (0.1 μM) alone treated neurons, compared with that of the control neurons (*P* > 0.05 **Figure 8B**). Down-regulation the expression level of CaSR also prevented the increased PGE2 content induced by Aβ<sub>1-42</sub> oligomers (*P* < 0.01, **Figure 8D**).

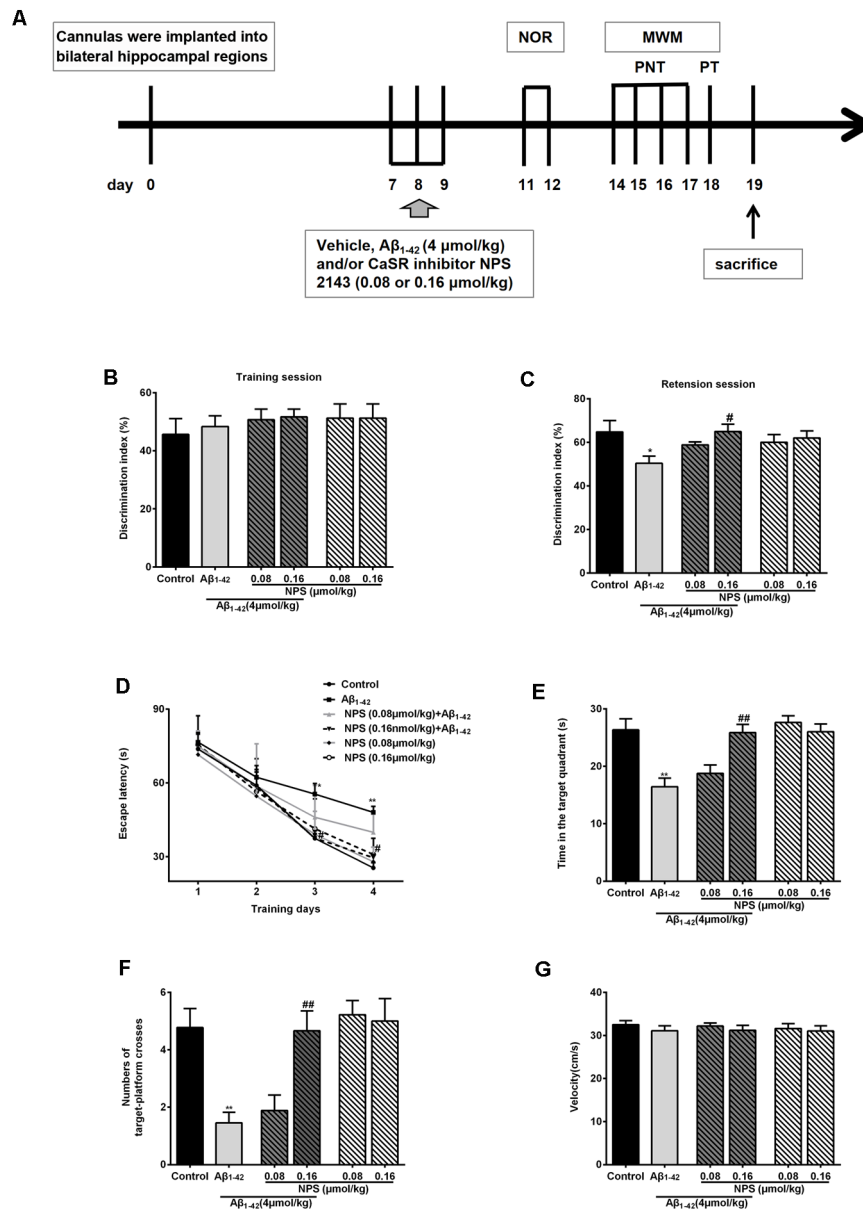

To verify the above results, the contents of cPLA2 and PGE2 in the hippocampus of the Aβ<sub>1-42</sub> (4 μmol/kg) and/or NPS

2143 (0.08 or 0.16 μmol/kg) treated mice were also measured. The contents of PGE2 and cPLA2 were significantly increased in the hippocampus of the Aβ<sub>1-42</sub>-treated mice (*P* < 0.01, **Figure 9A**; *P* < 0.01, **Figure 9B**). The NPS 2143 (0.16 μmol/kg) treatment reversed the increased levels of PGE2 and cPLA2 (*P* < 0.05, **Figure 9A**; *P* < 0.01, **Figure 9B**).

## DISCUSSION

To the best of our knowledge, our results, for the first, time demonstrate that the expression level of CaSR is increased by Aβ<sub>1-42</sub>. The increase expression or activity of CaSR mediates the AD-like phenotypes/pathology induced by Aβ<sub>1-42</sub> oligomers partially through activation of the cPLA2/PGE2 pathway. CaSR is located in nerve terminals which are related to synaptic plasticity and neuronal transmission (Bandyopadhyay et al., 2010). In this study, we provided novel insights to the possible role and underlying mechanisms of CaSR in AD.

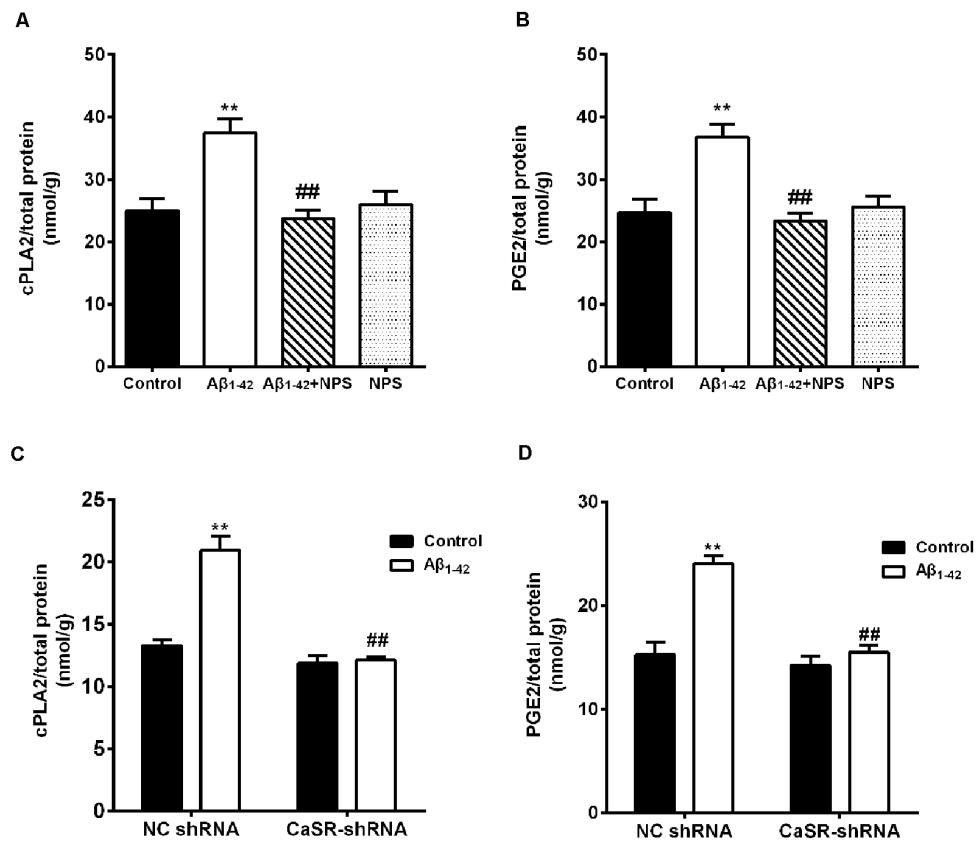

It is well accepted that the hippocampus is a region of the adult brain where neurogenesis occurs. Perturbations in synapse formation by forms of oligomeric Aβ are tightly correlated with memory deficits in AD (Bandyopadhyay et al., 2010; Marchetti and Marie, 2011; Ardiles et al., 2012; Ma and Klann, 2012; Sanchez et al., 2012; Xu et al., 2014). Growing evidence indicates that Aβ-induced synaptic loss in the hippocampus occurs at the early stage of AD (Teich et al., 2015; Wang X. et al., 2018). We demonstrated that exposure of Aβ<sub>1-42</sub> oligomers

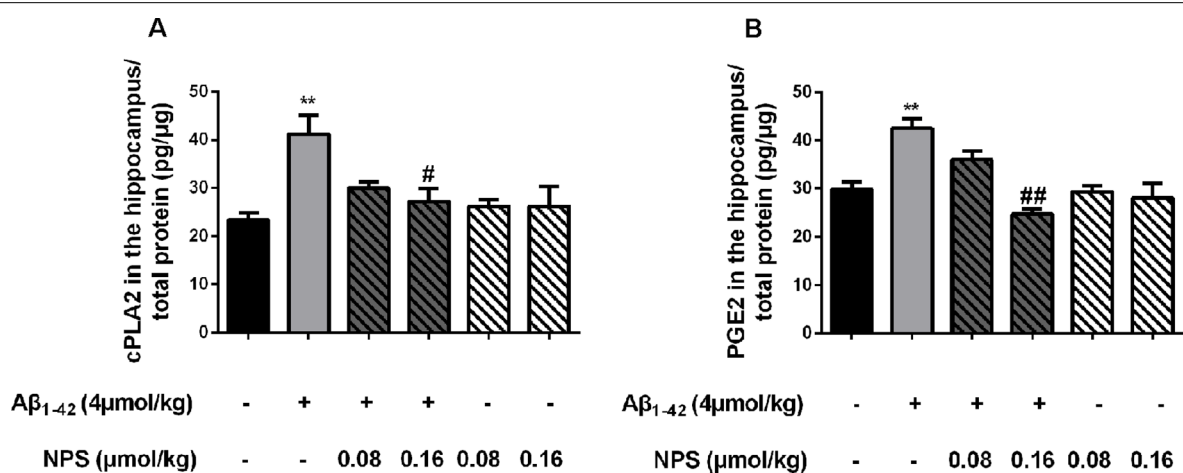

**FIGURE 7 |** Protective function of inhibiting CaSR on oligomeric Aβ<sub>1-42</sub>-induced cognitive and spatial learning deficits. **(A)** Experimental schedule of behavioral tests. Cannulas were implanted into bilateral hippocampal regions. Vehicle, Aβ<sub>1-42</sub> (4 μmol/kg) and/or CaSR inhibitor NPS 2143 (0.08 or 0.16 μmol/kg body weight per day) were microinjected for 3 days from day 7 to 9. From day 11 to day 12, the novel object recognition (NOR) tests were performed. Morris water maze (MWM) tests were conducted from day 14 to 18 day. Place navigation tests (PNT) of the MWM were conducted four times a day for four consecutive days, followed by a probe trial test (PT) 24 h after the last PNT. The mice were sacrificed after behavioral experiments. **(B)** Discrimination indexes displayed no significant difference among these groups in the training session. **(C)** Quantitative comparison of the discrimination indexes in the retention session,  $n = 8$  animals for each group. **(D)** The escape latency of the control, the oligomeric Aβ<sub>1-42</sub>-treated group (4 μmol/kg), and/or the NPS 2143-treated group (0.08 or 0.16 μmol/kg) during the four training days. **(E)** Quantitative comparison of the time in the target quadrant of the six groups. **(F)** Quantitative comparison of the number of target platform crosses of the six groups. **(G)** Swimming speed of the six groups did not show significant different. \* $P < 0.05$  vs. control group, \*\* $P < 0.01$  vs. control group, # $P < 0.05$  vs. Aβ<sub>1-42</sub> oligomer-treated group, ## $P < 0.01$  vs. Aβ<sub>1-42</sub> oligomer-treated group. Values represent mean  $\pm$  SEM,  $n = 8$  animals for each group.

potently decreased filopodium density in hippocampal neurons, while CaSR inhibitor NPS 2143 significantly prevented Aβ<sub>1-42</sub> oligomer-induced filopodium loss. These results suggest that CaSR is involved in the negative role of Aβ<sub>1-42</sub> during initial synapse formation. Dendritic spines, small membranous

protrusions from neuronal dendrites, are developed from filopodia. Consistent with the role of CaSR in the Aβ<sub>1-42</sub>-induced decrease in filopodium density, CaSR was also involved in the impairment of spine and synapse formation mediated by Aβ<sub>1-42</sub> oligomers. Both pharmacological inhibition of CaSR

**FIGURE 8 |** CaSR was involved in Aβ<sub>1-42</sub>-induced increase of cytosolic phospholipase A2 (cPLA2) and prostaglandin E2 (PGE2) in hippocampal neurons. **(A,B)** Quantitative comparison of the contents of cPLA2 and PGE2 in the Aβ<sub>1-42</sub>—(0.5 μM) and/or NPS 2143—(0.1 μM) treated groups. \*\**P* < 0.01 vs. control group, ##*P* < 0.01 vs. Aβ<sub>1-42</sub> oligomer-treated group. Values represent mean ± SEM, *n* = 12–13 independent replicates. **(C,D)** Quantitative comparison of the contents of cPLA2 and PGE2 in the Aβ<sub>1-42</sub> and/or CaSR-shRNA-lentivirus-treated groups. \*\**P* < 0.01 vs. NC shRNA group. ##*P* < 0.01 vs. Aβ<sub>1-42</sub> + NC shRNA group, *n* = 9 independent replicates.

**FIGURE 9 |** CaSR was involved in Aβ<sub>1-42</sub>-induced increase of cPLA2 and PGE2 in the hippocampus. **(A)** Quantitative comparison of the content of cPLA2 in the control, oligomeric Aβ<sub>1-42</sub>-treated group (4 μmol/kg), and/or NPS 2143-treated group (0.08 or 0.16 μmol/kg). **(B)** Quantitative comparison of the content of PGE2 in six groups. #*P* < 0.05 vs. Aβ<sub>1-42</sub> oligomer-treated group, \*\**P* < 0.01 vs. control group, ##*P* < 0.01 vs. Aβ<sub>1-42</sub> oligomer-treated group. Values represent mean ± SEM, *n* = 6 animals for each group.

and knockdown of CaSR prevented A $\beta$ <sub>1–42</sub>-induced synapse developmental deficits. Moreover, we found that CaSR also mediated A $\beta$ <sub>1–42</sub>-induced cognitive deficits. Using behavioral tasks, including MWM and NOR tests, we also showed that A $\beta$ <sub>1–42</sub> oligomers cause recognition and spatial memory impairment. Inhibition of CaSR with NPS 2143 prevented A $\beta$ <sub>1–42</sub>-induced cognitive deficits in a dose-dependent manner. Thus, CaSR mediates AD-like synaptic and cognitive impairment induced by A $\beta$ <sub>1–42</sub> oligomers.

cPLA2/PGE2 signaling pathways might be involved in the effects of CaSR on A $\beta$ -induced cognitive impairment. PGE2, a lipid molecule derived from arachidonic acid (AA; Brummett et al., 2014). cPLA2 affects the synthesis of PGE2 by promoting the release of AA (Bate and Williams, 2015a). It has been found that the activation of cPLA2/PGE2 is associated with multiple signaling pathways such as neuronal excitation, synaptic secretion, lipid metabolism, and neuroinflammation (Murakami and Kudo, 2004; Igarashi et al., 2011; Sun et al., 2014). Activation of cPLA2 enzymes plays an important role in age-associated neuronal and memory impairment (Hermann et al., 2014). Neurons isolated from mice deficient in cPLA2<sup>–/–</sup> showed resistance to the toxic effects of A $\beta$  (Desbène et al., 2012). PGE2 also regulates synaptic function and plasticity (Koch et al., 2010). Addition of PGE2 reduced the content of synaptic proteins in cortical neurons, and impaired hippocampal presynaptic long-term plasticity in a mouse model of AD (Bate et al., 2010; Maingret et al., 2017). Our results showed that the contents of cPLA2 and PGE2 in hippocampal neurons and hippocampal encephalic region were significantly increased due to oligomeric A $\beta$ <sub>1–42</sub> treatment. These results are consistent with previous studies showing that A $\beta$  oligomers could activate cPLA2 and increase the level of PGE2, resulting in a reduction of synaptic markers and a decline in cognitive function (Desbène et al., 2012; Bate and Williams, 2015b). Both pharmacological inhibition of CaSR and down-regulation of the expression of CaSR prevented A $\beta$ -induced increase of cPLA2/PGE2 and synaptic damage. Thus, CaSR might mediate A $\beta$ -induced synaptic and cognitive damage through increasing cPLA2 and PGE2 contents.

Besides activation of the cPLA2/PGE2 pathway, CaSR has also been reported to be involved in the A $\beta$ -induced increase of A $\beta$  and phospho-tau (Dal Prà et al., 2014; Chiarini et al., 2017); this might also contribute to the decrease in cognitive decline in AD mice. At physiological conditions, CaSR was only partially activated (Ruat and Traiffort, 2013; Díaz-Soto et al., 2016). Increased A $\beta$  made CaSR full or over activated, which

further induced the early impairment of synapse formation and cognitive function. Together with our observations, the current data showed that CaSR is an important factor mediating the progress of AD.

In conclusion, we demonstrated that CaSR is involved in oligomeric A $\beta$ <sub>1–42</sub>-induced cognitive dysfunction as well as synapse formation and developmental impairment in the pathogenesis of AD, in addition, our results indicated that cPLA2 and PGE2 are downstream targets of CaSR, which mediate cognitive decline in AD. Thus, we provided support for the efficacy of specific antagonists of CaSR in the treatment of AD.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

## ETHICS STATEMENT

The animal study was reviewed and approved by Institutional Animal Care and Use Committee of the Medical School of Ningbo University [permission: SYXK(ZHE)2013-0191].

## AUTHOR CONTRIBUTIONS

SX and XB were responsible for the design of the study. CF was in charge of molecular and cellular experiments. YL, YD, and YC were mainly involved in animal experiments and relative analysis. QW and JW provided valuable advice for the research. WC and LS provided language modification and data analysis. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by grants from the National Natural Science Foundation of China (81771166), the Natural Science Foundation of Zhejiang Province (LY20H090004), the Natural Science Foundation of Ningbo (2019A610288), the Ningbo municipal innovation team of life science and health (2015C110026), the Suzhou youth science and technology project (KJXW2017021) and the K.C. Wong Magna Fund at Ningbo University.

Current researches on default mode network (DMN) in normal elderly have mainly focused on finding some dysfunctional areas with decreased or increased connectivity. The global network dynamics of apolipoprotein E (APOE) e4 allele group is rarely studied. In our previous brain network study, we have demonstrated the advantage of persistent homology. It can distinguish robust and noisy topological features over multiscale nested networks, and the derived properties are more stable. In this study, for the first time we applied persistent homology to analyze APOE-related effects on whole-brain functional network. In our experiments, the risk allele group exhibited lower network radius and modularity in whole brain DMN based on graph theory, suggesting the abnormal organization structure. Moreover, two suggested measures from persistent homology detected significant differences between groups within the left hemisphere and in the whole brain in two datasets. They were more statistically sensitive to APOE genotypic differences than standard graph-based measures. In summary, we provide evidence that the e4 genotype leads to distinct DMN functional alterations in the early phases of Alzheimer's disease using persistent homology approach. Our study offers a novel insight to explore potential biomarkers in healthy elderly populations carrying APOE e4 allele.

**Keywords:** APOE, Alzheimer's disease, persistent homology, resting state functional magnetic resonance imaging, graph theory, network measure

## INTRODUCTION

Alzheimer's disease (AD) (Lane et al., 2018) is the most common form of dementia among the elderly and the sixth leading cause of death in the United States. There are more than 50 million patients worldwide in 2018, and it is expected to reach a staggering 152 million by 2050 (Patterson, 2018). It is crucial to develop the AD-related biomarkers early in the aging process before the onset of overt cognitive impairment and irreversible brain damage (Korthauer et al., 2018). One hypothesis (Reiman et al., 2009; Lambert et al., 2013; Yu et al., 2019) for the pathogenesis (Karch and Goate, 2015) of AD indicate the apolipoprotein E (APOE) e4 allele (Lane-Donovan and Herz, 2017) involves the accumulation of Amyloid- $\beta$  (Caselli et al., 2010), leading to increasing

neuronal atrophy and synapse loss. To date, APOE is a major genetic risk factor for developing AD (Thompson et al., 2013; Zhu et al., 2019). Functional neuroimaging genetics provides an effective strategy for characterizing the intermediate phenotype of AD and identifying genes that contribute to functional alterations in brain networks (Chiesa et al., 2017; Chiesa et al., 2019). In particular, recent research has demonstrated that default mode network (DMN) (Raichle, 2015) is associated with progressive brain dysfunction and is susceptible to APOE genotype (Song et al., 2015; Ma et al., 2016; Yuan et al., 2016; Palmqvist et al., 2017; Staffaroni et al., 2018; Chiesa et al., 2019).

Graph theory has increasingly been used as a theoretical framework for studying brain network characteristics. At the level of regional connection, functional connectivity between brain nodes as an important biomarker can identify early brain function alteration related to AD pathophysiology (Bokde et al., 2009). It is dedicated to investigating the distinct connectivity within the DMN that could represent the progressive biomarker. However, the results of resting state functional MRI (rs-fMRI) (Teipel et al., 2015) and APOE studies have reported mixed results (Cai et al., 2017; Luo et al., 2017; Caldwell et al., 2019; Zhu et al., 2019). Some reported decreased functional connectivity (Yan et al., 2015) in APOE  $\epsilon 4$  allele carriers (APOE4+) compared with non-carriers (APOE4-), the others found some increased functional connectivity (Song et al., 2015; Zhu et al., 2018), while others didn't find any differences (Chiesa et al., 2019). At the global whole-brain level, some neurobiologically meaningful graph-theoretic properties have become important indicators for measuring brain functional networks, through which we can understand the altered network architecture in those carrying risk genotype, including a loss of small-world network (Korthauer et al., 2018), a redistribution of hubs (Wink et al., 2018), and a disrupted modular organization (Li et al., 2019). However, there are currently few network measures based on graph theory have been studied in cognitively unimpaired elderly (Seo et al., 2013; Luo et al., 2017; Pietzuch et al., 2019) and some of their results were reported as inconsistent (Seo et al., 2013; Qiu et al., 2016; Luo et al., 2017). For instance, Wink et al. (2018) found decreased centrality of DMN in APOE4+ comparing to non-carriers, while Wang et al. (2017) didn't find such genotype difference of centrality in normal elderly. Overall, graph-theoretic methods cannot consistently demonstrate functional DMN difference between APOE4+ and APOE4- in normal elderly, and the reason has been debated in the literature (Chiesa et al., 2017).

Recently, persistent homology (Edelsbrunner and Harer, 2010) from algebraic topology has been adopted for the analysis of brain network. It uses graph filtration to construct a multiscale brain network with all possible thresholds wherever the persistent topological features over the network dynamics are identified (Giusti et al., 2016). This method can distinguish robust and noisy topological features over a wide range of filtration values in measuring global brain network organization. The typical approach of persistent homology is Betti number plot (BNP) (Edelsbrunner and Harer, 2010; Lee et al., 2012), which has successfully applied to the brain network research on epilepsy (Choi et al., 2014), autism spectrum disorder and attention-deficit hyperactivity disorder (Lee et al., 2012, 2017), etc. In our previous

works (Kuang et al., 2019a,b), we have developed some network properties based on persistent homology and have successfully applied them to measure the metabolic and functional networks of AD and MCI patients. Although the persistent homology works well in cognitively impaired elderly, it has never been applied to study the genetic influence on brain network yet, especially in unimpaired individuals.

In this paper, we study the effect of APOE genotype on functional DMN in cognitively unimpaired subjects. We hypothesized the topological properties of persistent homology may reveal the APOE-related alteration in DMN even before clinical symptoms appear better than graph-theoretic approaches. Using the cross-sectional rs-fMRI imaging data of 27 APOE4+ and 31 APOE4- normal elderly, we test this hypothesis by computing two persistent homology-based properties and measuring the differences between APOE4+ and APOE4- groups. We further run the statistical inference to validate their powers and compare them with some graph-theoretic methods.

## MATERIALS AND METHODS

We summarize the pipeline of our framework in **Figure 1**. The rs-fMRI (Teipel et al., 2015) data of each subject are preprocessed and the blood oxygen level dependent (BOLD) signals within each region-of-interest (ROI) are obtained. Then we construct one weighted DMN per subject and quantify its global topological structure using graph theory and persistent homology. The details are described in following subsections.

### Participants

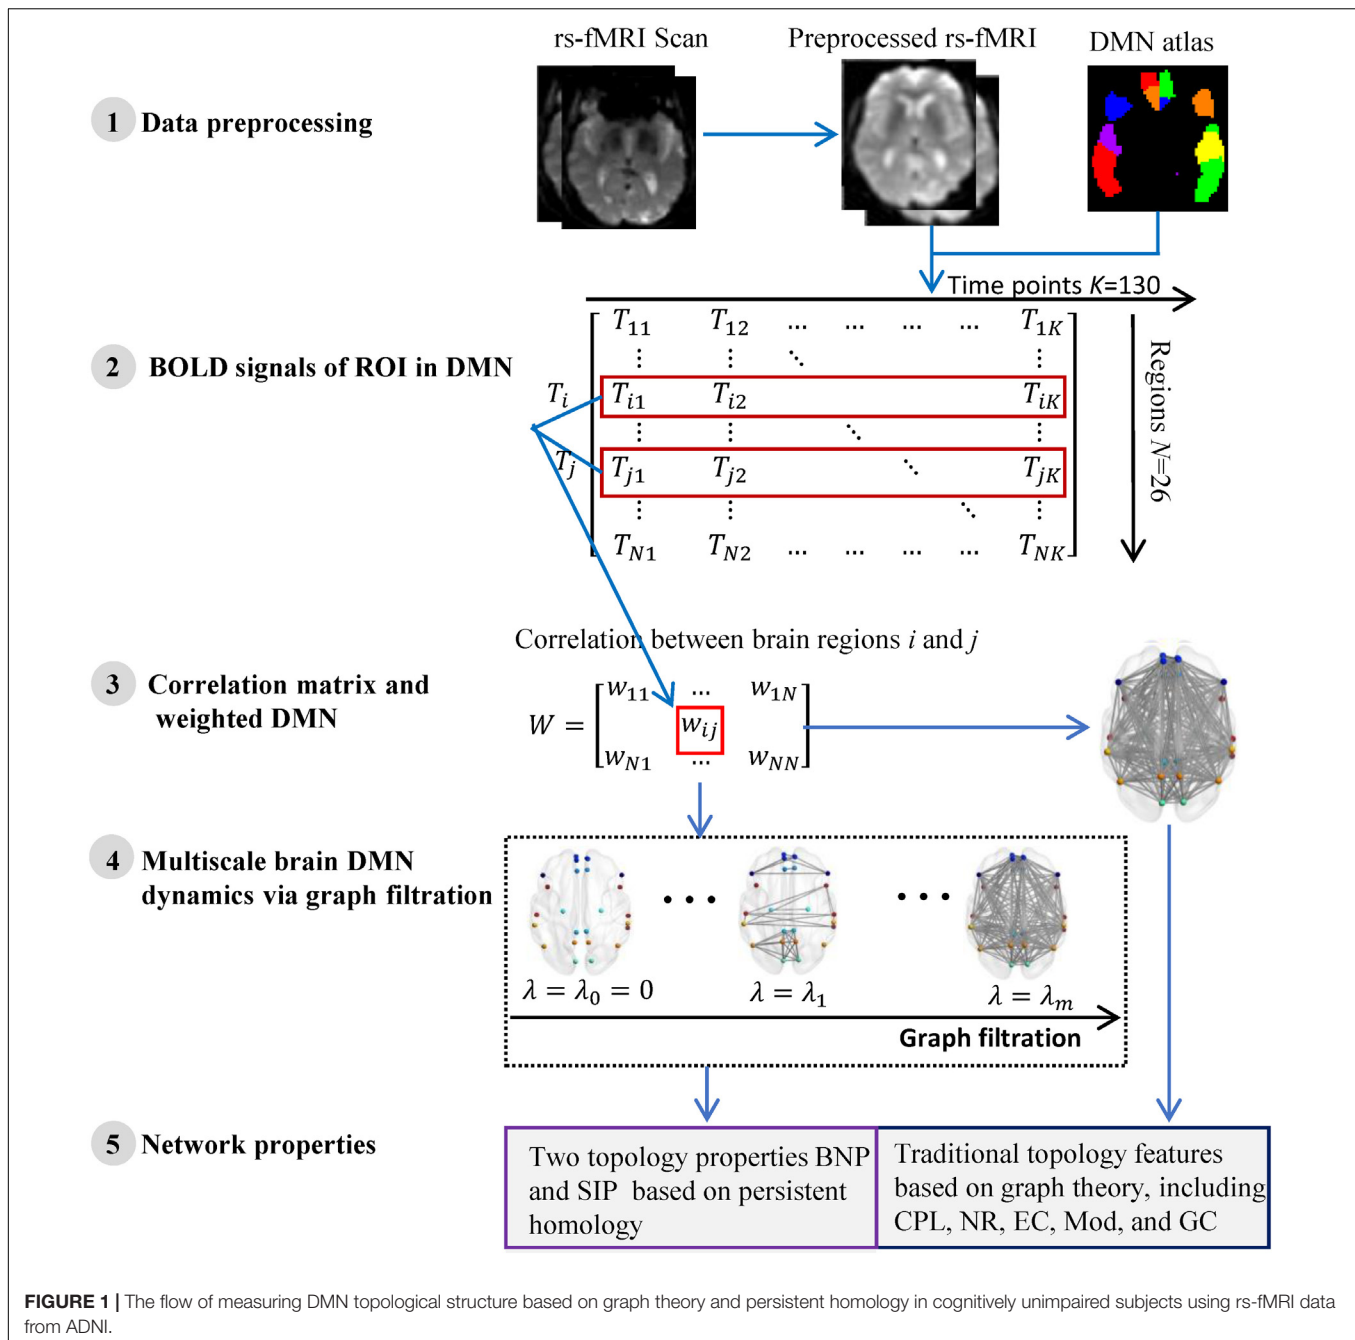

Data used in the preparation of this article were obtained from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database<sup>1</sup> (Jack et al., 2008; Jagust et al., 2010). The ADNI was launched in 2003 as a public-private partnership, led by Principal Investigator Michael W. Weiner, MD. The primary goal of ADNI has been to test whether serial magnetic resonance imaging (MRI), positron emission tomography (PET), other biological markers, and clinical and neuropsychological assessment can be combined to measure the progression of mild cognitive impairment (MCI) and early Alzheimer's disease (AD).

There were only 38 Normal Controls (NC) between the ages of 60 and 90 from the ADNI-2 who had available rs-fMRI and APOE data. Due to the small sample size of NC, we also introduced Subjective Memory Complaints (SMC), producing a dataset of cognitively unimpaired subjects in this study. The only difference from NC is that SMC reported memory problems by themselves. Individuals with two copies of the apolipoprotein  $\epsilon 2$  allele (APOE  $\epsilon 2/\epsilon 2$ ) were excluded due to its possible protective effects (Suri et al., 2013). Finally, individuals carrying at least one APOE  $\epsilon 4$  allele (genotype  $\epsilon 3/\epsilon 4$  and  $\epsilon 4/\epsilon 4$ ) were classified as APOE4+, while individuals with genotype  $\epsilon 3/\epsilon 3$  were classified as APOE4-.

### Data Acquisition and Preprocessing

The experimental dataset were acquired at multiple ADNI sites using 3.0 T Philips MRI scanners. All rs-fMRI data were obtained

<sup>1</sup>adni.loni.usc.edu

using an echo-planar imaging (EPI) sequence and the parameters included repetition time (TR) = 3000 ms, echo time (TE) = 30 ms, flip angle = 80°, number of slices = 48, slice thickness = 3.3 mm, voxel size = 3 mm × 3 mm × 3 mm, voxel matrix = 64 × 64, and time points = 140.

All functional images were pre-processed using SPM8 toolbox<sup>2</sup>, DPARSF<sup>3</sup> (Yan and Zang, 2010), and REST<sup>3</sup> (Song et al., 2011) according to well-accepted pipelines,

the same as our prior work (Kuang et al., 2019a). Briefly, the first ten time points were removed before temporal correction and spatial normalization. Then image smoothing, linear trend adjustment and band-pass filter were performed sequentially.

## Construction of DMN

First, the whole brain is divided into 90 functional ROI using standard automated anatomical labeling atlas (AAL90) (Tzourio-Mazoyer et al., 2002). Then 26 areas (Vriend et al., 2018) in AAL90 are identified as the ROI of DMN, as shown in **Table 1**.

<sup>2</sup><http://www.fil.ion.ucl.ac.uk/spm/>

<sup>3</sup><http://www.restfmri.net>

**TABLE 1** | The division of twenty six ROI nodes in DMN based on AAL90 atlas.

ROI node name	Left hemisphere		Right hemisphere	
	Index in AAL90	Abbreviation	Index in AAL90	Abbreviation
Inferior frontal gyrus pars triangularis	13	IFGtriang.L	14	IFGtriang.R
Medial frontal gyrus	23	SFGmed.L	24	SFGmed.R
Superior medial orbital frontal cortex	25	ORBsupmed.L	26	ORBsupmed.R
Anterior cingulate and paracingulate gyrus	31	ACG.L	32	ACG.R
Posterior cingulate gyrus	35	PCG.L	36	PCG.R
Parahippocampal gyrus	39	PHG.L	40	PHG.R
Cuneus	45	CUN.L	46	CUN.R
Supramarginal gyrus	63	SMG.L	64	SMG.R
Angular gyrus	65	ANG.L	66	ANG.R
Precuneus	67	PCUN.L	68	PCUN.R
Superior temporal gyrus	81	STG.L	82	STG.R
Temporal pole: superior temporal gyrus	83	TPOsup.L	84	TPOsup.R
Middle temporal gyrus	85	MTG.L	86	MTG.R

There are 13 ROI per hemisphere and each ROI is considered as a network node of DMN.

The average timing BOLD signal serial  $T_i = (T_{i1}, T_{i2}, \dots, T_{ik})$  within the  $i$ -th ROI node is used as its measurement (Step 2 in **Figure 1**). We define the functional connectivity (i.e., edge weight) between any pair of ROI as 1-Pearson coefficient of their BOLD signal serials, i.e.

$$W_{ij} = 1 - \frac{\text{cov}(T_i, T_j)}{\sigma_{T_i} \sigma_{T_j}} = 1 - \frac{\sum_{p=1}^k (T_{ip} - \bar{T}_i)(T_{jp} - \bar{T}_j)}{\sqrt{\sum_{p=1}^k (T_{ip} - \bar{T}_i)^2} \sqrt{\sum_{p=1}^k (T_{jp} - \bar{T}_j)^2}} \quad (1)$$

where  $T_{ip}$  represents the average BOLD signal within the  $i$ -th ROI at  $p$ -th time point and  $K = 130$  is total number of time points of the rs-fMRI data. Thus, the functional connection matrix ( $N \times N$ ) per subject is obtained (Step 3 in **Figure 1**) and each subject's DMN is constructed. Here  $N = 26$  if the DMN of entire brain is studied, otherwise  $N = 13$  if only one hemispheric DMN is studied.

## Measuring DMN Using Graph Theory

In the past decade, the neurobiologically meaningful network properties based on graph theory have become important indicators in measuring brain functional networks. We validate some widely used graph measures in this study (Right part of step 5 in **Figure 1**), including characteristic path length (CPL) (Li et al., 2019), global efficiency (GC) (Shu et al., 2015), network radius (NR) (Fujita et al., 2017), modularity (Mod) (Li et al., 2019), and eigenvector centrality (EC) (Luo et al., 2017). Briefly, the average shortest path length between all pairs of nodes in the network is CPL, while the average inverse shortest path length is called GC. Then NR is the minimum eccentricity of all nodes in the network and nodal eccentricity is the greatest distance between this node and any other nodes. Further, Mod measures the extent to which the network can be

subdivided into clearly delineated and non-overlapping groups, and EC computes the sum of centralities of the node's direct neighbors. All these network measures were calculated by Brain Connectivity Toolbox (BCT)<sup>4</sup> in Matlab R2017a.

## Measuring DMN Using Persistent Homology

Persistent homology (Edelsbrunner and Harer, 2010) is a mathematical concept derived from algebraic topology and is used to characterize topological features in complex data. There is an important tool, graph filtration (Giusti et al., 2016), in persistent homology that constructs a family of nested networks along an axis at their threshold values by thresholding original weighted network at every possible entry (Step 4 in **Figure 1**). Thus, it can distinguish robust and noisy topological characteristics in a wide range and enables reasonable inferences regarding the underlying organization. The classic network property based on persistent homology is BNP which detects the dynamic of the zeroth Betti number (i.e., the number of connected components) over all filtration values (Lee et al., 2012). It has been successfully applied to the some studies (Lee et al., 2012, 2017; Choi et al., 2014) of brain network in neurodegenerative diseases.

In our previous work (Kuang et al., 2019a), we proposed an integrated persistent feature (IPF) based on BNP, which introduced a connected component aggregation cost into the zeroth Betti number and thus achieves a holistic description of network dynamics. The IPF at filtration  $\lambda_i$  is defined as (Kuang et al., 2019a).

$$IPF\lambda_i = \begin{cases} \frac{m-i}{m(m-1)} \sum_{k=i+1}^{m-1} \lambda_k & 0 \leq i \leq m-2 \\ 0 & i = m-1 \end{cases} \quad (2)$$

Here,  $m$  is total number of network nodes and  $\lambda_0 = 0 < \lambda_0 < \lambda_1 < \lambda_2 < \dots < \lambda_{m-1}$  is the filtration

**TABLE 2 |** Demographic characteristics of the high-risk (APOE4+) and low-risk (APOE4-) groups.

	APOE4+ (n = 27)	APOE4- (n = 31)	p-value
NC/SMC	16/11	22/9	–
Age	73.26 ± 6.83	74.58 ± 5.18	0.407
Education	16.81 ± 2.17	17.22 ± 2.93	0.569
Male/Female	12/15	15/16	0.769
MMSE Score	28.17 ± 1.53	28.53 ± 1.55	0.734

Data is presented as means ± standard deviations. APOE4+, APOE e3/e4 and e4/e4 alleles; APOE4-, APOE e3/e3 allele; NC, Normal Control; SMC, Subjective Memory Complaint; MMSE, Mini-Mental State Examination; CDR, Clinical Dementia Rating.

value which is actually the set of weights of minimum spanning tree of the original weighted network. Previous work has proven that the IPF is a monotonically decreasing convergence function over all possible filtration. In summary, when  $\lambda$  increases from zero, the IPF value of the network will decrease to zero accordingly until all nodes are connected into a single connected component. Therefore, the slope of the IPF plot (SIP) can be used as an important network property to quantify the brain network dynamics. Both network measures BNP and SIP can be considered as information diffusion rate or convergence rate of the network. We provided their implementations at <http://gsl.lab.asu.edu/software/IPF> and applied them in this study (Left part of step 5 in **Figure 1**).

## RESULTS

### Demographic Information

In this experiment, 58 subjects without cognitive impairment were selected from ADNI-2, and were divided into two groups, APOE e4 carriers and non-carriers, according to their APOE genotype. Among them, 20 subjects were identified as SMC and remaining 38 subjects were NC. The only difference from NC is that SMC reported memory problems by themselves. We considered both as cognitively impairment subjects in this study. As shown in **Table 2**, there were no significant differences in age, education, Mini Mental State Examination (MMSE) score, and Clinical Dementia Rating (CDR) global scores between groups. All subjects had MMSE of 24–30, CDR = 0, and were cognitively unimpaired. Furthermore, all studied images did not have excessive head motion (six-parameter rigid body) defined by a displacement of less than 1 mm or an angular rotation of less than in any direction 1°.

### Multiscale Brain DMN Dynamics

We constructed one original weighted DMN per subject. The 26 network nodes in whole brain DMN were determined according to **Table 2** and are visualized in **Figure 2** using Brain Net Viewer software (Xia et al., 2013). Then, the edge weights between them were calculated using Eq. (1). We further constructed multiscale networks based on the original DMN using graph filtration tool (Step 4 in **Figure 1**). As we only observe the zeroth homology in this study, the filtration value  $\lambda$  is actually the set of weights of

minimum spanning tree of DMN. **Figure 3** shows the multiscale network dynamics for two mean DMN of two groups over some filtration values. **Figure 4** shows the change of zeroth Betti number using single linkage dendrogram (Lee et al., 2012). All the nodes on the left are connected to form the larger component on the right, until finally a fully connected network is constructed. The zeroth Betti number starts at 26, and gradually decreases to 1 while more and more nodes are connected.

From **Figures 3, 4**, we intuitively saw that the connected components in APOE+ aggregated slightly faster than APOE-, especially after  $\lambda$  is larger than 0.35. However, it needs to be further quantitatively measured by network properties based on persistent homology.

### Brain DMN Properties

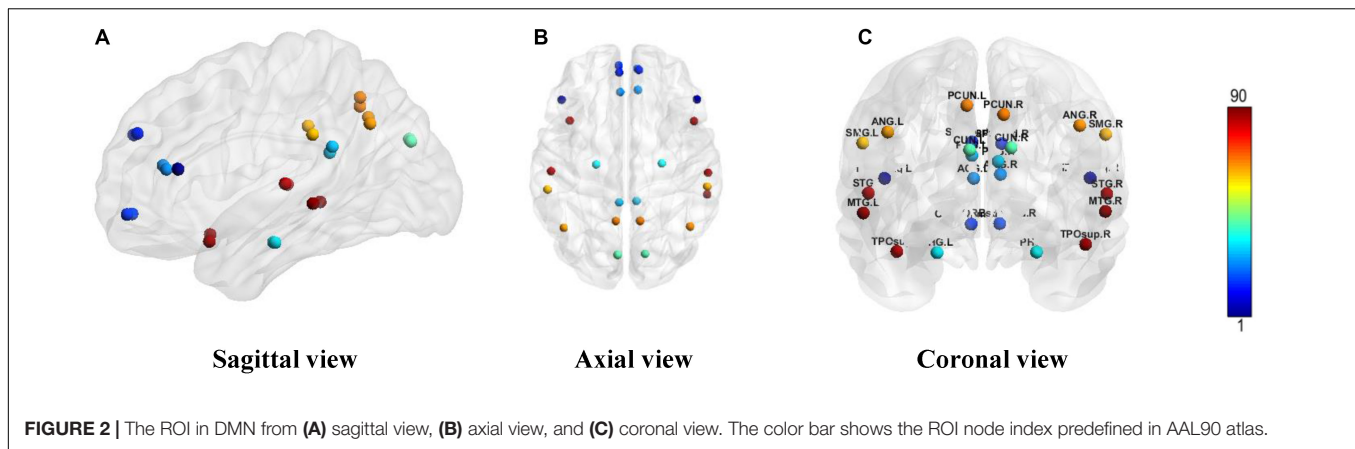

We calculated the corresponding Betti number  $\beta_0$  and IPF of the multiscale DMN at all different filtration values for two group means, and plotted them, as shown in **Figure 5**. We found that the APOE+ curve in both Betti number plot and IPF plot were steeper than the APOE- curve, suggesting the faster aggregation of APOE+, which is consistent with the above observation of multiscale brain dynamics (see **Figures 3, 4**). All subjects' values of BNP and SIP properties based on persistent homology were summarized using box plot as shown in **Figures 6A,B**, separately, where 1 represents APOE4+ and 2 is APOE4-. The distributions of both BNP and SIP property values between groups are obviously different, indicating both persistent features may be able to discriminate APOE4+ from APOE4-.

Traditionally, brain network properties have been measured using graph theory methods. In order to compare with our suggested methods based on persistent homology, we also calculated some classical graph theory properties, including CPL, NR, EC, Mod, and GC. The distributions of all attribute values are shown in **Figures 6C–G** where 1 and 2 represents APOE4+ and APOE4-, respectively. We observed that the between-group differences of SIP, BNP, NR, and Mod are more apparent than those of CPL, EC, and GC.

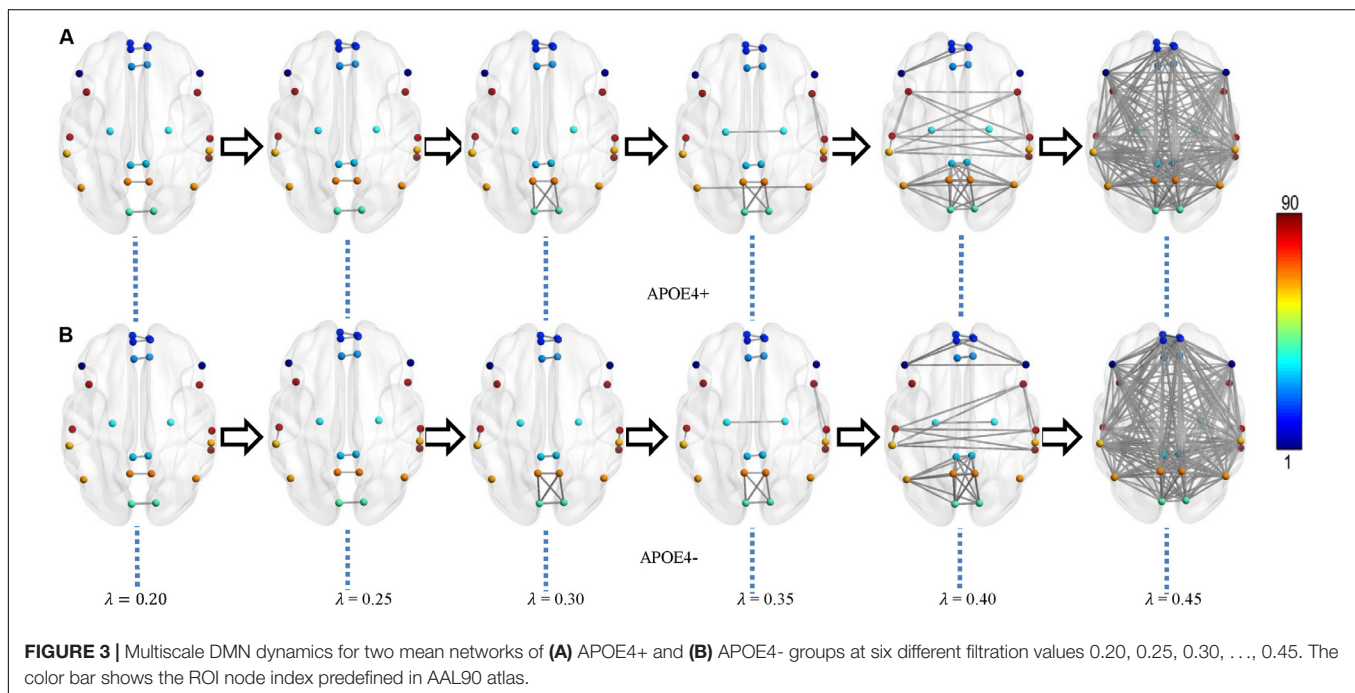

### Statistical Group Difference

In the statistical analysis of differences between groups of APOE4+ and APOE4-, we performed the permutation test of 10,000 permutations on all network properties using Matlab R2017a and calculated their resulting  $p$ -values as shown in **Table 3**. First, the differences between groups in whole brain DMN with 26 ROI nodes were measured. Two persistent features SIP and BNP obtained significant differences at significance level of 0.05, which were  $p = 0.021$  and  $p = 0.009$ , respectively. In the statistic inferences for five compared graph theory-based properties, only NR and Mod obtained significant differences with  $p = 0.024$  and  $p = 0.037$ , respectively, while there were no significant differences in other three properties, CPL, EC, and GC. Then, we analyzed the group differences within the single hemisphere and only two measures SIP and BNP achieved significant differences ( $p = 0.027$ , both) within the left hemisphere. We did not find any differences within the right hemisphere.

**FIGURE 2 |** The ROI in DMN from (A) sagittal view, (B) axial view, and (C) coronal view. The color bar shows the ROI node index predefined in AAL90 atlas.

**FIGURE 3 |** Multiscale DMN dynamics for two mean networks of (A) APOE4+ and (B) APOE4- groups at six different filtration values 0.20, 0.25, 0.30, ..., 0.45. The color bar shows the ROI node index predefined in AAL90 atlas.

In short, our experimental results show that both persistent properties achieved more significant group differences between APOE4+ and APOE4- than traditional graph-theoretic measures, and BNP obtained the most significant difference ( $p = 0.009$ ) in the study of whole brain DMN.

## DISCUSSION

### Present Findings

There are three main findings in this study.

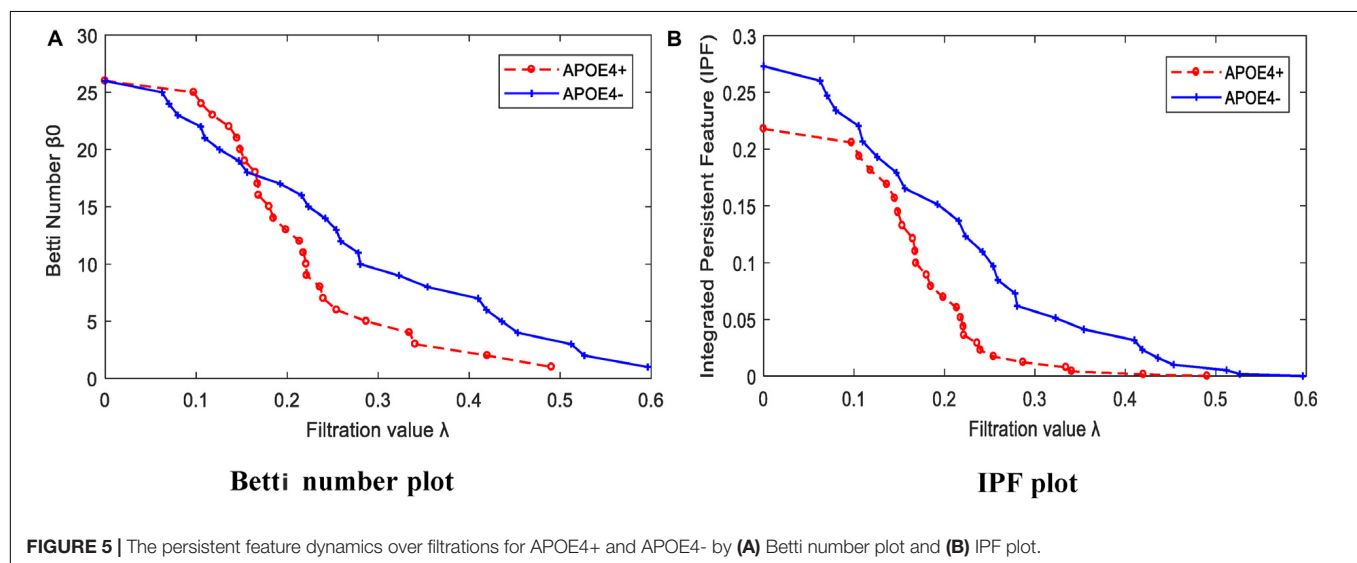

First, we found that the e4 allele carriers exhibited lower NR and Mod ( $p = 0.024, 0.037$ , respectively) in the study of whole brain DMN using traditional graph-theoretic methods, suggesting the abnormal organization structure in the risk allele group. To our knowledge, there have been few studies (Luo et al., 2017; Pietzuch et al., 2019) on graph theory that have

reported APOE genotypic differences in functional network properties of whole brain DMN in normal elderly, although a lot of studies have found differences in functional network properties between AD/MCI and NC. Some studies (Staffaroni et al., 2018; Chiesa et al., 2019) even found no difference between elderly APOE4+ and APOE4- groups in functional DMN. The reason why findings of DMN on unimpaired individuals do not consistently demonstrate differences between APOE4+ and APOE4- is still debated in the literature (Chiesa et al., 2017). In our study, we found two measures could detect their differences significantly, which would further enhance the APOE research based on graph theory.

Second, we introduced two measures from our previous studies based on persistent homology and found they were more statistically powerful than graph-theoretic measures in discriminating APOE4+ from APOE4- in our experiment, and the BNP obtained the most significant difference ( $p = 0.009$ )

**FIGURE 4 |** The single linkage dendrograms of (A) APOE4 carriers and (B) non-carriers groups show the change of the zeroth Betti number. The color represents the target distance (total edge weight) from current connected component to the full connected component (the rightmost line).

**FIGURE 5 |** The persistent feature dynamics over filtrations for APOE4+ and APOE4- by (A) Betti number plot and (B) IPF plot.

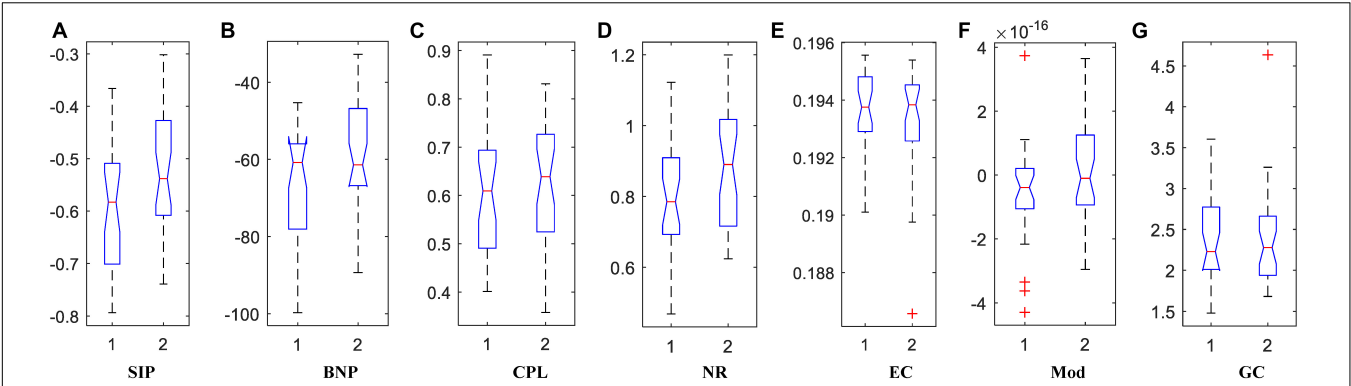

between groups. The persistent homology approach can distinguish robust and noisy topological features over multiscale nested networks, and the obtained properties are more persistent and stable. So far, many studies of brain network based on persistent homology have demonstrated the superiority of the performance. To our knowledge, it is the first time we introduced persistent homology to study the APOE genotype effect on DMN.

Finally, the functional disruption within the left hemisphere may be more pronounced than the right one. All persistent homology-based features SIP and BNP detected the significant differences of DMN in whole brain and left hemisphere. However, no significant differences were found within the right hemispheric DMN using any network measures. This finding is consistent with existing APOE studies documenting the effect of

the e4 allele on left hippocampus rather than right hippocampus of non-demented individuals (Shi et al., 2014; Li et al., 2016; Dong et al., 2019).

### Verification on Normal Control Subjects

As there were only 16 NC individuals who had e4 allele and available rs-fMRI data in ADNI-2, we expanded our experimental sample size by including SMC subjects. However, some studies (Caldwell et al., 2019) on APOE have only investigated NC individuals from ADNI. Thus, we excluded all SMC subjects (see Table 2) and further repeated our experiment on NC subjects. As shown in Table 4, there were no significant differences in age, education, sex, and MMSE between APOE+ and APOE- in NC dataset. We calculated the differences of DMN between

**FIGURE 6 |** The box plots of property values for APOE4 carriers (1) and non-carriers (2) groups using two persistent homology properties, **(A)** SIP and **(B)** BNP, and five graph-theoretic properties, **(C)** CPL, **(D)** NR, **(E)** EC, **(F)** Mod, and **(G)** GC.

groups using different measures, as shown in **Table 5**. Again, two measures based on persistent homology obtained stronger statistical power than graph theory methods, and the differences within the left hemispheric DMN is more significant than the right one. Moreover, compared to experiments performed on cognitively unimpaired dataset (**Table 3**), the SIP obtained very significant difference ( $p = 0.006$ ) on NC dataset.

**Limitation and Future Works**

Despite the promising results were obtained by applying two suggested network properties SIP and BNP based on persistent

homology to discriminate APOE e4 allele carriers from non-carriers in cognitively unimpaired subjects, there are three important caveats.

First, both persistent homology-based properties BNP and SIP adopted in this study only investigated the dynamics of the zeroth persistent homology. Higher-dimensional persistent homology characterizes higher-dimensional topological features, and more complexed topological structures such as circular holes can be detected. Therefore, the performance of network measurement may be further boosted if higher-dimensional homology is applied, especially in the sparse network that tends to have more holes.

Then, although the DMN have been heavily studied and are reported as a promising kind of network to study, current researches have mainly focused on finding some dysfunctional areas with decreased or increased connectivity (Song et al., 2015; Yan et al., 2015; Zhu et al., 2018; Chiesa et al., 2019). There are relatively few studies on global network dynamics of e4 allele group in normal elderly. In this study, we measured the global brain network in two datasets (cognitively unimpaired dataset and its subset NC) and found some statistically powerful measures. In future, we will validate these measures in other independent datasets.

**TABLE 3 |** Statistical  $p$ -values of different network properties between APOE4+ and APOE4- groups.

Finally, current findings are achieved based on cross-sectional study. With longitudinal analysis, we may further study the longitudinal trajectories (Chiesa et al., 2019) of functional brain dynamics and the impact of  $\epsilon 4$  allele on individuals at risk for Alzheimer's disease by quantifying the difference of their persistent features. In addition, the more aggregated structure in APOE  $\epsilon 4$  allele carriers may be due to worse development in childhood. Examining longitudinal MRI since childhood, the possibility of this phenomenon could be further assessed.

## CONCLUSION

This work measured the DMN structure of rs-fMRI on cognitively unimpaired  $\epsilon 4$  allele carriers based on our prior work of persistent homology, which encodes a great deal of dynamic information over all possible scales. The significant differences between APOE4+ and APOE4- are identified within the left hemispheric DMN and in the whole brain DMN in two datasets, providing evidence that the APOE  $\epsilon 4$  genotype leads to distinct alterations of functional DMN several years before the occurrence of dementia symptoms. Moreover, our suggested approaches of persistent homology are more sensitive to APOE genotypic differences than standard graph-based network measures. To the best of our knowledge, this is the first study applying persistent homology to analyze APOE-related effect on whole-brain functional network. This study offers a novel insight to explore potential biomarkers in healthy elderly populations carrying APOE  $\epsilon 4$  allele.

## DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. This data can be found from the ADNI (<http://adni.loni.usc.edu>).

## ETHICS STATEMENT

In this study, all subjects were selected from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database (<http://adni.loni.usc.edu/>). All ADNI subjects gave written informed consent at enrollment for data collection, storage, and use for research.

## AUTHOR CONTRIBUTIONS

LK and YW designed the study and revised the manuscript. FX acquired the data. JJ, DZ, and LK analyzed and interpreted the results of the data. LK and XH drafted the manuscript. All authors contributed to the article and approved the submitted version.

Lu J, Bao W, Li M, Li L, Zhang Z, Alberts I, Brendel M, Cumming P, Lu H, Xiao Z, Zuo C, Guan Y, Zhao Q and Rominger A (2020) Associations of [ $^{18}\text{F}$ ]-APN-1607 Tau PET Binding in the Brain of Alzheimer's Disease Patients With Cognition and Glucose Metabolism. *Front. Neurosci.* 14:604. doi: 10.3389/fnins.2020.00604

Molecular imaging of tauopathies is complicated by the differing specificities and off-target binding properties of available radioligands for positron emission tomography (PET). [ $^{18}\text{F}$ ]-APN-1607 ([ $^{18}\text{F}$ ]-PM-PBB3) is a newly developed PET tracer with promising properties for tau imaging. We aimed to characterize the cerebral binding of [ $^{18}\text{F}$ ]-APN-1607 in Alzheimer's disease (AD) patients compared to normal control (NC) subjects. Therefore, we obtained static late frame PET recordings with [ $^{18}\text{F}$ ]-APN-1607 and [ $^{18}\text{F}$ ]-FDG in patients with a clinical diagnosis of AD group, along with an age-matched NC group ([ $^{18}\text{F}$ ]-APN-1607 only). Using statistical parametric mapping (SPM) and volume of interest (VOI) analyses of the reference region normalized standardized uptake value ratio maps, we then tested for group differences and relationships between both PET biomarkers, as well as their associations with clinical general cognition. In the AD group, [ $^{18}\text{F}$ ]-APN-1607 binding was elevated in widespread cortical regions ( $P < 0.001$  for VOI analysis, familywise error-corrected  $P < 0.01$  for SPM analysis). The regional uptake in AD patients correlated negatively with Mini-Mental State Examination score (frontal lobe:  $R = -0.632$ ,  $P = 0.004$ ; temporal lobe:  $R = -0.593$ ,  $P = 0.008$ ; parietal lobe:  $R = -0.552$ ,  $P = 0.014$ ; insula:  $R = -0.650$ ,  $P = 0.003$ ; cingulum:  $R = -0.665$ ,  $P = 0.002$ ) except occipital lobe ( $R = -0.417$ ,  $P = 0.076$ ). The hypometabolism to [ $^{18}\text{F}$ ]-FDG PET in AD patients also showed negative correlations with regional [ $^{18}\text{F}$ ]-APN-1607 binding in some signature areas of AD (temporal lobe:  $R = -0.530$ ,  $P = 0.020$ ; parietal lobe:  $R = -0.637$ ,  $P = 0.003$ ; occipital lobe:  $R = -0.567$ ,  $P = 0.011$ ). In conclusion, our results suggested that [ $^{18}\text{F}$ ]-APN-1607 PET sensitively detected tau deposition in AD and that individual tauopathy correlated with impaired cerebral glucose metabolism and cognitive function.

## INTRODUCTION

The hyperphosphorylated, aggregated tau that comprises intracellular filamentous inclusions is implicated in a number of neurodegenerative pathologies (Spillantini and Goedert, 2013). In healthy adults, equal amounts of tau protein isoforms with three microtubule-binding domains (3R) and four microtubule-binding domains (4R) occur in the cerebral cortex (Goedert and Jakes, 1990). Misassembly of the normally unfolded microtubule-associated protein tau into a highly structured amyloid fibril is implicated in the pathological process underlying human tauopathies (Goedert et al., 2017). Alzheimer's disease (AD), which is primarily associated with 3R and 4R tau (Rosler et al., 2019), is one of the most clinically relevant tauopathies and is the most common neurodegenerative disorder globally, bringing enormous burdens to society and caregivers.

Consequently, molecular imaging of tauopathies has garnered much interest in recent years, and there is increasing recognition of tauopathy as a potential target in the early detection of neurodegenerative disease or indeed as a potential therapeutic target. Among available tracers for positron emission tomography (PET), the selectivity for tau isoforms determines their suitability for particular neurodegenerative disease. For example, a head-to-head comparison of [<sup>11</sup>C]-THK5351 and [<sup>11</sup>C]-PBB3 in AD patients revealed distinct binding patterns for the two tracers in the same patients. [<sup>11</sup>C]-THK5351 binding matched the tau pathology expected for AD, whereas [<sup>11</sup>C]-PBB3 binding showed a greater affiliation with  $\beta$ -amyloid distribution (Chiotis et al., 2018). An immunofluorescence study with PBB3 and AV-1451 both showed intense labeling of non-ghost and ghost tangles, whereas detection of dystrophic neurites in brain of AD patients was clearer for PBB3 (Ono et al., 2017). Further quantitative autoradiographic analysis post-mortem showed moderate [<sup>11</sup>C]-PBB3 autoradiographic binding vs. relatively faint [<sup>18</sup>F]-AV-1451 labeling of the 3R isoforms in brains of patients dying with Pick's disease (PiD), and likewise for the 4R isoforms in brains of patients dying with progressive supranuclear palsy (PSP) or corticobasal degeneration. However, the binding of the two ligands was similar for paired helical filament (PHF)-tau in patients dying with AD (Ono et al., 2017).

Off-target binding, at present one of the great challenges in molecular neuroimaging of tauopathy, occurs when the tracer has affinity to an unintended molecular target in the brain. For example, the interpretation of tau burden in PET scans with [<sup>18</sup>F]-THK5351 (Ng et al., 2017) and several other ostensibly tau-selective tracers (Murugan et al., 2019) was complicated by off-target binding to monoamine oxidase B (MAO-B). Furthermore, the tau tracers [<sup>18</sup>F]-AV-1451, [<sup>18</sup>F]-THK5351, and [<sup>18</sup>F]-MK6240 all showed additional binding to neuromelanin (Aguero et al., 2019; Tago et al., 2019), which likely accounted for their binding in the midbrain dopamine neurons of the substantia nigra (Marquie et al., 2015; Harada et al., 2016).

PBB3-based tracers show much promise in overcoming the problem of incomplete specificity for tau. Previous studies

regarding the prototype [<sup>11</sup>C]-PBB3 revealed no cross-reactivity with monoamine oxidase A (MAO-A) and MAO-B (Ni et al., 2018), although there was a low affinity for non-tau fibrils such as assemblages of amyloid- $\beta$  (Maruyama et al., 2013; Ono et al., 2017) and  $\alpha$ -synuclein aggregates (Koga et al., 2017). Nevertheless, [<sup>11</sup>C]-PBB3 binding was highly selective for tau at the nm radioligand concentrations typically achieved in a human PET study (Koga et al., 2017; Ni et al., 2018). However, routine clinical use of the compound [<sup>11</sup>C]-PBB3 presented logistic difficulties due to the short physical half-life of carbon-11 (Hashimoto et al., 2014, 2015; Shimada et al., 2017). A PBB3 derivative labeled with longer-lived fluorine-18 might overcome this limitation.

Moreover, according to the latest National Institute on Aging – Alzheimer's Association framework on AD (Jack et al., 2018; Cummings, 2019), a framework comprising three biomarkers  $\beta$ -amyloid (A), tau (T), and neurodegeneration (N) is recommended for defining the AD spectrum and for distinguishing AD from non-AD causes of cognitive impairment. Detection of  $\beta$ -amyloid is accomplished with established PET tracers such as [<sup>11</sup>C]-PiB (Klunk et al., 2004; Jimenez-Bonilla et al., 2016) and [<sup>18</sup>F]-AV45 (Nemmi et al., 2014; Brendel et al., 2015; Lin et al., 2016). These tracers show progressive accumulation of  $\beta$ -amyloid first in isocortical areas and later in limbic and cortical structures. Positron emission tomography with [<sup>18</sup>F]-FDG reveals a characteristic pattern of hypometabolism in temporoparietal cortex and posterior cingulate of AD patients (Minoshima et al., 1995; Kato et al., 2016; Hsu et al., 2017; Rice and Bisdas, 2017; Blazhenets et al., 2019). Multimodal studies combining A/T/N biomarkers showed tau deposition as measured by [<sup>18</sup>F]-AV-1451 (Sintini et al., 2019) or [<sup>18</sup>F]-THK5351 (Baghel et al., 2019) PET, which correlated with hypometabolism to [<sup>18</sup>F]-FDG PET and with atrophy, as measured by structural magnetic resonance imaging (MRI) (Sintini et al., 2019).

In this context, we presented [<sup>18</sup>F]-APN-1607 ([<sup>18</sup>F]-PM-PBB3), a next-generation tau tracer derived from the PBB3 series, but possessing a superior drug metabolism and pharmacokinetic profile, improved specific binding in brain, and the logistic advantage imparted by fluorine-18 (Shimada et al., 2017, 2018; Tagai et al., 2020; see **Supplementary Table 1**). We aimed in this study to characterize the cerebral uptake pattern of [<sup>18</sup>F]-APN-1607 as a marker for hyperphosphorylated tau in patients with clinically diagnosed AD in comparison to a normal control (NC) group and to investigate the correlation of this regional uptake with hypometabolism to [<sup>18</sup>F]-FDG PET and in relation to impaired cognitive function.

## MATERIALS AND METHODS

### Subjects

Nineteen clinically diagnosed and amyloid PET-positive AD patients (6 underwent [<sup>11</sup>C]-PiB PET, and 13 underwent [<sup>18</sup>F]-AV45 PET) and 11 NC subjects who also underwent [<sup>18</sup>F]-APN-1607 PET in Huashan Hospital, Shanghai, China, were

enrolled in this study from 2018/11 to 2019/11. All subjects underwent anatomical MRI, and all AD patients underwent an [<sup>18</sup>F]-FDG PET within 1 month before or after [<sup>18</sup>F]-APN-1607 PET. The diagnosis of clinically probable AD was based on current diagnostic criteria (McKhann et al., 2011). Experienced radiologists assessed medial temporal lobe atrophy (MTA) using MTA–Visual Rating Scale (VRS) blinded to clinical conditions in all subjects. Experienced neurologists from the cognitive impairment clinic administered the Mini-Mental State Examination (MMSE) and Clinical Dementia Rating (CDR) test for all patients. Meanwhile, the NC group also accepted CDR test. None of the NCs had a history of cognitive impairment, psychiatric illness, central nervous system disease, or head injury. Furthermore, dementia caused by other reasons and mild cognitive impairment (MCI) were excluded after clinical screening by experienced neurologist/cognitive specialists. This study was approved by the ethics committee of Huashan Hospital (no. 2018-363). All procedures performed in this study were in accordance with the ethical standards of the institutional research committee and with the Helsinki Declaration of 1975 and its later amendments. All subjects or a legally responsible relative gave written informed consent before the study.

## Imaging and Processing

### Radiosynthesis

[<sup>18</sup>F]-APN-1607 was prepared in Huashan Hospital by a nucleophilic substitution reaction followed by an acid hydrolysis carried out with an [<sup>18</sup>F]-multifunction synthesizer (Beijing PET Technology Co., Ltd., Beijing, China). APRINOIA Therapeutics (Suzhou, China) provided the tosylate precursor used for the radiosynthesis. After purification with semipreparative high-performance liquid chromatography, the product [<sup>18</sup>F]-APN-1607 was formulated in ascorbate-containing normal saline for injection and was filtered through a sterile membrane filter. The radiosynthesis was completed in 90 min, giving [<sup>18</sup>F]-APN-1607 with a radiochemical purity of ≥90% and a molar activity of ≥37 MBq/μmol at the end of synthesis. The production was conducted under the green light-emitting diode light (510 nm) illumination, and the product was sterile and negative for pyrogens.

### Image Acquisition and Reconstruction

All subjects were scanned on a Siemens Biograph 64 PET/computed tomography (CT) (Siemens, Erlangen, Germany) in three-dimensional (3D) mode in Huashan Hospital. A low-dose CT transmission scan was performed before PET scanning for attenuation correction. Static emission recordings were acquired during the interval of 90–110 min after intravenous injection of 370 MBq [<sup>18</sup>F]-APN-1607. Image reconstruction was obtained by the ordered subset expectation maximization 3D (OSEM 3D) method. Patients with AD underwent [<sup>18</sup>F]-FDG PET on another scanning day with intravenous injection of 185 MBq, following a scanning procedure and OSEM 3D reconstruction as described in a previous study (Wu et al., 2013). All subjects also underwent anatomical MRI in a 3.0-T horizontal magnet (Discovery MR750; GE Medical Systems, Milwaukee, WI, United States) at Huashan Hospital.

## Semiquantitative Volume of Interest–Based PET Analyses

The PNEURO data processing pipeline of PMOD version 4.005 (PMOD Technologies Ltd., Zurich, Switzerland) was used for spatial normalization of all PET images to the Montreal Neurological Institute (MNI) space, using the individual MRI as an intermediate. Both [<sup>18</sup>F]-APN-1607 and [<sup>18</sup>F]-FDG PET images were analyzed in the following manner: we first segmented the individual MRI into gray matter (GM), white matter (WM), and cerebrospinal fluid (CSF) and made the spatial normalization to the MNI space. Subsequently, each subject's individual PET images were spatially matched to MRI and then resampled using the normalization arising from the GM/WM/CSF MRI segmentation procedure (Ashburner, 2007). Based on the Atlas template [adult brain maximum probability map (“Hammersmith atlas”; n30r83)], the whole brain was parcellated into the following regions for standardized uptake value ratio (SUVR) calculations: frontal, temporal, occipital, and parietal lobes; insula; cingulum; caudate; putamen; pallidum; thalamus; midbrain; pons; medulla; and cerebellar cortex. The cerebellar cortex was selected as the reference region for tau images because it has negligible tau pathology to examination post-mortem AD cerebellum (Herrmann et al., 1999; Baghel et al., 2019). The same reference region was used for [<sup>18</sup>F]-FDG PET images (Leuzy et al., 2018; Baghel et al., 2019).

### Voxel-Wise Analyses

Statistical parametric mapping (SPM) analysis was performed using SPM8 (Wellcome Department of Cognitive Neurology, London, United Kingdom) implemented in MATLAB 8.4 (R2014) (Mathworks Inc., Sherborn, MA, United States). The [<sup>18</sup>F]-APN-1607 SUVR maps from the AD and NC groups were compared by a voxel-wise two-tailed Student *t*-test after 10-mm Gaussian smoothing. To evaluate significant differences, we set the voxel threshold at  $P < 0.01$  [familywise error (FWE)-corrected] over the whole brain with an extent threshold empirically chosen to be at least twice of the expected number of voxels per cluster estimated in the SPM run. Significant regions were localized by Talairach–Daemon software (Research Imaging Center, University of Texas Health Science Center, San Antonio, TX, United States). The SPM maps for abnormal [<sup>18</sup>F]-APN-1607 uptakes were overlaid on a standard structural MRI brain template in stereotaxic space. We then used multiple regression analyses to determine the relationship between [<sup>18</sup>F]-APN-1607 uptake values and MMSE in the AD patients. Voxels surviving  $P < 0.01$  (uncorrected) with an extent threshold of at least twice of the expected number of voxels per cluster estimated in the SPM run were considered significant for the multiple regression analyses. Moreover, clusters surviving at FWE  $P < 0.05$  were also searched for these multiple regression analyses.

## Statistical Analysis

Demographic characteristics and semiquantitative PET results in different target volumes of interest (VOIs) were compared between AD and NC groups using the independent two-tailed Student *t*-test,  $\chi^2$  test, or Mann-Whitney *U* test as appropriate. Effect sizes for the discrimination between patients and NC

subjects were evaluated by Cohen *d*. Correlation analyses between PET SUVR in target VOIs and clinical parameter (MMSE), as well as intermodality correlations, were performed using Spearman correlation. All statistical analyses were performed in SPSS version 22.0 software (SPSS Inc., Chicago, IL, United States).  $P < 0.05$  was considered significant.

## RESULTS

### Demographic Information and Clinical Characteristics

Our AD group consisted of 7 males and 12 females with mean age 61.8 ( $\pm 11.3$ ) years, whereas NC group included seven males and four females with mean age 61.8 years ( $\pm 4.6$ ) years. There were 14 early onset AD, who showed symptoms younger than 65 years old and five late-onset AD (LOAD) in our cohort. Both groups were comparable for age of scanning ( $P = 0.992$ ) and gender ( $P = 0.156$ ). The general cognition of the AD group as assessed by CDR-Global Score (CDR-GS) and MMSE score showed that our patient cohort was mainly at moderate to advanced stages of the disease (CDR-GS: 1 (1–2); MMSE:  $17.0 \pm 7.6$ ). The MTA-VRS showed that AD group had abnormal brain atrophy while NC group showed normal (Table 1).

### Semiquantitative VOI-Based PET Analyses

Figure 1 shows the representative examples of [<sup>18</sup>F]-APN-1607 PET and anatomical MRI superimposed images of AD and NC subjects.

The AD group showed abnormally higher [<sup>18</sup>F]-APN-1607 binding than did the NC group in all cerebral lobes ( $P < 0.001$ , Cohen *d* varying from 1.5 to 2.1), as well as in caudate ( $P < 0.05$ , Cohen *d* = 0.9) and putamen ( $P < 0.001$ , Cohen *d* = 1.5). Meanwhile, the AD group showed lower uptake of [<sup>18</sup>F]-APN-1607 in midbrain ( $P < 0.01$ , Cohen *d* = 1.0), pons ( $P < 0.001$ , Cohen *d* = 1.4), and medulla ( $P < 0.001$ , Cohen *d* = 1.5) (Table 2 and Figure 2).

As for clinical associations, [<sup>18</sup>F]-APN-1607 binding in all cerebral lobes (with the exception of the occipital lobe) correlated negatively with the MMSE score (frontal lobe:  $R = -0.632$ ,  $P = 0.004$ ; temporal lobe:  $R = -0.593$ ,  $P = 0.008$ ; parietal lobe:  $R = -0.552$ ,  $P = 0.014$ ; insula:  $R = -0.650$ ,  $P = 0.003$ ; cingulum:  $R = -0.665$ ,  $P = 0.002$ ). Likewise, [<sup>18</sup>F]-APN-1607 binding in putamen, thalamus and medulla showed similar correlations (putamen:  $R = -0.557$ ,  $P = 0.013$ ; thalamus:  $R = -0.595$ ,  $P = 0.007$ ; medulla:  $R = -0.469$ ,  $P = 0.043$ ). [<sup>18</sup>F]-FDG uptake, as a surrogate marker for neuronal metabolic activity, showed positive correlations with MMSE in the frontal and parietal lobes (frontal lobe:  $R = 0.469$ ,  $P = 0.043$ ; parietal lobe:  $R = 0.550$ ,  $P = 0.015$ ). The temporal lobe also showed a broadly similar correlation with MMSE, albeit without reaching significance ( $R = 0.444$ ,  $P = 0.057$ ) (Table 3).

We then interrogated the relationships between [<sup>18</sup>F]-APN-1607 and [<sup>18</sup>F]-FDG. We found negative correlations between tau deposition and FDG uptake in the temporal, parietal, and

occipital lobes (temporal lobe:  $R = -0.530$ ,  $P = 0.020$ ; parietal lobe:  $R = -0.637$ ,  $P = 0.003$ ; occipital lobe:  $R = -0.567$ ,  $P = 0.011$ ). A similar pattern was observed for the frontal lobe, albeit without reaching statistical significance ( $R = -0.421$ ,  $P = 0.073$ ) (Table 3).

### Voxel-Wise PET Analyses

Compared to the NC group, the AD group had elevated [<sup>18</sup>F]-APN-1607 binding in fusiform gyrus (BA 37), superior temporal gyrus (BA 21), inferior temporal gyrus (BA 20), middle frontal gyrus (BA 8, 9, 11), and cingulate gyrus (BA 32) at FWE  $P < 0.01$  (Table 4 and Figure 3).

Significantly negative correlations between MMSE and brain [<sup>18</sup>F]-APN-1607 binding were found mainly in superior frontal gyrus (BA 10), middle frontal gyrus (BA 9, 10, 11, 47), parahippocampal gyrus (BA 36) and lateral globus pallidus at  $P < 0.01$  (uncorrected). Of these, both the superior frontal gyrus (BA 10) and middle frontal gyrus (BA 9, 10) survived FWE at  $P < 0.05$  (Table 5 and Figure 4).

## DISCUSSION

In this present study, we characterized the [<sup>18</sup>F]-APN-1607 uptake pattern in patients with AD in comparison with NC subjects. Furthermore, we assessed the correlation with between tau PET with [<sup>18</sup>F]-FDG PET and clinical parameters (MMSE). Our main objective was to characterize the utility of this next-generation tau tracer in terms of effect size for detecting disease-specific tau deposition, thus confirming the known relationship between tau deposition and decreased FDG uptake and cognitive impairment in AD patients.

In the regional analysis of [<sup>18</sup>F]-APN-1607, we found AD patients had higher binding than NC subjects in widespread regions of the cerebral cortex, caudate, and putamen and conversely relatively low uptake in the brainstem. The voxel-wise analysis results were in agreement with those of the region-based analysis, and the cerebral regions with increased tau deposition to [<sup>18</sup>F]-APN-1607 were consistent with previously published studies for previous-generation tau tracers (Table 6).

Hitherto, only limited data for second-generation tau tracers have been reported (Leuzy et al., 2019). Some novel tau tracers generally presented a number of advantages over the previous generation, notably with respect to target selectivity. For example, *in vitro* studies suggested that [<sup>18</sup>F]-MK6240 and [<sup>18</sup>F]-JNJ-067 bound with neurofibrillary tangle (NFT) (Hostetler et al., 2016), whereas [<sup>18</sup>F]-RO948 bound to both NFT and neuropil threads (Honer et al., 2018), whereas [<sup>18</sup>F]-JNJ64349311 interacted with PHF-tau and neuropil threads (Declercq et al., 2017). [<sup>18</sup>F]-PI2620 showed ambivalent binding to 3R-tau from PiD brain and to 4R-tau from PSP samples (Kroth et al., 2019). [<sup>18</sup>F]-APN-1607 showed specific binding with tau aggregates in AD and PSP (Shimada et al., 2018). Furthermore, such tracers showed improvement in off-target binding. [<sup>18</sup>F]-APN-1607 showed no off-target binding in the basal ganglia and thalamus (Shimada et al., 2017), and [<sup>18</sup>F]-APN-1607, [<sup>18</sup>F]-MK6240, [<sup>18</sup>F]-JNJ-607, and [<sup>18</sup>F]-PI2620 revealed no off-target binding with MAO-A

**TABLE 1** | Demographic information and clinical characteristics.

Group	No.	Gender (male/female)	Age of scanning (y)	Age at onset (y)	Education (y)	MMSE score	CDR-GS	MTA-VRS

and MAO-B. Extensive screening of [<sup>18</sup>F]-RO948 also revealed no off-target binding. These limited available data suggested that novel-generation tau tracers had significant advantages in

**FIGURE 2** | Differences of regional [<sup>18</sup>F]-APN-1607 SUVR between AD and NC groups. AD, Alzheimer's disease; NC, normal control. \**P* < 0.05, \*\**P* < 0.01, \*\*\**P* < 0.001.

comparison to previous generation tracers. The selectivity for tau isoforms of the different series renders them particularly suitable for the investigation of neurodegenerative disease apparent. Further clinical studies are required to demonstrate their diagnostic utility and to further evaluate their performance.

The limited *in vivo* data reported for other new-generation tau tracers showed similar results to our study: [<sup>18</sup>F]-MK6240, [<sup>18</sup>F]RO-948, and [<sup>18</sup>F]-PI6260 showed elevated signals in

\*Significant at FWE-corrected voxel threshold of  $P < 0.01$ , extent threshold = 58 voxels (464 mm<sup>3</sup>). <sup>†</sup>Coordinates are displayed in MNI standard space. BA, Brodmann area; FWE, familywise error.

temporal areas and more broadly throughout the cortex in AD patients compared to NC subjects. The SUVRs in temporal lobe of AD/MCI patients were 1.64 ( $\pm 0.72$ ) with [<sup>18</sup>F]-MK6240 [MMSE = 18.8 ( $\pm 6.9$ ), Cohen  $d = 1.3$ ] (Lohith et al., 2019), 2.75 ( $\pm 1.40$ ) with [<sup>18</sup>F]-RO-948 (inferior temporal lobe, MMSE = 20.8 ( $\pm 2.7$ ), Cohen  $d = 1.6$ ) (Wong et al., 2018), and 1.80 ( $\pm 0.40$ ) with [<sup>18</sup>F]-PI2620 [inferior temporal, MMSE = 20.4 ( $\pm 6.3$ ), Cohen  $d = 2.4$ ] (Mueller et al., 2019). Our findings of [<sup>18</sup>F]-APN-1607 had relatively lower SUVR in the present study [temporal lobe: 1.64 ( $\pm 0.50$ ), MMSE = 17.0 ( $\pm 7.6$ ), Cohen  $d = 2.1$ ] comparing to [<sup>18</sup>F]-RO-948 and [<sup>18</sup>F]-PI2620, which might arise from the relatively rough ROI; however, the relatively high Cohen  $d$  value indicated that [<sup>18</sup>F]-APN-1607 was a highly sensitive tracer for detecting tau aggregates in AD. Findings in other brain regions were also comparable among the next-generation tau tracers, including [<sup>18</sup>F]-APN-1607 (Table 6).

In addition to the finding of distinctly elevated [<sup>18</sup>F]-APN-1607 binding in the widespread cerebral cortex of patients

with AD of moderate severity, we also saw increased signals in the striatum. We noted that [<sup>18</sup>F]-AV-1451, [<sup>18</sup>F]-RO948, and [<sup>18</sup>F]-PI2620 likewise showed similarly increased signals in the striatum (Shcherbinin et al., 2016; Wong et al., 2018; Mueller et al., 2019). Previous neuropathological observation addressed that NFT occurs in striatum in late Braak stages of AD (V and VI) (Chan and Shea, 2006). Another autopsied study reinforced AD cases with severe putaminal tauopathy at the advanced stages and indicated that severe microtubule-associated protein tau accumulation in the basal ganglia might occur most frequently in AD cases, without comorbidity of other neurodegenerative diseases in a general aging population (Hamasaki et al., 2019). Accordingly, the higher [<sup>18</sup>F]-APN-1607 PET signal seen in caudate and putamen of our AD group might suggest higher than expected tauopathy (Su et al., 2015). Nonetheless, previous MRI studies reported iron overloading in striatum in AD (Bartzokis et al., 1993, 1994; Acosta-Cabronero et al., 2013). Iron is a known component of neuritic plaques

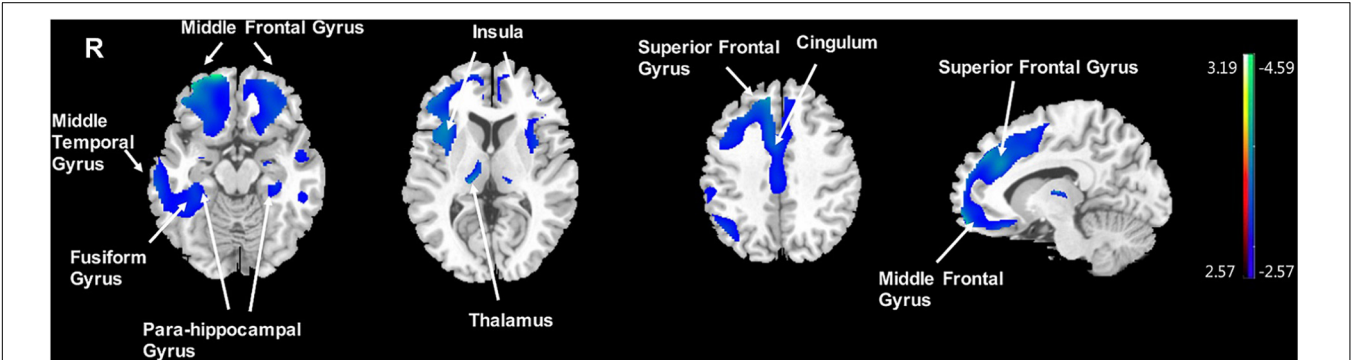

**FIGURE 3 |** Voxel-wise differences of whole-brain [<sup>18</sup>F]-APN-1607 binding in the AD group compared to the NC Group. AD, Alzheimer's disease; NC, normal control. AD, Alzheimer's disease; NC, normal control.

Leskovjan et al., 2011). Furthermore, iron can induce hyperphosphorylation and aggregation of tau (Lovell et al., 2004; Chan and Shea, 2006). Altogether, we interpreted these findings with much caution, given that previous generation tau tracers such as [<sup>18</sup>F]-AV-1451 demonstrated off-target binding to ferrous iron (Lowe et al., 2016; Passamonti et al., 2017; Choi et al., 2018; Baker et al., 2019), which as described above was implicated in the neuropathology of neurofibrillary tangle formation. Noteworthy, [<sup>18</sup>F]-AV-1451 has shown non-specific binding in the striatum in healthy elderly subjects (Marquie et al., 2015; Passamonti et al., 2017; Smith et al., 2017), and its binding appeared to increase with healthy aging (Smith et al., 2017). Similarly, the first-generation [<sup>11</sup>C]-PBB3 also showed off-target binding in the basal ganglia, the reason for which was yet to be determined (Ono et al., 2017), although a recent abstract indicated there was no off-target binding in the basal ganglia and thalamus for [<sup>18</sup>F]-APN-1607 (Shimada et al., 2017).

In this study, we investigated clinical correlations for [<sup>18</sup>F]-APN-1607 and [<sup>18</sup>F]-FDG uptakes separately. The MMSE score, as a surrogate for general cognition, showed strong correlations with [<sup>18</sup>F]-APN-1607 SUVR in all cerebral cortical regions except the occipital lobe, and with [<sup>18</sup>F]-FDG SUVR in the frontal and parietal lobes (Table 3). In [<sup>18</sup>F]-APN-1607, we also saw relatively weaker correlations in the putamen, thalamus, and medulla.

It was hypothesized that accumulation of toxic intracellular aggregate accompanied by a loss of soluble tau capable of stabilizing microtubules might synergistically lead to compromised neuronal survival (Lee et al., 2011), accounting for the putative relationship between NFT burden and cognitive decline in AD patients (Terry et al., 1981; Gomez-Isla et al., 1997). According to the Braak theory of AD propagation (Braak and Braak, 1991b; Braak and Del Tredici, 2011), tau deposition spreads widely and aggregates in neocortical areas in advanced AD patients. The association we observed between tau depositions to [<sup>18</sup>F]-APN-1607 and general cognitive impairment was consistent with these known relationships, which we could now confirm here with a new-generation tau tracer. The occipital lobe was thought to be affected at only a late stage of typical AD progression (Delacourte et al., 1999) and likewise showed tau accumulation only at a late stage (Alafuzoff et al., 2008). In this regard, our study's failure to show a correlation between tau deposition and [<sup>18</sup>F]-APN-1607 in the occipital lobe, and MMSE score was consistent with the moderate severity of disease in our patient group.

We found a negative correlation between tau deposition to [<sup>18</sup>F]-APN-1607 in some subcortical regions and MMSE score. Degeneration of deep gray matter structures other than the hippocampus and the amygdala occurred in the process of AD and ultimately contributes to cognitive deterioration. The thalamus pathology played an increasingly recognized role in early memory loss of AD patients (Aggleton and Brown, 1999; Harding et al., 2000; Taber et al., 2004; Carlesimo et al., 2011). The anterodorsal thalamic nucleus was posited to undergo neurofibrillary changes concomitant with the hippocampus (Braak Stages III–IV) (Braak and Braak, 1991b). Nonetheless, some thalamic nuclei appeared unaffected or show only mild neurofibrillary changes, even in cases of severe AD (Braak and Braak, 1991b). Recent studies have provided evidence that AD-related tau cytoskeletal pathology is initiated in subcortical regions, which supports the widely held hypothesis that early occurring subcortical tau cytoskeletal pathology, including that in the thalamus, may play a crucial role in the cascade of the early pathological events of AD (Rub et al., 2000; Grinberg et al., 2009; Stratmann et al., 2016). In addition, the clinical manifestation and progression of AD correlated with loss of neurons, synaptic degeneration in the neocortex and the topographical distribution of the tau cytoskeletal pathology in diseased brains (Jack et al., 2016). The role of the cortical and subcortical regions of the limbic system in the performance of normal cognitive and memory functions was well-known. The presence of severe tau cytoskeletal pathology in the thalamic nuclei with limbic connectivity likely contributed to impaired neural processing in limbic circuits, manifesting in certain cardinal symptoms of AD (Braak and Braak, 1991a,b; Rub et al., 2000, 2002; Blennow et al., 2006; Lace et al., 2007; Grinberg et al., 2009; Braak and Del Tredici, 2015). Structural MRI studies also showed that overall thalamic volume correlates with cognitive status in MCI and AD patients (de Jong et al., 2008; Pedro et al., 2012; Yi et al., 2016), further highlighting its role in the pathogenesis of AD. In this regard, the negative correlation between [<sup>18</sup>F]-APN-1607 binding in the thalamus and MMSE score in the AD group offered further support, a link between thalamic pathology and cognitive impairment. Like thalamus, the basal nuclei participated in many different neuronal pathways, with functions extending to emotional, motivational, associative, and cognitive processes (Herrero et al., 2002). A previous MRI study has found significantly reduced putamen volumes in AD patients, correlating with

impaired cognition (de Jong et al., 2008). Combined with the neuropathological observation that NFT occurs in striatum in Braak stages V and VI in AD (Chan and Shea, 2006), our findings strongly suggested that the tau deposition in the subcortical regions may also contribute to cognitive decline in AD.

Cerebral [<sup>18</sup>F]-FDG uptake provides a surrogate marker for neuronal metabolism. [<sup>18</sup>F]-FDG uptake in the frontal ( $R = 0.469$ ,  $P = 0.043$ ) and parietal lobes ( $R = 0.550$ ,  $P = 0.015$ ) correlated with MMSE score of our AD group, with weaker association for the temporal lobe ( $R = 0.444$ ,  $P = 0.057$ ). Numerous PET studies have demonstrated hypometabolism in the temporoparietal cortex of AD patients (Minoshima et al., 1995; Kato et al., 2016; Rice and Bisdas, 2017), whereas hypometabolism in the frontal lobe is often observed during the progression of AD dementia (Herholz et al., 2007). Thus, our present findings of regional correlation were concordant with the known hypometabolic regions in AD. The relatively weak correlation in the temporal lobe could be indicative of involvement at an early stage of neurodegeneration, with stabilization of the hypometabolism late in this disease, resulting in a weakening of the relationship between temporal hypometabolism with cognitive scores. Indeed, previous [<sup>18</sup>F]-FDG PET studies have suggested that temporal hypometabolism peaks at the MCI stage and does not progress at later stages of the disease (Dukart et al., 2013), which seems consistent with present findings.

Our multimodal analysis revealed several brain regions showing correlations between uptake of both tracers. Previous studies posited that cognitive deficits in AD could arise directly from both tau pathology and subsequent downstream neurodegeneration (Bejanin et al., 2017). We found that SUVRs in the temporal ( $R = -0.530$ ,  $P = 0.020$ ), parietal ( $R = -0.637$ ,  $P = 0.003$ ), and occipital ( $R = -0.567$ ,  $P = 0.011$ ) lobes correlated negatively between [<sup>18</sup>F]-APN-1607 and [<sup>18</sup>F]-FDG uptakes, with a trend toward negative correlation in the frontal lobe ( $P = 0.073$ ,  $R = -0.421$ ). These findings were consistent with results disclosed using other tau tracers [[<sup>18</sup>F]-AV-1451 (Gordon et al., 2019; Sintini et al., 2019) and [<sup>18</sup>F]-THK5351 (Baghel et al., 2019)]. Previous stereological and non-stereological quantitative post-mortem studies of cerebral cortex (Terry et al., 1981, 1987; Cras et al., 1995; Schwab et al., 1998, 1999; Bussiere et al., 2002; Kril et al., 2002) and clinicopathologic studies (Giannakopoulos et al., 2003) reported a close association between NFT counts and neuron loss. However, non-NFT-related mechanisms of neurodegeneration may also play a role in the loss of cortical neurons in AD (Gomez-Isla et al., 1997).

In summary, this preliminary clinical study confirmed the utility of the new compound [<sup>18</sup>F]-APN-1607 for the detection of tau pathology and reinforced previous studies showing an overlap between cerebral glucose hypometabolism (using [<sup>18</sup>F]-FDG PET) and tau deposition and their association with dementia.

## Limitations

We noted several shortcomings in this study. First, our group size in this preliminary study was relatively small. Second, to reduce the radiation exposure to the NC group, we did not perform additional  $\beta$ -amyloid or [<sup>18</sup>F]-FDG PET scanning

to conform lack of pathology. However, clinical and MRI assessment revealed normal results. Although the abnormal metabolic regions of AD patients are well-described from a plethora of previous publications, we lacked [<sup>18</sup>F]-FDG PET data for the NC group. In mitigation, we restricted our exploration in the AD group with region-to-region analysis, aiming to explore anatomic relationships between tau deposition and abnormal metabolism. We draw attention to the fact that MMSE reflected only general cognition, whereas individuals may suffer from cognitive impairment in different domains. Future studies involving more detailed cognitive assessments would support a better exploration of the relationships between tauopathy and cognition.

We were cognizant of the methodological challenges associated with choice of reference region. We used cerebellum, a commonly chosen region, for normalization of [<sup>18</sup>F]-APN-1607 and [<sup>18</sup>F]-FDG scans to SUVR maps. Validity of this approach naturally required absence of important pathologies in cerebellum. In future studies, we shall consider other possible methods of normalization. Finally, clinical studies of prospective design are required to further validate the promising results reported here.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation, to any qualified researcher.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Institutional Review Board of Huashan Hospital (HIRB), Fudan University. The patients/participants provided their written informed consent to participate in this study.

**Background:** Periodontitis is one of the most common oral diseases and is a potential risk factor for systemic diseases. In this study, we aimed to investigate the association between periodontitis and learning and memory impairment.

**Methods:** We established a periodontitis model by topical application of *Porphyromonas gingivalis* lipopolysaccharide (*P. gingivalis*-LPS) into the palatal gingival sulcus of the maxillary first molars of 10-week-old male rats for a 10-week period. We assessed alveolar bone resorption using micro-computed tomography analysis and learning and memory ability using the Morris water maze test. We determined the levels of cytokines [interleukin (IL)-1 $\beta$ , IL-6, IL-8, and IL-21] and LPS in the peripheral blood and cortex, as well as toll-like receptor 4 (TLR4)/NF- $\kappa$ B signaling pathway activation, using reverse transcription-polymerase chain reaction (RT-PCR), enzyme-linked immunosorbent assay (ELISA), and western blot. We determined activation of microglia and astrocytes, expression of A $\beta$ 1-42, APP and Tau by immunohistochemistry. Finally, we measured the expression of amyloid precursor protein (APP) and its key secretases, as well as the A $\beta$ 1-40/1-42 ratio, by RT-PCR, western blot, and ELISA.

**Results:** We found that periodontitis induced learning and memory impairment in the rats. Further, we observed that it induced significant alveolar bone resorption. There was an increase in the levels of inflammatory cytokines and LPS. Moreover, we confirmed TLR4/NF- $\kappa$ B signaling pathway activation. We also observed activated microglia and astrocytes with enlarged cell bodies and irregular protrusions. Finally, we observed the promotion of  $\beta$ - and  $\gamma$ -secretases APP processing.

**Conclusion:** Our findings indicated that periodontitis was associated with learning and memory impairment, probably induced by neuroinflammation via activating the TLR4/NF- $\kappa$ B signaling pathway. Furthermore, abnormal APP processing could be involved in this progress.

**Keywords:** periodontitis, neuroinflammation, learning and memory impairment, APP processing, TLR4/NF- $\kappa$ B signaling pathway

## INTRODUCTION

Periodontitis is a potentially transmissible chronic infection caused by plaque biofilm. It is responsible for 70% of the global population presenting one or more damages in the periodontium (Oppermann et al., 2015). Considering that periodontitis involves interacting bacterial pathogens, including their toxic factors and host inflammatory responses, it has a multifactorial etiology with a marked inflammatory profile (Papapanou et al., 2018). Chronic recurrent periodontal inflammation could destroy the tooth support organization; further, there is increasing evidence that periodontal disease is an important risk factor for systemic diseases, including cardiovascular disease, diabetes, and reduced respiratory function (Preshaw et al., 2012; Hamilton et al., 2017; Winning et al., 2019).

Given the accelerating trend of population aging, the harm caused by cognitive disorders on human health has become increasingly prominent. It clinically manifests as gradual cognitive dysfunction and psychosis (Wimo et al., 2017; Brookmeyer et al., 2018). Epidemiological surveys reported that periodontitis was associated with an increase in the rate of cognitive decline (Ide et al., 2016; Harding et al., 2017). Periodontitis is not only an oral localized inflammatory disease, but also elicits low-grade inflammation via both the release of pro-inflammatory cytokines and the invasion of periodontitis bacteria along with their components (Hashioka et al., 2019). Level of pro-inflammatory cytokines could increase with worsened periodontal status and cognitive decline (Sochocka et al., 2017). Keeping oral hygiene could decrease the risk of dementia (Harding et al., 2017).

Periodontal pathogens and virulence factors that cause chronic periodontitis may also possibly contribute to the development of dementia (Olsen and Singhrao, 2015). *Porphyromonas gingivalis* (*P. gingivalis*), the most important periodontal pathogen, and its virulence factor lipopolysaccharide (LPS) are main pathogenic factor of periodontitis (Jain and Darveau, 2010; Poole et al., 2013). Dominy et al. (2019) reported *P. gingivalis* in brain samples of patients with AD, which indicates that it could be a risk factor for AD. Ilievski et al. (2018) reported brain inflammation and neurodegeneration after oral administration of *P. gingivalis*. Wu et al. (2017) reported that intraperitoneal injection of *P. gingivalis*-LPS promoted learning and memory deficits and intracellular accumulation of A $\beta$ . Our previous study also suggested that intraperitoneal injection of *P. gingivalis*-LPS, which induced systemic inflammation, could impair cognition through neuroinflammation (Zhang et al., 2018). However, the association between topical application of *P. gingivalis*-LPS into the gingival sulcus and learning and memory ability remains unclear.

In this study, we aimed to investigate the effects of periodontitis with topical application of *P. gingivalis*-LPS on learning and memory using the Morris Water Maze test. We used micro-computed tomography to assess bone resorption. Activation of microglial and astrocyte was confirmed through immunohistochemistry. The relative level of LPS and expression of inflammatory factors, as well as TLR4/NF- $\kappa$ B signaling

pathway activation were analyzed using reverse transcription-polymerase chain reaction, enzyme-linked immunosorbent assay, and western blot. For further analysis of the underlying mechanism, we assessed APP processing.

## MATERIALS AND METHODS

### Animals

All experimental protocols were approved by the ethical committee of the Animal Care and Experimental Committee of Shanghai Jiao Tong University School of Medicine and were performed according to the guidelines of the EU Directive 2010/63/EU. Efforts were made to minimize surgery-induced suffering and reduce the overall number of animals used.

We obtained 10-week-old male Sprague-Dawley rats of specific pathogen-free (SPF) grade from the Shanghai SIPPR-BK Laboratory Animal Co., Ltd. The rats were provided with standard housing at temperature (18–22°C) and humidity (55–65%) with a 12-h light/dark cycle and free access to food and water. We randomly divided 32 rats into four groups, namely, the control group (Control), *P. gingivalis*-LPS group (LPS), *P. gingivalis*-LPS plus TAK-242 group (LPS+TAK-242), and TAK-242 group. TAK-242 (also known as CLI-095), a novel cyclohexene derivative, is an effectively/specifically TLR4 inhibitor (Li et al., 2006). After inducing anesthesia using 10% chloral hydrate, the rats in the LPS and LPS+TAK-242 groups were topical applied with *P. gingivalis*-LPS (0.5 mg/kg, twice a week) into the palatal gingival sulcus of the maxillary first molars for 10 weeks using a 5- $\mu$ l microsyringe (Hamilton, Switzerland). Moreover, we injected TAK-242 (0.5 mg/kg, i.p., twice a week) in rats in the LPS+TAK-242 group in advance. The rats in the TAK-242 group were injected with TAK-242 (0.5 mg/kg, i.p., twice a week). The rats in the control group received an equivalent saline volume. The LPS and TAK-242 amounts were determined based on previous studies (Nishida et al., 2001; Gárate et al., 2014). Three days after the last administration, the rats underwent behavioral tests for learning and memory ability assessment. We purchased *P. gingivalis*-LPS Ultrapure and TAK-242 from Invivogen (tlrl-pgglps and tlrl-cli95, San Diego, CA, United States) and dissolved them according to the manufacturer's instructions.

### Open Field Test (OFT)

The open field in the present study consisted of a rectangular arena (530 mm  $\times$  478 mm), enclosed by a black wall, 590 mm in height (Mobile Datum, Shanghai, China). The test was initiated by gently placing a single rat in the middle of the arena, allowing the animal to move freely for 5 min while being recorded.

### Morris Water Maze (MWM) Test

The MWM test was conducted in a round pool 160 cm in diameter and 55 cm in depth (Mobile Datum, Shanghai, China). The pool was filled with water made opaque with white non-toxic water-based tempura paint. The water temperature was controlled to remain with a range equivalent to that of room temperature (22  $\pm$  1°C). The platform was placed in the center

of one quadrant of the pool and submerged 2.5 cm beneath the water surface; it remained in the same position throughout the learning trials and was removed from the pool during the probe test. A video-tracking system (Shanghai Jiliang Software Technology Co., Ltd.) was used to monitor and record the swimming activity of the rats. The rats should have learned to use the visual tips around the pool to find the hidden platform within 90 s, otherwise it would be gently guided to the platform and allowed to re-orient for an additional 10 s. Each rat was trained four times per day with a 30 s of rest per training interval. To examine spatial reference memory, a probe test was carried out on the sixth day when the platform was removed from the pool and each rat was placed into the water at the two quadrants furthest from the platform used on days 1–5, being allowed to navigate freely for 60 s.

### Measurement of Alveolar Bone Resorption by Micro-Computed Tomography (CT)

The maxillae of rats were obtained to detect bone parameters by micro-CT. Fixed in 4% paraformaldehyde, the bone morphometry was assessed using Skyscan1172 (Bruker, Kontich, Belgium) with an accuracy of 18  $\mu$ m. Parameters including Bone volume/total volume (BV/TV), Bone surface/volume ratio (BS/BV) and Bone mineral density (BMD) were calculated.

### Isolation of Peripheral Blood Mononuclear Cells (PBMCs)

Peripheral blood from rats (5 ml per rat) was collected from abdominal aorta in the presence of heparin as the anticoagulant. Three milliliters of the whole blood was diluted with sterile PBS of the same volume and gently resuspended. Six milliliters of the diluted whole blood fraction was overlaid onto 3 ml of the Ficoll-Paque Plus (GE Healthcare Bio-Sciences Corp., Piscataway, NJ, United States) and then subjected to  $800 \times g$  for 20 min at RT with the centrifuge brake “off.” Then PBMC layers were washed twice with RPMI 1640 media by centrifugation at 1200 rpm for 5 min at 4°C. After isolation, all samples were dissolved in Trizol reagent (Takara, Kusatsu, Shiga, Japan) for lysis of cells to extract RNA.

### RNA Extraction and RT-PCR Analysis

The RNA was extracted from PBMCs and homogenization of cortex using Trizol reagent (Takara, Kusatsu, Shiga, Japan) and the Total RNA Kit (Omega Bio-Tek, Inc., Norcross, GA, United States), respectively. The purity and concentration of RNA, as well as the cDNA synthesis, were conducted according to Li et al. (2018). Subsequently, an RT-PCR assay was performed using SYBR Premix Ex Taq<sup>TM</sup> (Takara, Kusatsu, Shiga, Japan) on a Roche LightCycler 480 Real-Time PCR Detection System (Roche, Basel, Switzerland) according to the manufacturer's protocol. Data were then processed using the  $2^{-\Delta\Delta CT}$  method. All results were based on at least three independent tests, and the final results were expressed as normalized fold values relative to the control group. The sequences of genes including Glyceraldehyde-3-phosphate dehydrogenase (GAPDH), IL-1 $\beta$ ,

IL-6, IL-8 and IL-21, APP, amyloid precursor-like protein 1 (APLP1), APLP2, a disintegrin and metalloproteinase 10 (ADAM10),  $\beta$ -site APP cleaving enzyme 1 (BACE1), presenilin 1 (PS1), PS2, TLR4, cluster of differentiation 14 (CD14) and their primer pairs were listed in **Table 1**.

### Measurements of Interleukins, A $\beta$ and LPS by ELISA

Of the approximately 5 ml of blood collected as previously described, 2 ml of blood were collected in heparinized tubes for the measurement of plasma cytokines. After centrifuging (4°C, 2500 rpm\*15 min), supernatant medium was separated and immediately aliquoted into 1.5 ml cryogenic tubes and frozen at -80°C until use. For tissue, radioimmunoprecipitation assay (RIPA) lysis buffer (Beyotime, Beijing, China), 1% protease inhibitor cocktail (Sigma, St. Louis, MO, United States), and 1% PMSF (Beyotime, Beijing, China) were used to homogenize samples of the cerebral cortex. Protein qualification was performed by BCA Protein Assay Kit (Beyotime, Beijing, China). Equal amounts of protein were used in ELISA to measure levels of IL-1 $\beta$ , IL-6, IL-8, IL-21 (UBI, Sunnyvale, CA, United States) and A $\beta$ 1-40, A $\beta$ 1-42 (Enzyme-linked Biotechnology, Shanghai, China) both in the cortex and plasma according to the manufacturer's instructions. Level of LPS in the plasma of

rats was detected by ELISA as well (SAB, College Park, Maryland, United States).

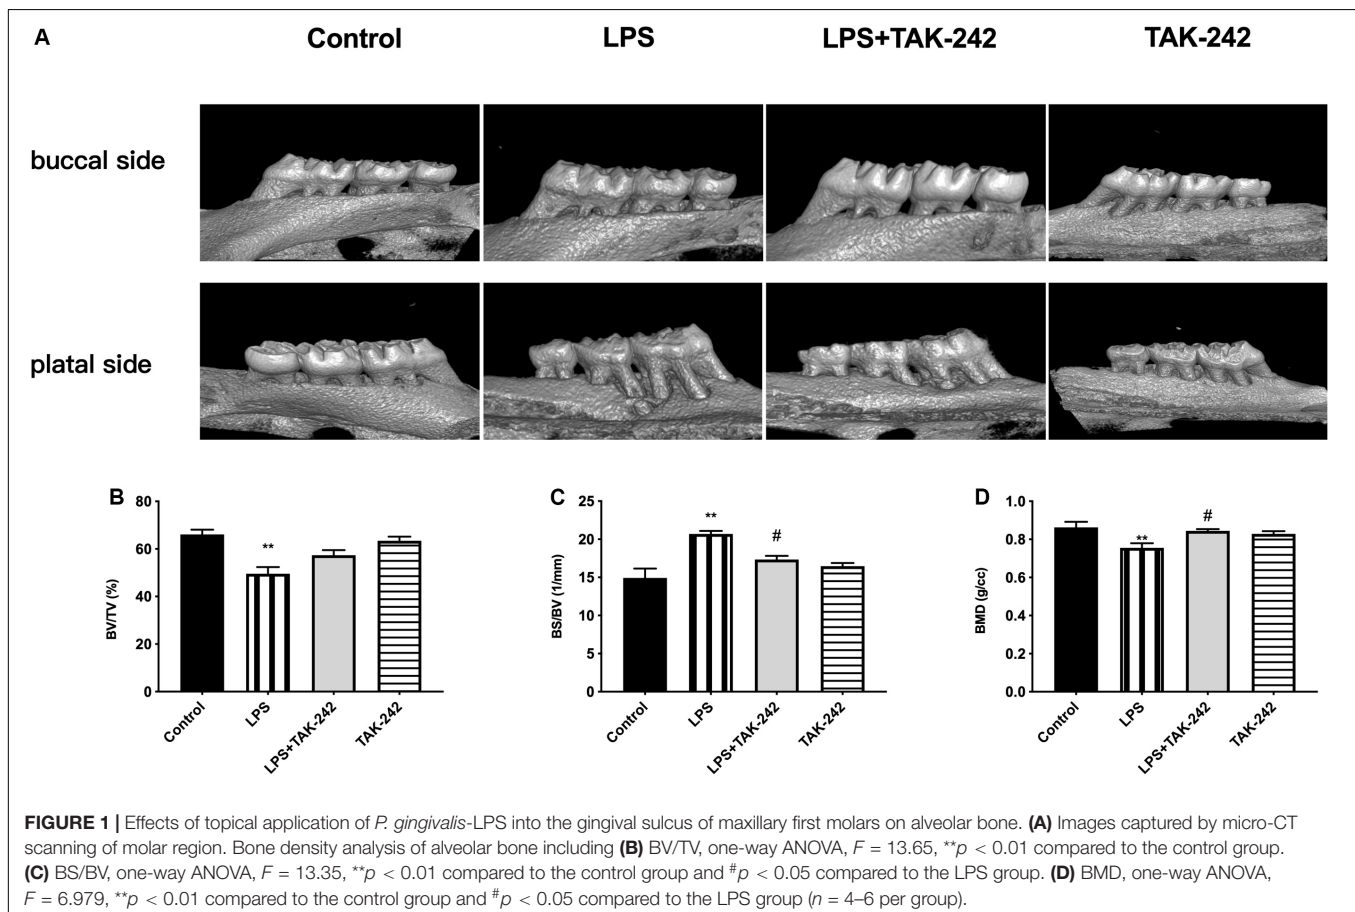

## Western Blot

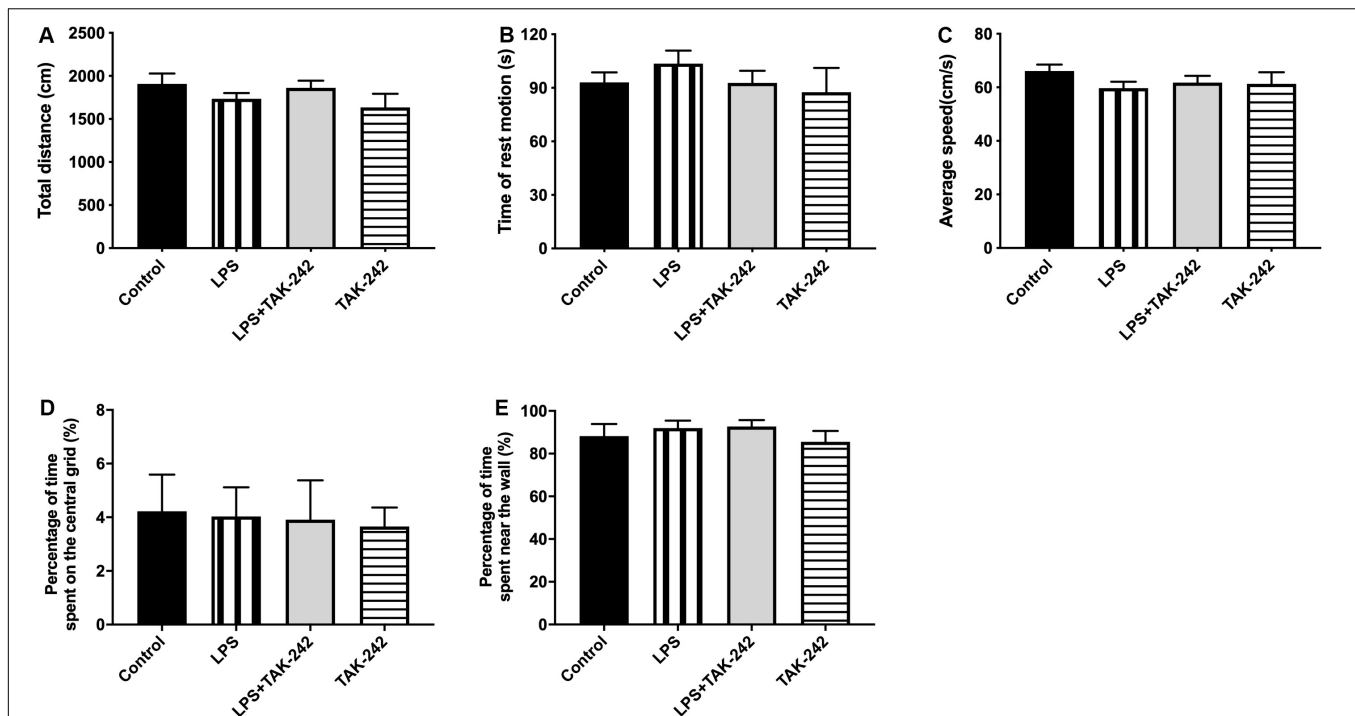

The samples of the cerebral cortex of rats in four groups were homogenized and lysed by RIPA containing 1% protease inhibitor cocktail and 1% PMSF (Beyotime, Shanghai, China). Equal amounts of protein were separated by SDS polyacrylamide gel electrophoresis and transferred onto PVDF membrane blocked with 5% skimmed milk as previously described (Li et al., 2018). A pre-stained protein marker (Thermo Fisher Scientific, MA, United States) was run in parallel to detect the molecular weight of proteins. Proteins were probed with appropriate antibodies including anti-TLR4 (1:1000, abs132000; Absin Bioscience Inc., Shanghai, China), anti-CD14 (1:500, abs121538; Absin Bioscience Inc., Shanghai, China), anti-IRAK1 (1:1000, abs143411; Absin Bioscience Inc., Shanghai, China), anti-p65 (1:1000, no. 8242; Cell Signaling Technology, United States), anti-pp65 (1:1000, no.3033; Cell Signaling Technology, United States) anti-BACE1 (1:1000, no. 5606; Cell Signaling Technology, United States), anti-APP (1:1000, no. 2452; Cell Signaling Technology, United States) and anti-GAPDH (1:1000, AB-P-R001, Goodhere Biotechnology Co., Hangzhou, China). The data were quantified using the Image Studio Lite ver. 5.2 software.

## Immunohistochemistry

Rats were anesthetized with 10% chloral hydrate and perfused with cool PBS before removal of the brain. One hemisphere was placed in 4% paraformaldehyde overnight at 4°C, after which paraffin sections were prepared. This procedure is consistent with the previous study (Zhang et al., 2018). Briefly, brain sections were incubated with 3% H<sub>2</sub>O<sub>2</sub> in methanol, blocked with 10% goat serum and incubated overnight at 4°C with the following primary antibodies: Ionized calciumbinding adaptor molecule 1 (Iba1) (1:400, ARG63338; Arigo Biolaboratories, Hsinchu City, Taiwan, China), Glial fibrillary acidic protein (GFAP) (1:400, ab7260; Abcam) to label microglia and astrocytes, anti-beta Amyloid1-42 antibody (1:50, ab10148; Abcam), anti-Tau antibody (1:400, ab32057; Abcam) and anti-APP antibody (1:100, MAB348; Millipore). After being washed, sections were incubated with biotinylated goat anti-rabbit or goat secondary antibody (1:200; Vector Laboratories, Burlingame, CA, United States). Images were obtained with a Leica camera.

The quantification of the immunohistochemical analysis for Iba1, GFAP, Aβ1-42, APP and Tau positive cells was performed by Image J software. The endpoints and process length were evaluated, and the numbers of positive cells were determined according to previous studies (Zhang et al., 2017; Young and

**FIGURE 2 |** Effects of periodontal inflammation on animal activities. The open field test (OFT) was used to evaluate the locomotor activities of rats 3 days after the final administration (A–E): (A) Total distance; one-way ANOVA,  $p = 0.3170$ . (B) Time of rest motion; one-way ANOVA,  $F = 0.2203$ ,  $p = 0.8812$ . (C) Average speed.  $F = 0.8259$ ,  $p = 0.4950$ . (D) Percentage of time spent on the central grid (%); one-way ANOVA,  $F = 0.03944$ ,  $p = 0.9891$ . (E) Percentage of time spent near the wall; one-way ANOVA,  $F = 0.5656$ ,  $p = 0.6455$ . Overall, no significant differences were observed between groups in OFT ( $n = 4$ –6 per group).

Morrison, 2018). The average of the individual measurements was used to calculate group means.

## Statistical Analysis

All data are presented as the mean  $\pm$  standard error of the mean (SEM).  $P$ -values were calculated with one-way ANOVA and two-way ANOVA with the GraphPad Prism software. An analysis of variance was performed using Turkey's *post-hoc* multiple comparison test. A value of  $p < 0.05$  was indicative of statistical significance.

## RESULTS

### Assessment of Alveolar Bone Resorption

As shown in **Figure 1A**, *P. gingivalis*-LPS led to posterior maxillary bone loss. There was a decrease in BV/TV and BMD ( $66.13 \pm 1.98\%$  vs.  $49.56 \pm 2.83\%$  and  $0.8743 \pm 0.02$  g/cc vs.  $0.755 \pm 0.02$  g/cc, respectively) and an increase in BS/BV ( $14.92 \pm 1.22/\text{mm}$  vs.  $20.7 \pm 0.40/\text{mm}$ ) in the LPS group, which was reversed by TAK-242 (**Figures 1B–D**). This indicated that *P. gingivalis*-LPS could induce bone resorption similar to that in periodontitis. Moreover, these changes induced by *P. gingivalis*-LPS could be alleviated by TAK-242.

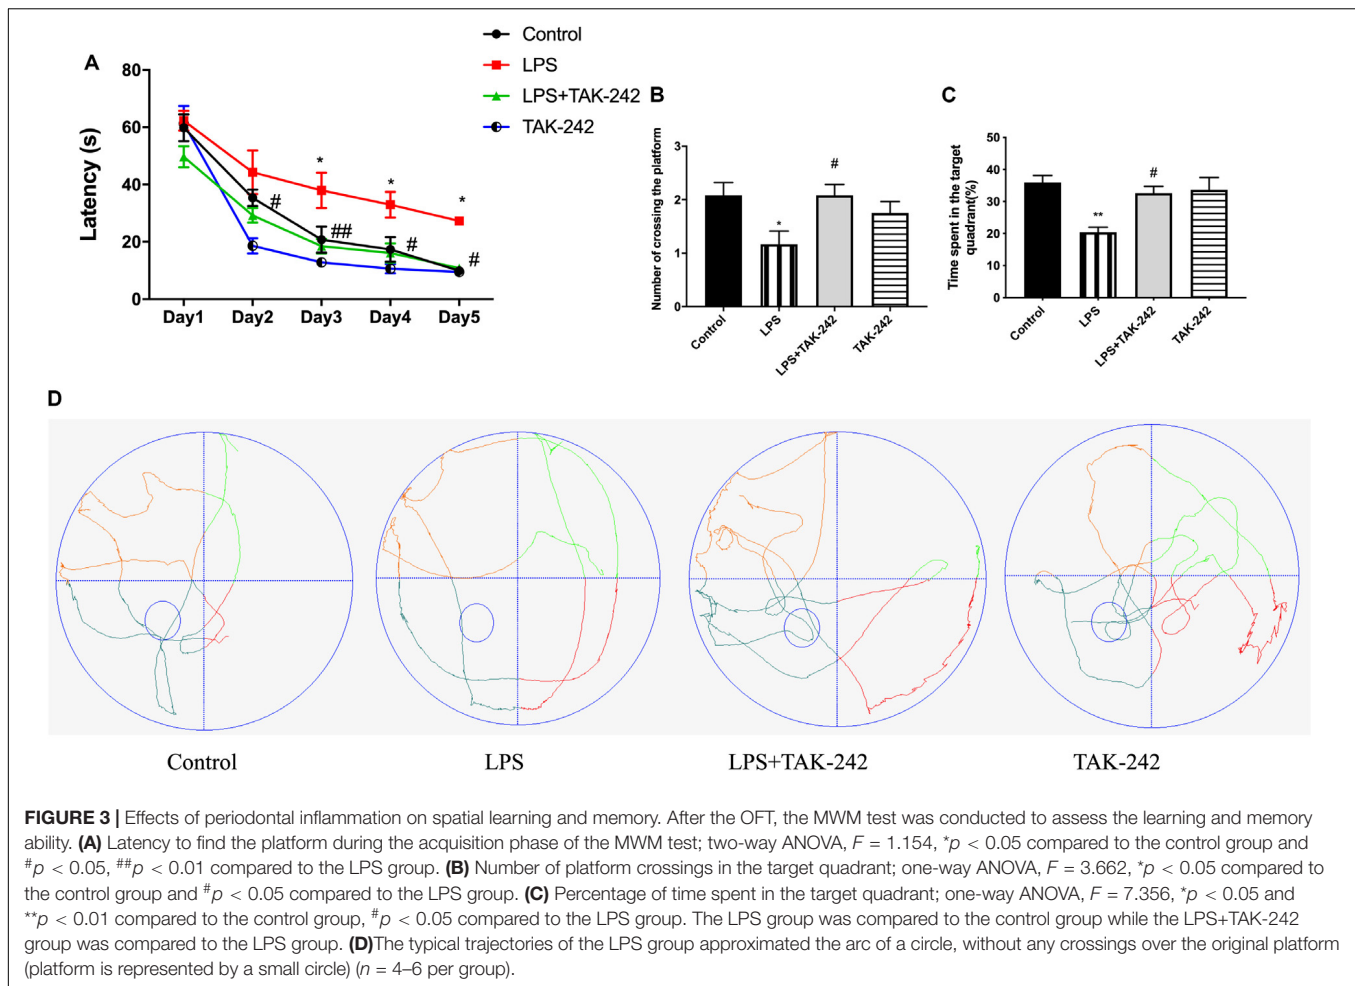

### Effects of Periodontal Inflammation on Locomotor Activity

We used the OFT to assess whether periodontitis induced by *P. gingivalis*-LPS with/without intraperitoneal administration of TAK-242 could affect spontaneous activity in rats. As shown in **Figure 2**, there was no significant among-group difference in the behaviors, including total distance covered (**Figure 2A**), time of rest motion (**Figure 2B**), average speed (**Figure 2C**), percentage of time spent on the central (%) (**Figure 2D**), percentage of time spent near the wall (%) (**Figure 2E**). This indicated that the locomotor activity of the rats was not affected by *P. gingivalis*-LPS or TAK-242.

### Effects of Periodontal Inflammation on Spatial Learning and Memory

We used the MWM test to determine whether topical application of *P. gingivalis*-LPS into the palatal gingival sulcus of the maxillary first molars could affect learning and memory ability in rats. There was a chronological latency decrease in all the groups over the 5-day training period (**Figure 3A**). In the LPS group, the escape latency was significantly longer than it was in the control group at days 3, 4, and 5. There were no significant differences between the control group and the LPS+TAK-242 group. We removed the platform on the sixth day and found a significant decrease in the number of platform crossings in the target quadrant and the percentage of time spent in the target quadrant

in the LPS group (Figures 3B,C). During the probe test, rats in the control group learned to directly navigate to the quadrant containing the hidden platform; however, this was not observed in the LPS group (Figure 3D). The changes mentioned above could be restored by TAK-242 administration. This indicated that periodontitis induced by *P. gingivalis*-LPS could be an important risk factor for learning and memory impairment.

### Effects of Periodontal Inflammation on the Plasma Levels of LPS and Inflammatory Cytokines

Plasma levels of IL-1 $\beta$ , IL-6, IL-8, IL-21, and LPS were significantly higher in the LPS group than in the control group. Compared to the LPS group, the LPS+TAK-242 group showed reduced levels of IL-1 $\beta$ , IL-6, IL-8, and IL-21 proteins and LPS (Figure 4).

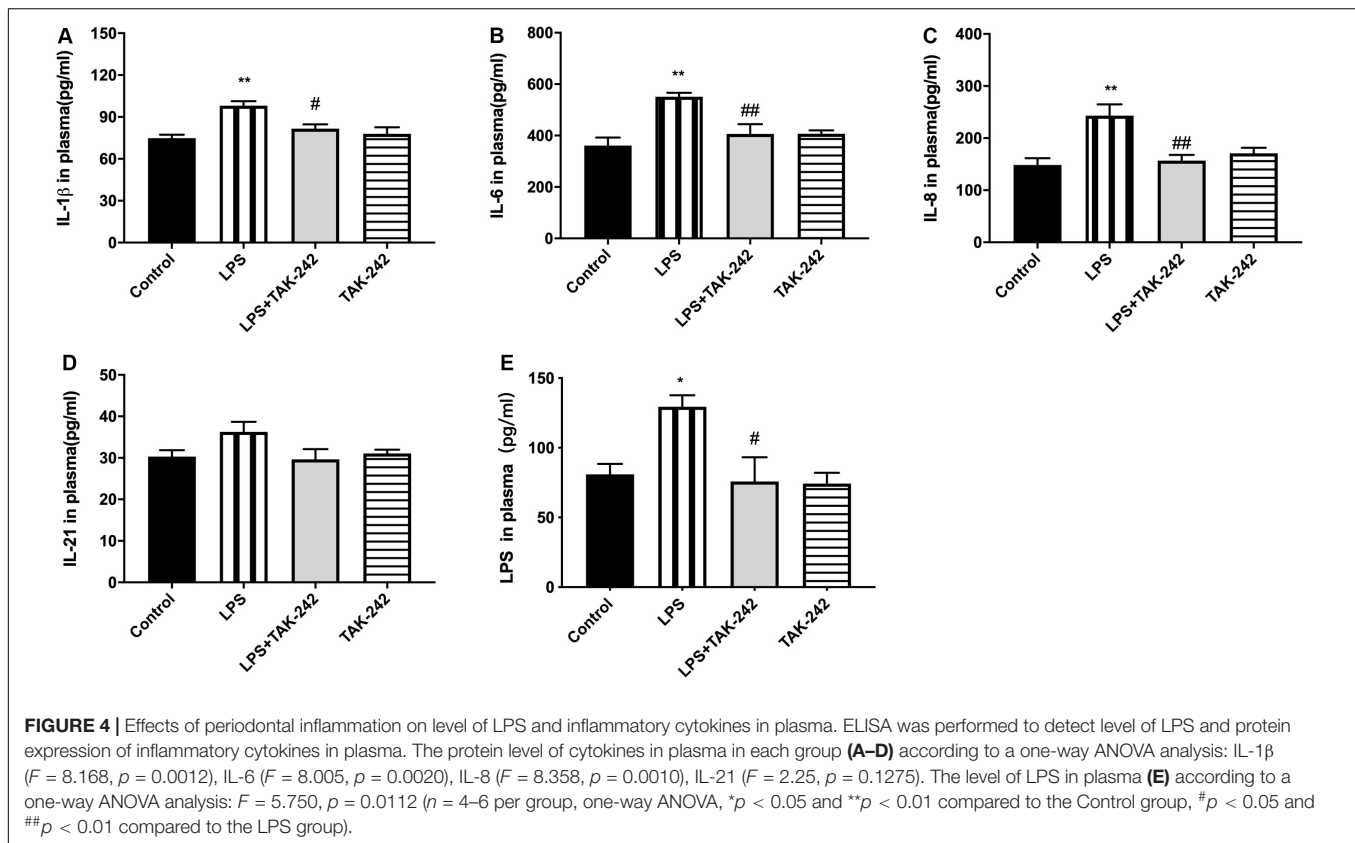

### Effects of Periodontal Inflammation on Microglia and Astrocytes in the Cortex

As shown in Figure 5, activation of microglia and astrocytes could be found in the LPS group. Activated microglia, which are characterized by irregular protrusions and increased volume of

cell bodies, were positively stained with Iba1. Activated microglia were observed in the cortex of the LPS group but rarely in the control group while activated astrocytes were positively stained with GFAP (Figures 5A,E). A relative increase in endpoints and process length was found, presenting as volume hypertrophy and irregular protrusions (Figures 5B–D,F–H). Changes mentioned above could be reversed by TAK-242 administration. These findings indicate that periodontitis induced by *P. gingivalis*-LPS could play an important role in neuroinflammation.

### Effects of Periodontal Inflammation on Inflammatory Cytokine Levels in the Cortex

Compared to the control group, there were significantly higher mRNA and protein levels of IL-1 $\beta$ , IL-6, IL-8, and IL-21 in the cortex in the LPS group. Compared to the LPS group, the LPS+TAK-242 group showed reduced levels of IL-1 $\beta$ , IL-6, and IL-8 proteins (Figure 6). These findings demonstrate that periodontitis induced by *P. gingivalis*-LPS increases the expression of inflammatory factors in the central nervous system, which is significantly prevented by TAK-242.

## Effects of Periodontal Inflammation on APP Processing and Tau

Periodontitis induced by *P. gingivalis*-LPS increased the expression of APP and its homologs (APLP1 and APLP2) (Figures 7A–C). Further, it induced an increase in BACE1 and PS2 mRNA expression. In the control group, there was a decrease in ADAM10 mRNA expression (Figures 7D–G). Increased intracellular levels of A $\beta$ 1-42 and APP were observed in the LPS group, presenting as cytoplasmic yellow/brown particles (Figure 8). Besides, detection of Tau showed similar results. The number of positive cells were increased in the LPS group (Figures 8A–C). All the changes mentioned above could be alleviated by TLR4 inhibitor. The A $\beta$  ratio (A $\beta$ 1-40/A $\beta$ 1-42) was upregulated in both the plasma and cortex (Figures 9A,B). Moreover, we measured BACE1 and APP protein expression in the cortex to confirm the increase in  $\beta$ -site APP cleaving in the LPS group (Figures 9C–E). Compared with the LPS group, the LPS+TAK-242 group showed reduced mRNA and protein expression related to APP processing.

## Role of the TLR4/NF- $\kappa$ B Signaling Pathway

Results of RT-PCR revealed that periodontal inflammation significantly increased the mRNA levels of TLR4 and CD14. Compared to the control group, the LPS group showed 2-fold and 1.5-fold increases in TLR4 and CD14 mRNA expression in the PBMCs and the cortex, respectively, which could be reversed

by TAK-242 (Figures 10A–D). As shown in Figures 10E–J, we conducted western blot analysis to assess the underlying mechanisms of the neuroinflammation induced by periodontitis. We observed increased expression of TLR4, CD14, IRAK1, p65, and pp65 in the cortex of rats in the LPS group, which was reduced by TAK-242 administration. This indicated that periodontitis induced neuroinflammation through TLR4/NF- $\kappa$ B pathway cascades.

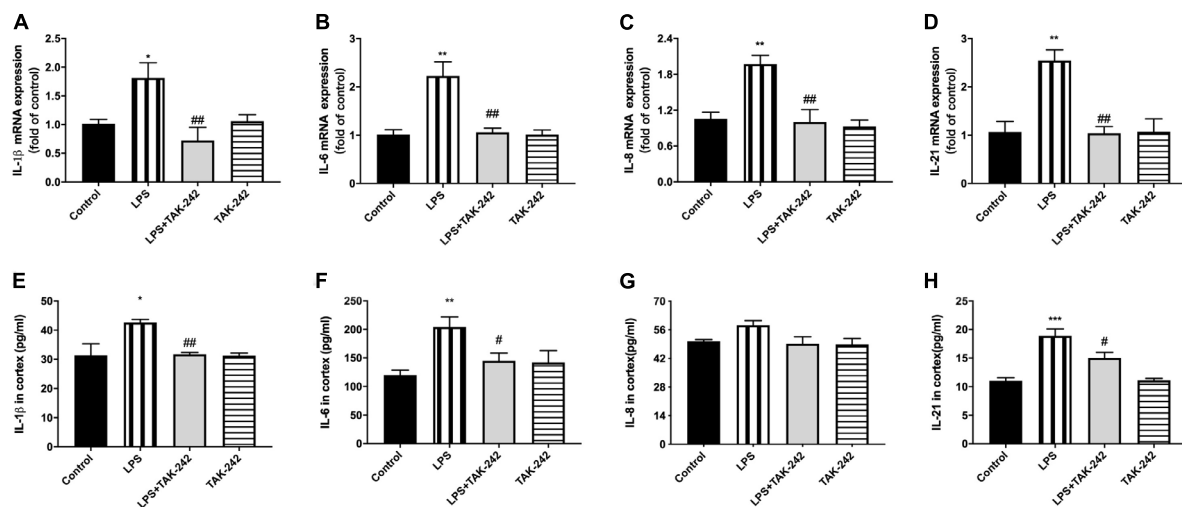

## DISCUSSION

In this study, we demonstrated the association between periodontitis induced by topical application of *P. gingivalis*-LPS and learning and memory impairment *in vivo*. Micro-CT showed alveolar bone resorption. The MWM test showed that periodontitis impaired learning and memory ability. There was an increase in cortical and peripheral blood levels of inflammatory factors, as well as TLR4/NF- $\kappa$ B signaling pathway activation, which could be reversed by the TLR4 inhibitor TAK-242. Significant microglia and astrocyte activation were found in the cortex, which induced neuroinflammation. Furthermore, APP processing could be involved in this progress.

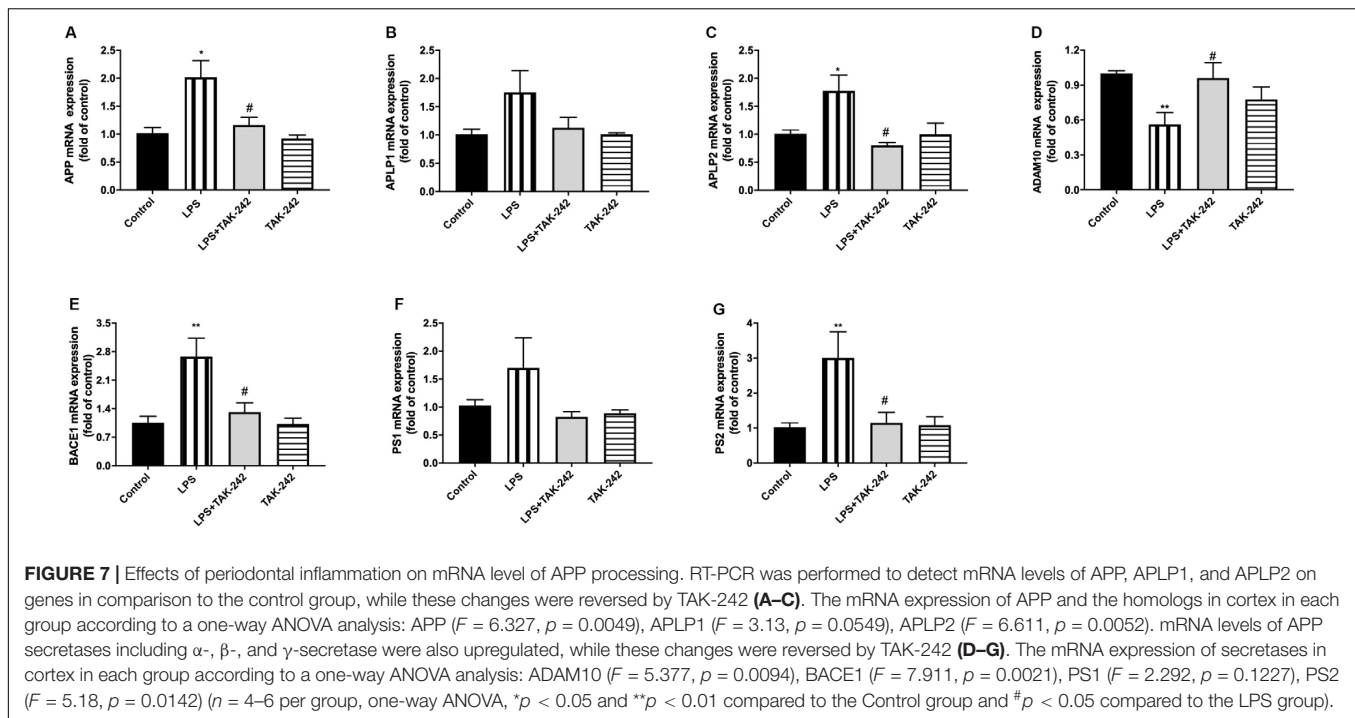

The association between systemic infection/inflammation and cognitive impairment has been reported (Zhang et al., 2018; Nie et al., 2019). In the present research, topical application of *P. gingivalis*-LPS into the gingival sulcus of maxillary first molars was used to cause periodontal

**FIGURE 5 |** Effects of periodontal inflammation on microglia and astrocytes in the cortex. Histopathological analysis of brain sections was performed using immunohistochemistry. As shown in (A,B), activated microglia labeled by Iba1 with irregular protrusions were observed in cortex of the LPS group, while a similar situation could be found in astrocytes labeled by GFAP (E,F). The changes mentioned above could be attenuated by TAK-242 (200 $\times$  and 400 $\times$ , bar = 200  $\mu$ m). The endpoints (C,G) and process length (D,H) according to a one-way ANOVA analysis: endpoints ( $F = 6.219$ ,  $p = 0.0174$ ) and process length ( $F = 10.74$ ,  $p = 0.0025$ ) of microglia, endpoints ( $F = 8.354$ ,  $p = 0.0076$ ) and process length ( $F = 2.595$ ,  $p = 0.1249$ ) of astrocytes ( $n = 3-4$  per group, one-way ANOVA,  $^*p < 0.05$  and  $^{**}p < 0.01$  compared to the Control group,  $^{\#}p < 0.05$  compared to the LPS group).

**FIGURE 6 |** Effects of periodontal inflammation on protein expression of inflammatory cytokines in cortex. RT-PCR was performed to detect mRNA levels of IL-1 $\beta$  ( $F = 6.861$ ,  $p = 0.0045$ ), IL-6 ( $F = 11.05$ ,  $p = 0.0007$ ), IL-8 ( $F = 9.223$ ,  $p = 0.0013$ ), IL-21 ( $F = 11.89$ ,  $p = 0.0007$ ) in cortex of rats, while these changes were relieved by TAK-242 (A-D). ELISA was performed to detect protein levels in cortex (E-H) in each group according to a one-way ANOVA analysis: IL-1 $\beta$  ( $F = 7.045$ ,  $p = 0.0020$ ), IL-6 ( $F = 7.145$ ,  $p = 0.0019$ ), IL-8 ( $F = 3.866$ ,  $p = 0.0248$ ), IL-21 ( $F = 15.22$ ,  $p < 0.0001$ ) ( $n = 4-6$  per group, one-way ANOVA,  $^*p < 0.05$ ,  $^{**}p < 0.01$ , and  $^{***}p < 0.001$  compared to the Control group,  $^{\#}p < 0.05$  and  $^{\#\#}p < 0.01$  compared to the LPS group).

inflammation according to a previous study (Yoshinaga et al., 2012). The most significant difference was the way of drug administration. Previous studies mostly used intraperitoneal injection that induced systemic inflammation, while we established periodontitis via topical application into the gingival sulcus. As the result of Micro-CT showed, a decrease in the trabecular bone volume fraction and bone mineral density could be found. This model was more similar to clinical periodontitis, considering it could mimic the damage of junctional epithelium and the formation of periodontal pocket (Bosshardt, 2018).

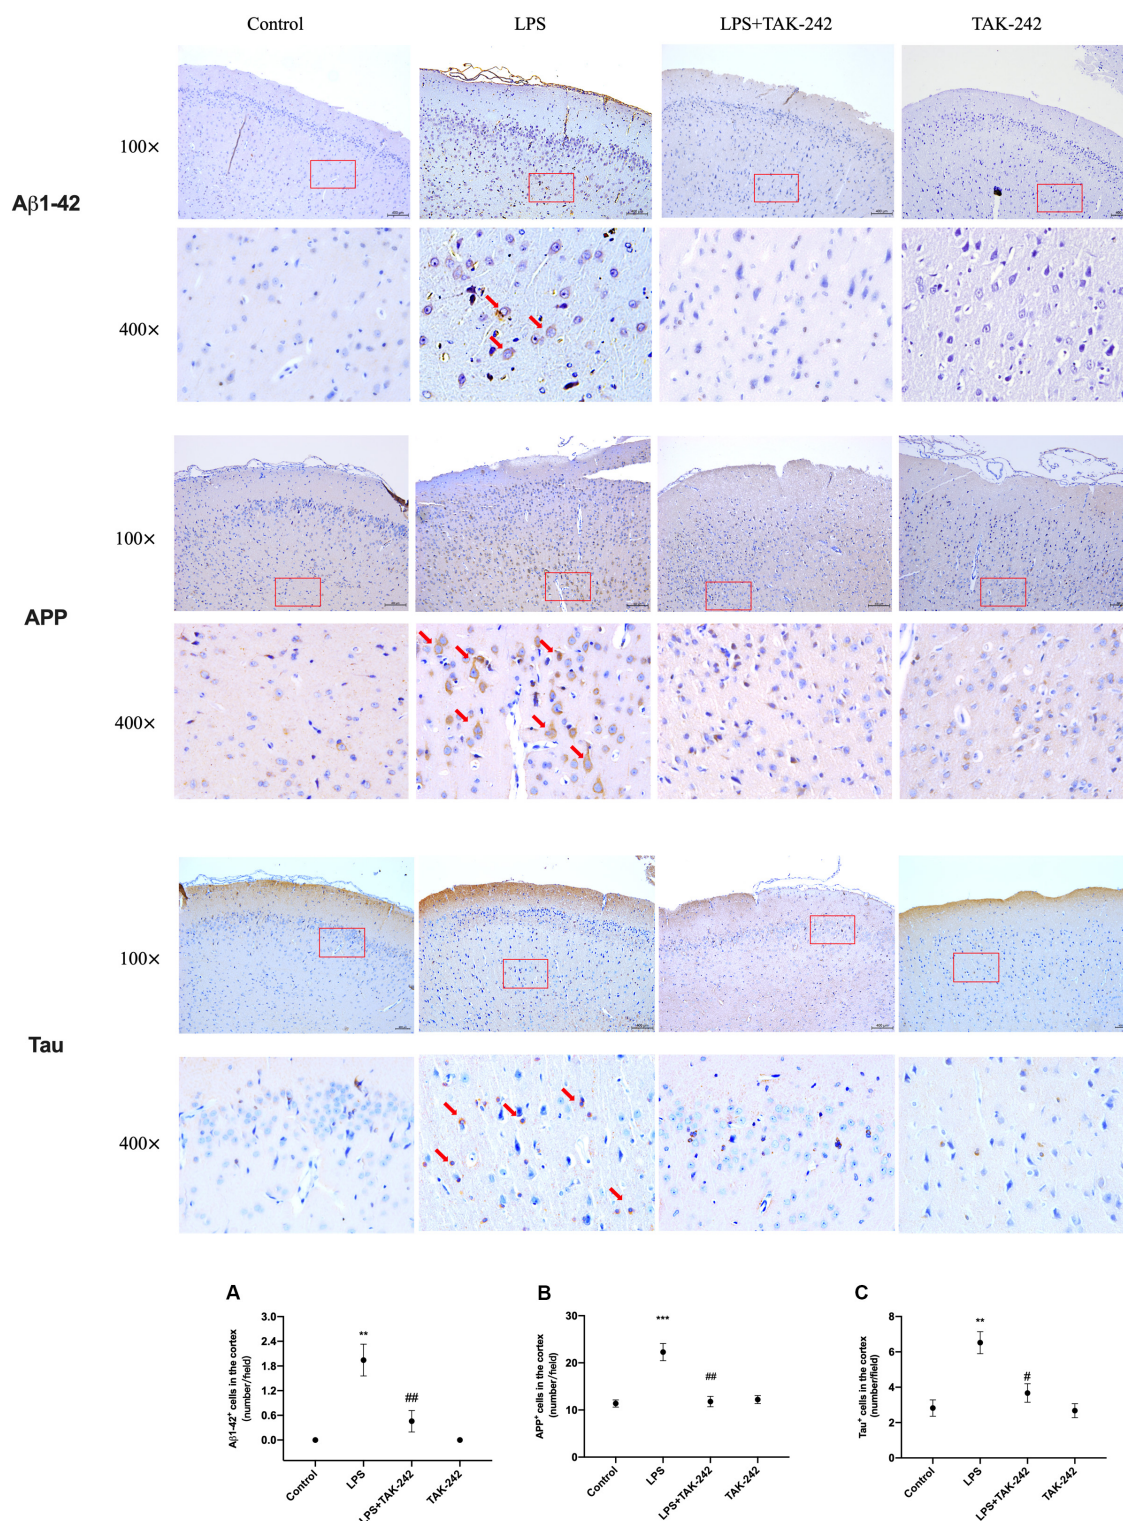

The locomotor activity of rats were not affected by topical application of *P. gingivalis*-LPST according to the results of the OFT. During the MWM test, however, the learning and memory ability could be impaired by periodontitis. Behavioral assessments demonstrated that topical application of *P. gingivalis*-LPS could induce learning and memory impairment. To investigate the association more comprehensively, more cognitive evaluation should be included in behavioral assessments using AD models in the following studies.

Periodontitis elicits a significant inflammatory response (Wu and Nakanishi, 2014). It has been proposed that peripheral inflammation/infection may be not only a contributor but also indeed a key determinant of the cognitive decline (Sochocka et al., 2017). Recent studies have shown that systemic infection/inflammation could induce cognitive impairment through neuroinflammation (Wu et al., 2017; Zhang et al., 2018). In periodontitis, local pro-inflammatory cytokines can enter the circulation, in turn contributing to atherosclerosis or exacerbating intra-uterine inflammation (Paraskevas et al., 2008). Patients with severe periodontitis have increased systemic

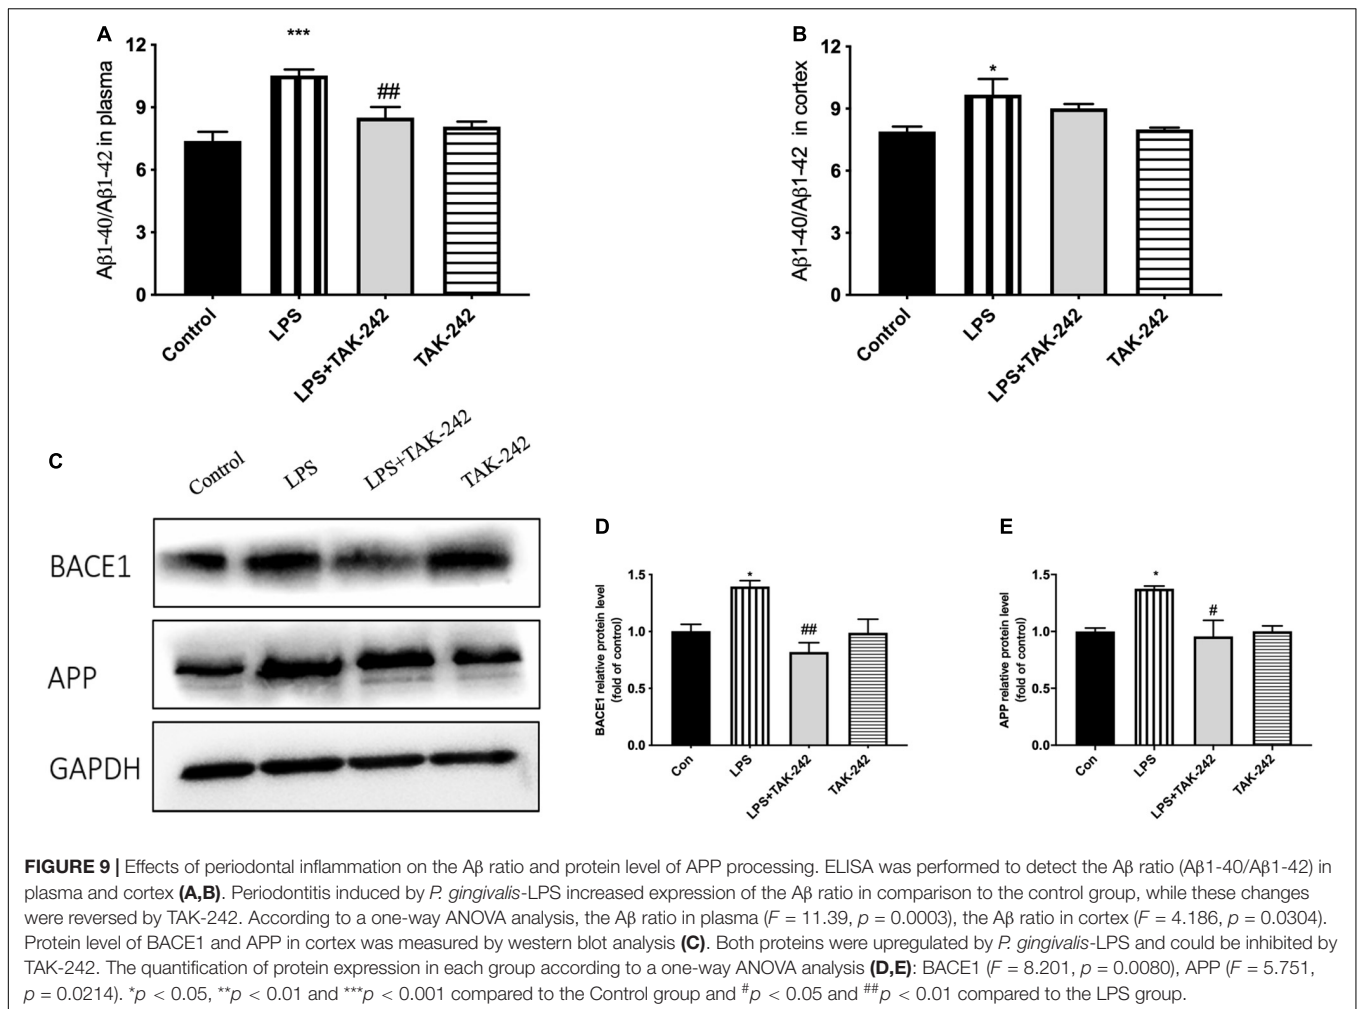

inflammation (elevated cytokines such as IL-6) compared with healthy controls, whereas treatment of periodontitis reduces inflammation load (Friedewald et al., 2009). Similarly, we found significantly increased inflammatory cytokine expression (IL-1 $\beta$ , IL-6, IL-8, and IL-21) in the peripheral blood, which could be alleviated by TAK-242.

Neuroinflammation could play a significant role in cognitive dysfunction (Lyman et al., 2014). Inflammation in the brain is mainly caused by microglia and astrocyte activation, as well as the release of cytokines, chemokines or growth factors, which typically occur prior to cognitive dysfunction (Michelucci et al., 2009). We observed stimulation of microglia and astrocytes, which were labeled with Iba1 and GFAP, respectively, from a resting state to an activated state, which might have had toxic effects. Activated microglia could secrete proinflammatory mediators (Schwab and McGeer, 2008; Venneti et al., 2008). Over-activated astrocytes could induce the production of inflammatory cytokines, which subsequently causes neuronal death and contributes to cognitive decline (Choi et al., 2016; Lian et al., 2016). Among these cytokines, IL-1 $\beta$  is the key molecule involved in neuroinflammation, which stimulates the release of multiple inflammatory mediators by activated microglia and leads to self-propagating neuroinflammation (Lai et al., 2017; Mendiola and Cardona, 2018). Regarding IL-6, an upstream IL-21 target, has been reported to enhance neuronal damage (Ringheim et al., 1998; Qiu and Gruol, 2003). IL-8 upregulation could be a very early event in neurodegeneration (Arosio et al., 2004; Galimberti et al., 2006). We found a positive correlation between levels of these cytokines in periphery and cortex. Therefore, we speculated that periodontitis could induce learning and memory impairment through neuroinflammation, which

**FIGURE 8 |** Effects of periodontal inflammation on expression of Aβ1-42, APP and Tau in the cortex. Histopathological analysis of brain sections was performed using immunohistochemistry. As shown in **Figure 8**, the positive expression of Aβ1-42 and APP in cytoplasm was observed in the LPS group, presenting as cytoplasmic yellow/brown particles. The number of Aβ1-42, APP, and Tau positive cells was increased. The changes mentioned above could be attenuated by TAK-242. Quantification of Aβ1-42, APP and Tau levels in cortex are shown, including **(A)** Aβ1-42 positive cells (number/field) ( $F = 15.59$ ,  $p = 0.0011$ ); **(B)** APP positive cells (number/field) ( $F = 18.9$ ,  $p = 0.0005$ ), and **(C)** Tau positive cells (number/field) ( $F = 12.35$ ,  $p = 0.0023$ ) ( $n = 3$  per group, one-way ANOVA, \*\* $p < 0.01$  and \*\*\* $p < 0.001$  compared to the Control group, # $p < 0.05$  and ## $p < 0.01$  compared to the LPS group) (100× and 400×, bar = 400 μm).

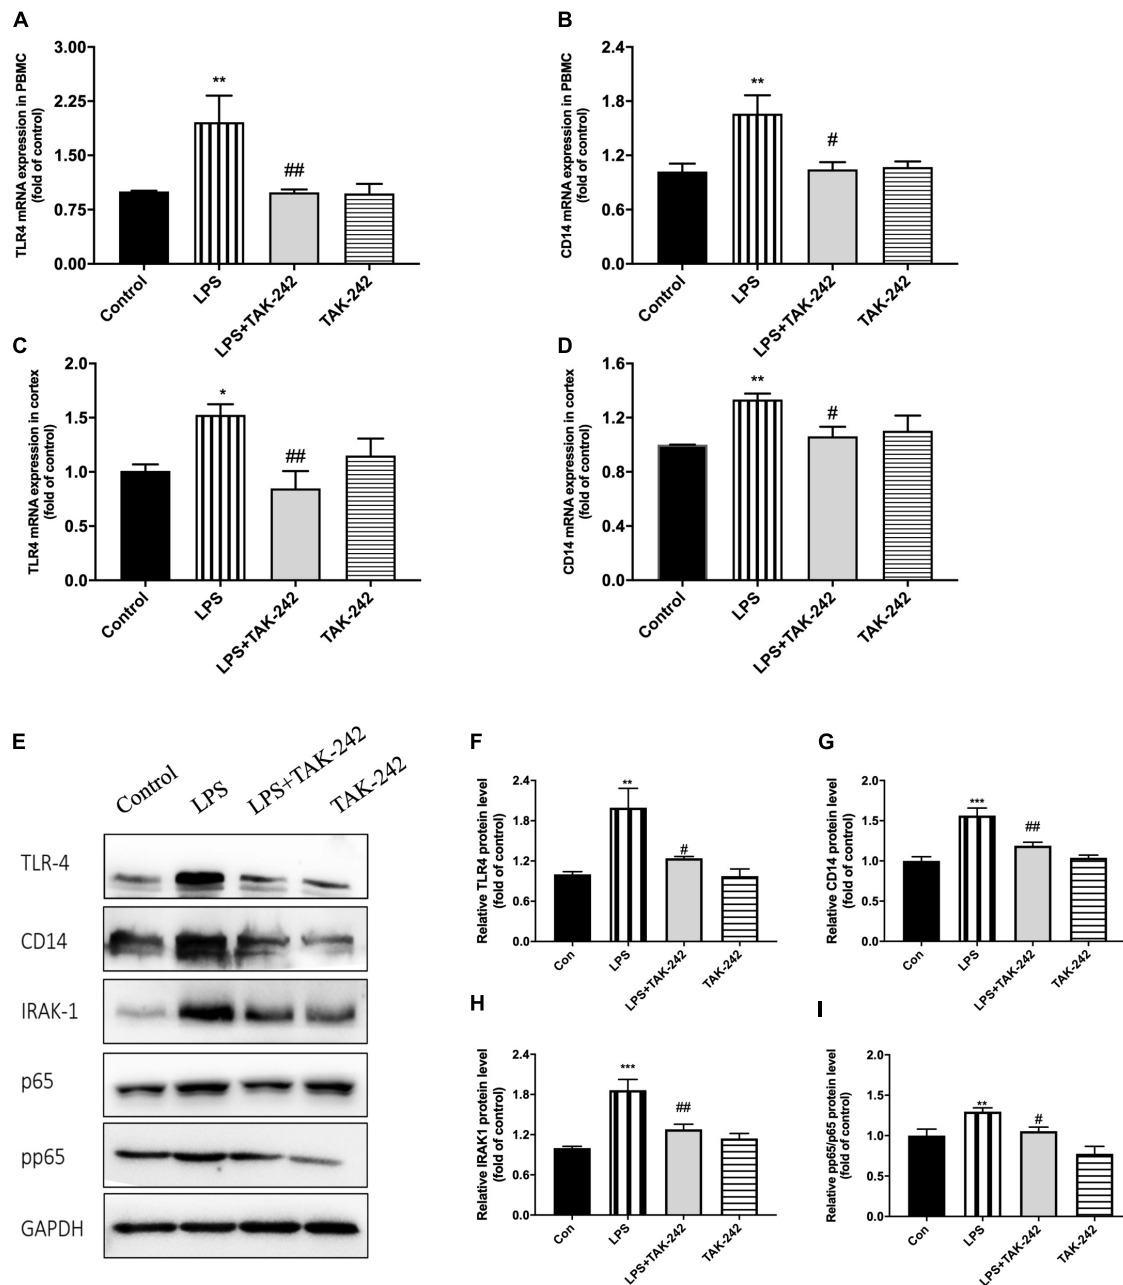

presented as microglial and astrocyte activation. Similar results could be found in previous studies (Martin et al., 2001; Liu et al., 2008; Terrando et al., 2010).

As one of the main triggers of inflammatory response, not only could the TLR4 signaling pathway regulate peripheral inflammation, but also neuroinflammation (Laflamme and Rivest, 2001). Specifically, TLR4 plays an important role in microglial neurotoxicity given that it is activated by LPS binding to initiate signal transduction and pro-inflammatory cytokines (Walter et al., 2007). Moreover, increased expression of TLR4, CD14, IRAK1, and p65/p65 could be attenuated by the TLR4 selective blocker TAK-242. Consistent with the findings of Zakaria et al. (2017), this suggests that *P. gingivalis*-LPS could stimulate brain secretion of inflammatory cytokines via TLR4 activation, which subsequently induces neuroinflammation.

Besides, activated TLR4 signaling pathway and dysregulated cytokines might stimulate inflammatory processes by affecting APP processing (Reed-Geaghan et al., 2009). Multiple proinflammatory cytokines have been shown to upregulate APP expression and BACE1 activity in the brain (Brugg et al., 1995; Chen et al., 2012). The APP family has two mammalian homologs; namely, APLP1 and APLP2 (Müller and Zheng,

2012; Müller et al., 2017). Several common features of the APP family members include processing by  $\alpha$ -(ADAM10),  $\beta$ -(BACE1), and  $\gamma$ -secretase (PS1 and PS2) (Eggert et al., 2004; Li and Südhof, 2004). As a rate-limiting enzyme that initiates A $\beta$  formation, BACE1 plays an essential role (Trojanowski et al., 1993). Expression of APP, BACE1, and PS1/2 was increased. All the changes mentioned above could be alleviated by TLR4 inhibitor. Our study demonstrated that periodontitis induced by *P. gingivalis*-LPS could facilitate abnormal APP processing. This indicated that periodontitis induced by *P. gingivalis*-LPS could modulate APP processing through enhanced  $\beta$ - and  $\gamma$ -site secretase activity, consistent with the increase of APP in patients with chronic periodontitis (Abe et al., 2011). According to our results, cytoplasmic yellow/brown particles could be found and intracellular levels of A $\beta$ 1-42 as well as APP were increased in the cortex of LPS group, indicating that periodontitis could induce abnormal APP processing. Due to the process of A $\beta$  extracellular deposition may occur at a later time point due to severe neuronal dysfunction and degeneration, it was hard to find obvious A $\beta$ 1-42 plaques in the present model induced by LPS, similar to the results of Sheng et al. (2003) and Pintado et al. (2012).

**FIGURE 10 |** Periodontal inflammation could induce neuroinflammation via the activation of TLR4/NF- $\kappa$ B signaling pathway. RT-PCR was performed to detect mRNA levels of TLR4 and CD14 in PBMCs (**A,B**) and cortex (**C,D**). RNA expression of TLR4 and CD14 was both upregulated by *P. gingivalis*-LPS; however, similar effects were not observed in LPS plus TAK-242 group. The mRNA expression in PBMCs in each group according to a one-way ANOVA analysis: TLR4 ( $F = 9.042$ ,  $p = 0.0008$ ), CD14 ( $F = 6.004$ ,  $p = 0.0061$ ) (**A,B**). The mRNA expression in cortex in each group according to a one-way ANOVA analysis: TLR4 ( $F = 5.346$ ,  $p = 0.0105$ ), CD14 ( $F = 5.186$ ,  $p = 0.0117$ ) (**C,D**). Expression of TLR4, CD14, IRAK1, p65, and pp65 was further measured by western blot analysis (**E**). All above proteins was upregulated by *P. gingivalis*-LPS. High expression of these proteins was effectively inhibited by TAK-242. (**F–I**) The quantification of related protein expression in each group according to a one-way ANOVA analysis: TLR4 ( $F = 10.85$ ,  $p = 0.0024$ ), CD14 ( $F = 18.54$ ,  $p = 0.0003$ ), IRAK1 ( $F = 15.4$ ,  $p < 0.0011$ ), pp65 ( $F = 17.59$ ,  $p = 0.0003$ ) ( $n = 4–6$  per group, one-way ANOVA, \* $p < 0.05$ , \*\* $p < 0.01$ , and \*\*\* $p < 0.001$  compared to the Control group, # $p < 0.05$  and ## $p < 0.01$  compared to the LPS group).

Abnormal APP processing could generate A $\beta$ , which plays a pivotal role in the pathogenesis of cognitive disorders. It has traditionally been thought that A $\beta$  in the brain originates from the brain tissue itself (Bu et al., 2018). However, some have

suggested that the source of cerebral amyloid may originate in the periphery, including platelets, liver monocytes/macrophages, skin fibroblasts, skeletal muscles and cerebrovascular smooth muscle cells (Citron et al., 1994; Li et al., 1995; Kuo et al., 2000;

Van Nostrand and Melchor, 2001; DeMattos et al., 2002; Nie et al., 2019). A $\beta$  produced in peripheral tissues or cells could be secreted into blood circulation and subsequently entered brain (Li et al., 1995; Bu et al., 2018; Nie et al., 2019). Our results showed an increase in the ratio of A $\beta$ 1-40/A $\beta$ 1-42 in both plasma and cortex, which was in concordance with Anantharaman et al. (2006). We speculated that periodontitis could directly/indirectly expand A $\beta$  pools in periphery and thereby contributes to the increase of A $\beta$  in the brain.

In this work, we established a periodontitis model and indicated the association between periodontitis and learning and memory impairment. Increase of inflammatory factors, activation of microglia and astrocytes and abnormal APP processing were found, suggesting that periodontitis might be a possible contributor to AD-like pathology. However, AD models should be used in following researches for further assessment of AD-pathologies and more sophisticated evaluation of association between periodontitis and AD.

## CONCLUSION

Our findings indicated that periodontitis induced by topical application of *P. gingivalis*-LPS could contribute to learning and memory impairment via neuroinflammation induced by TLR4/NF- $\kappa$ B signaling pathway activation in SD rats. Furthermore, abnormal APP processing could be involved in this progress. Therefore, periodontitis could not only affect the teeth-supporting structures but also cause a significant inflammatory load in both the peripheral blood and central nervous system, which leads to learning and memory impairment.

doi: 10.3389/fnins.2020.00715

**Background:** Objective motor ratings and subjective motor complaints are both widely used in Parkinson's disease (PD). However, the objective basis to the self-perceived mobility quality is still not well elucidated.

**Purposes:** We aimed to figure out the relevancy between the UPDRS motor scores and PDQ39 mobility sub-scores, and further explore whether physician-assessed motor dysfunctions and patients-reported mobility deficits have some shared mechanisms.

**Methods:** 49 patients with PD who completed the PDQ39 scale were retrospectively included. The relevancy between mobility quality and UPDRS scores was assessed, as well as the related presynaptic dopaminergic binding (<sup>11</sup>C-CFT) and glucose metabolism (<sup>18</sup>F-FDG) in this dual-tracer PET imaging study.

**Results:** Modest correlation was found between UPDRS motor score and the PDQ39 mobility sub-score ( $r = 0.440$ ,  $p = 0.002$ ). No correlation was found between PDQ39 mobility SI and the dopaminergic lesions in putamen; however, the strict correlation was found with the UPDRS motor scores. In terms of global PD related pattern (PDRP) scores, the two motor scores both correlated strictly. In the further regional metabolism exploration, cerebellum correlated positively with PDQ39 mobility sub-scores, and the frontal and parietal regions mainly correlated negatively with the motor quality scores.

**Conclusion:** UPDRS motor scores and PDQ39 mobility scores were only modestly correlated. The mechanisms involved under mobility quality were beyond dopaminergic deficiency, including motor related cerebellum hyper-metabolism and non-motor related frontal hypo-metabolism. Conclusively, the self-reported mobility experience may have the neurophysiological basis related to both motor and non-motor manifestations in PD.

## INTRODUCTION

Parkinson's disease is a most common neurodegenerative movement disorder, in which the motor evaluation is of great importance. In clinical practices, the motor assessment can be obtained by objective motor rating from physicians and subjective motor complaints from patients. The UPDRS is the most commonly used scales by physicians for motor evaluation (Goetz et al., 2008). The 39-item Parkinson's Disease Questionnaire is the most commonly adopted patient completed rating scale in PD QoL evaluation (Marinus et al., 2002), in which mobility is one of eight subdomains. Such assessments are quite helpful for disease severity assessment and therapeutic evaluation.

Though higher UPDRS motor scores contribute to poor QoL in PD patients, the improvement of motor symptoms does not necessarily guarantee better subjective feeling. In our previous study (Liu et al., 2019) including 45 PD patients with 1-year follow-up after DBS, the motor severities were greatly improved, however, only half participants were satisfied with the QoL improvement. Similarly, in a study (Daniels et al., 2011) including 61 PD patients after bilateral STN-DBS surgery, 57.0% of them did feel improved about their QoL despite 43.0% patients didn't show satisfaction. Therefore, there should be similarities and differences between the subjective and objective motor assessments.

Objective motor evaluation may have some correlation with subjective motor experience, and such correlation should be fixed on some common material base. PET imaging has proven useful to explore the underlying mechanisms for clinical phenomenon of PD.  $^{11}\text{C}$ -CFT PET imaging could reflect the presynaptic DAT dysfunction (Nandhagopal et al., 2009), and  $^{18}\text{F}$ -fluorodeoxyglucose ( $^{18}\text{F}$ -FDG) PET has been used for measuring the metabolic abnormalities in PD patients. Our previous findings revealed the relationship between clinical manifestations, dopaminergic and glucose-metabolic PET imaging in a dual-tracer PET imaging cohort (Liu et al., 2018). However, until now almost no study pays attention to the subjective bias of individual feelings related to the motor symptoms, and PET imaging may be helpful to understand the neurobiological basis in the patients' subjective bias to the motor deficits in PD.

In our retrospective study, we aimed to figure out the relevancy between UPDRS motor score and QoL mobility subdomain, the two motor evaluation methods in PD. Furthermore, we attempted to figure out whether physician-assessed and patients-reported mobility dysfunctions had some shared material basis via cerebral presynaptic dopaminergic and glucose metabolic characteristics in our dual-tracer PET imaging cohort.

## SUBJECTS AND METHODS

### Subjects

We retrospectively included 49 patients (31 males/18 females,  $53.43 \pm 12.06$  years old) who completed the QoL evaluation

(PDQ39 scale) from our previous DTPD cohort (Liu et al., 2018). DTPD study was a dual-tracer PET imaging study in Parkinson's disease ever performed in Huashan Hospital between January 2010 and June 2014 (Liu et al., 2018). In the DTPD cohort, 103 patients (65 males/38 females,  $54.1 \pm 12.0$  years old) diagnosed as PD were scanned with both  $^{11}\text{C}$ -CFT and  $^{18}\text{F}$ -FDG PET. All subjects have written informed consent according to the Declaration of Helsinki. The study was approved by the Human Studies Institutional Review Board, Huashan Hospital, Fudan University.

### Study Design

This is a retrospective study. The 49 PD subjects completed the PDQ39 scale, the UPDRS and H&Y scale in the "off" state. After the clinical assessments, all subjects were scanned with  $^{11}\text{C}$ -CFT PET and  $^{18}\text{F}$ -FDG PET.

### PET Imaging and Imaging Processing

Before the scanning, all the subjects withdrew anti-parkinsonian drugs for at least 12 h and started the fast for 6 h. Before the injection and PET imaging, all the participants should be settled under dark and quiet environment and stay sober during the whole examination. The equipment used for PET imaging in our center is Siemens' Biograph 64 PET/CT scanner. During the scanning, cranial computed tomography (CT) was firstly conducted for photon attenuation correction.

In  $^{11}\text{C}$ -CFT PET imaging, 60 to 80 min after the intravenous injection of CFT (350–400 MBq), scanning data were obtained and then reconstructed with the OSEM method. In  $^{18}\text{F}$ -FDG PET imaging, within 45 to 55 min post-injection (150–200 MBq), scanning data were obtained for 10 min and then reconstructed with the OSEM method. All the PET data was captured in a three-dimensional (3D) mode.  $^{18}\text{F}$ -FDG was used to calculate rCMRglc.

$^{11}\text{C}$ -CFT and  $^{18}\text{F}$ -FDG PET data were both reconstructed using SPM5 software (Statistical Parametric Mapping; Wellcome Department of Imaging Neuroscience, Institute of Neurology, London, United Kingdom) implemented in Matlab7.4.0 (MathWorks Inc., Sherborn, MA, United States). A brain DAT binding template in Montreal Neurological Institute (MNI) space that was created by using  $^{11}\text{C}$ -CFT PET and corresponding structural MR images of another group consisting of 16 normal controls was used to normalize the  $^{11}\text{C}$ -CFT images. The procedures were presented in detail in former studies (Bu et al., 2018). As for  $^{18}\text{F}$ -FDG images, template within the SPM software was used for normalization. The normalized PET images were smoothed by a Gaussian filter of 10 mm FWHM (Full Width at Half Maximum) over a 3D space to increase signal to noise ratio for statistical analysis.

### Quantitative Analysis of Imaging Processing

To realize the individualized quantitative analysis of  $^{11}\text{C}$ -CFT binding of every participant, we placed standardized ROIs for caudate, anterior putamen, posterior putamen and occipital cortex on the mean image summed over central slices and manually adjust their position to meet the requirement, and

subsequently, confirm the individual data with reference to standardized cerebral template in SPM5. The standard uptake value ratio (SUVR) of regional  $^{11}\text{C}$ -CFT binding in striatum was calculated by (striatum -occipital)/occipital counts as described previously (Ma et al., 2002).

The analysis of PDRP was based on an independent Chinese cohort (Wu et al., 2013). PET data of every patient can be calculated with independent network value using voxel-based algorithm (ScAnVP software<sup>1</sup>; at the Centre for Neuroscience, the Feinstein Institute for Medical Research, Manhasset, NY, United States), and then transformed into Z value (Z score) using subject scores of the healthy controls in the Chinese derivation cohort for PDRP as described previously.

To investigate the relationship between whole-brain metabolism and the mobility sub-scores, a multiple regression analysis was performed in SPM5. The global metabolic values of individual patient were entered as covariates in the ANCOVA model. To evaluate the significant correlation, we set the voxel threshold at  $P < 0.001$  over whole-brain and search.

## Statistics Analysis

Quantitative data was performed as Mean  $\pm$  Standard Deviation (SD). Kolmogorov–Smirnov test was used to evaluate the normal distribution of the continuous variables, if the data in different groups meets the standard of normal distribution,  $T$ -test was applied to compare the variable differences of clinical information, PDRP Z score and SUVRs of regional DAT binding in striatum between PD-QoL group and PD-Non-QoL group, if not, Mann Whitney's  $U$  test was employed. Pearson correlation analysis was performed to analyze the correlation among DAT binding (ROIs), PDRP value and the two motor ratings in all patients. All analyses were settled with SPSS 22.0 (SPSS Inc., Chicago, IL, United States), and the two tailed  $P < 0.05$  was considered as significant.

## RESULTS

The demographic and clinical information were demonstrated in Table 1, and there was no obvious difference between the 49 included PD patients with QoL assessment (PD-QoL patients) and those without QoL assessment (PD-Non-QoL patients) ( $p > 0.05$ ). In both  $^{11}\text{C}$ -CFT PET imaging and  $^{18}\text{F}$ -FDG PET imaging, the two groups matched well with each other, with no significant differences (Table 1).

### Correlation Between the Physician-Assessed and Patients-Reported Mobility Deficits

In the Pearson correlation analysis, a modest correlation between the UPDRS motor score and PDQ39 mobility SI was found ( $r = 0.440$ ,  $p = 0.002$ ) (Figure 1A), supporting the correlation between the physician-assessed and patients-reported mobility deficits.

**TABLE 1 |** Demographic and clinical characteristics (including PET information) in the PD patients.

	DTPD-QoL	DTPD-non-QoL
Gender (Male/Female)	31/18	34/20

Data are given as mean  $\pm$  standard deviation (SD) values or median (interquartile range). DTPD, dual-tracer PET imaging of Parkinson's disease. QoL, quality of life. LEDD, Levodopa equivalent daily dosage. UPDRS, Unified Parkinson's Disease Rating Scale. Rar1, Rating of akinesia and rigidity.

### Correlations Between Striatal DAT Bindings (ROIs), UPDRS Motor Scores and PDQ39 Mobility SI

In our study, UPDRS III score correlated significantly ( $p < 0.01$ ) with the striatal DAT binding (ROIs) (on the contralateral side, caudate:  $r = -0.462$ ,  $p = 0.001$ ; anterior putamen:  $r = -0.486$ ,  $p = 0.000$ ; posterior putamen:  $r = -0.419$ ,  $p = 0.003$ ; on the ipsilateral side, caudate:  $r = -0.450$ ,  $p = 0.001$ ; anterior putamen:  $r = -0.495$ ,  $p < 0.001$ ; posterior putamen:  $r = -0.409$ ,  $p = 0.004$ ). However, no significant correlation ( $p > 0.05$ ) was found between the PDQ39 mobility SI and the DAT binding (ROIs) in putamen, but weak correlation was found in the caudate (on the contralateral side, caudate:  $r = -0.304$ ,  $p = 0.033$ ; anterior putamen:  $r = -0.202$ ,  $p = 0.163$ ; posterior putamen:  $r = -0.130$ ,  $p = 0.374$ ; on the ipsilateral side, caudate:  $r = -0.310$ ,  $p = 0.030$ ; anterior putamen:  $r = -0.258$ ,  $p = 0.073$ ; posterior putamen:  $r = -0.135$ ,  $p = 0.357$ ).

### Correlations Between Brain Glucose Metabolism, UPDRS III Scores and PDQ39 Mobility SI

In our study with  $^{18}\text{F}$ -FDG PET imaging, the PDRP z scores correlated positively with the UPDRS motor scores ( $r = 0.368$ ,  $p = 0.009$ ) (Figure 1B), as well as a positive interaction with PDQ39 mobility SI ( $r = 0.406$ ,  $p = 0.004$ ) (Figure 1C).

Besides the PDRP scores, we also explored the brain regions correlating with the PDQ39 mobility SI. As was shown in the Table 2 and Figure 2, cerebellum correlated positively with the PDQ39 mobility subdomain, and brain regions that correlated negatively with the mobility subdomain were mainly distributed in the caudate, inferior and middle frontal lobe and parietal lobe regions. The cerebral regions related to PDQ39 mobility SI

<sup>1</sup> <http://www.feinsteinneuroscience.org>

was similar to the regions previously reported in the PD-related metabolic pattern.

# DISCUSSION

In this retrospective study, a modest correlation was found between UPDRS motor ratings and PDQ39 mobility sub-scores. The UPDRS motor scores correlated strictly with striatal dopaminergic lesions. However, the mechanisms related to

PDQ39 mobility were beyond striatal dopaminergic deficiency. In the glucose metabolic analysis, the poor mobility quality was found to correlate with higher global PDRP scores, increased metabolism in cerebellum and decreased metabolism in prefrontal gyrus. Our study might offer a new perspective in understanding the objectively assessed and self-reported motor dysfunctions in PD.

As shown in our study, the UPDRS motor scores correlated modestly with the self-reported mobility dysfunction affecting the QoL. Although they both reflected the motor dysfunction, they lay emphasis on different aspects of motor deficits in PD. UPDRS motor scores record detailed motor descriptions and severities, nevertheless, PDQ39 is dedicated on the QoL of PD patients, more inclined to individual experience. Besides the different contents between the two scales, as aforementioned, subjective improvement of motor symptoms was not equivalent to better objective experience. Skorvanek et al. (2015) reported the overall burden of non-motor symptoms in PD was prior to motor symptoms with regard to QoL, and similar outcome was acquired that PDQ39 mobility sub-score was related to the MDS-UPDRS items pain and other sensations, fatigue and higher MDS-UPDRS part III scores.

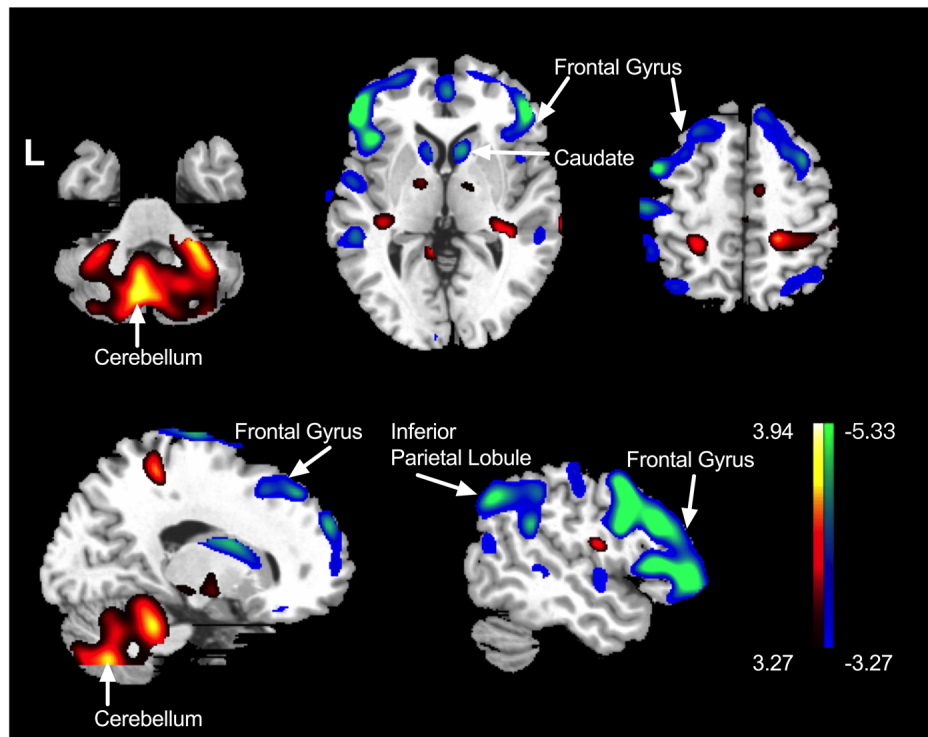

Similar to our previous reports, the motor deficits as detected by UPDRS III scores correlated significantly with the dopaminergic lesions in putamen. To our surprise, the mobility QoL was irrelevant with the dopaminergic loss in putamen, but correlated more with specific cerebral glucose metabolism. This result inspired us that the perception of mobility dysfunction was beyond dopaminergic lesions.

The parkinsonian motor features could not be fully explained by dopamine depletion alone, and the brain energy metabolism might offer another perspective to understand the cause of motor symptoms. Schrack et al. (2010) performed a research on metabolic change with aging based on the BLSA and indicated that the changing movement performance may be an adaption to aging and neurodegeneration since available energy supplied for human physical needs in addition to RMR declined with aging. Some studies (Amano et al., 2015) further supported the hypothesis that neural metabolic dysfunction could play a role in Parkinsonian

Voxel threshold was set at  $P < 0.001$ .

motor symptoms. In our previous dual-tracer PET study (Liu et al., 2018), the tremor severities did not correlate with striatal dopaminergic lesions, but correlated with the global PDRP values and related regional glucose metabolism. Therefore, the cerebral changes related to the motor lesions were beyond dopaminergic dysfunctions.

In our study, the metabolism in cerebellum correlated positively with PDQ39 mobility sub-scores, and the metabolism in inferior and middle frontal gyrus correlated negatively with mobility sub-scores. In detail, the higher PDQ39 mobility scores, indicating poorer movement performances, tended to be accompanied by elevated metabolism in cerebellum and decreased metabolism in frontal cortex.

The hyper-metabolism in cerebellum was a typical feature as suggested in the PDRP (Ma et al., 2007). In PD, the dopamine depletion in striatum consequently lead to dysfunctions in cortico–striatal–thalamic–cortical circuits (Alexander et al., 1986), inducing many functional compensation pathways including cerebellum (Wu and Hallett, 2005). Such compensatory effects by cerebellum might be mediated by the overlapping cortical areas between cerebello-thalamo-cortical circuits (Middleton and Strick, 2001) and BG circuits (Middleton and Strick, 2000), or direct projections from the cerebellum to the BG (Ichinohe et al., 2000; Hoshi et al., 2005). In our study, the increased metabolism in cerebellum accompanied poor mobility quality,

supporting some neurophysiological basis to the self-perceived mobility feelings.

Besides cerebellum, the metabolism in prefrontal cortex was also found to be involved in mobility quality perception. As previously reported, decreased functional connectivity between these prefrontal regions and the putamen should be responsible for cognitive deficits in PD patients, and more severe cortical thinning in frontal and temporo-parietal cortices has been found in PD patients with mild cognitive deficits (Wilson et al., 2019). Also, an  $^{18}\text{F}$ -FDG-PET study (Wang et al., 2017) including 28 PD patients with anxiety has revealed decreased glucose metabolism in the bilateral orbitofrontal cortex. All these data supported the clinical findings that complex non-motor symptoms would interfere in the subjective experience in addition to motor symptoms. However, the underlying pathophysiological mechanism still remains to be defined.

## CONCLUSION

Though both of them were widely used to assess motor dysfunctions in PD, UPDRS motor scores, and PDQ39 mobility scores were not completely a same thing, showing only modest correlations. In this dual tracer PET imaging study, the mechanisms involved under mobility quality were beyond

dopaminergic deficiency. The motor related cerebellum hyper-metabolism and non-motor related frontal hypo-metabolism contributed to the poor mobility quality. Conclusively, the self-reported mobility experience may have the neurophysiological basis related to both motor and non-motor manifestations in PD.

Cyclooxygenases (COX) are enzymes catalyzing arachidonic acid into prostanoids. COX exists in three isoforms: COX-1, 2, and 3. COX-1 and COX-2 have been widely studied in order to explore and understand their involvement in Alzheimer's disease (AD), a progressive neuroinflammatory dementia. COX-2 was traditionally viewed to be expressed only under pathological conditions and to have detrimental effects in AD pathophysiology and neurodegeneration. However, an increasing number of reports point to much more complex roles of COX-2 in AD. Mammalian/mechanistic target of rapamycin (mTOR) has been considered as a hub which integrates multiple signaling cascades, some of which are also involved in AD progression. COX-2 and mTOR are both involved in environmental sensing, growth, and metabolic processes of the cell. They are also known to act in cooperation in many different cancers and thus, their role together in normal cellular functions as well as AD has been explored in this review. Some of the therapeutic approaches targeting COX-2 and mTOR in AD and cancer are also discussed.

**Keywords:** COX, neuro-inflammatory, Alzheimer's, mTOR, cellular pathways

## CYCLOOXYGENASE AND ITS ISOFORMS

Cyclooxygenase-2 (COX-2) is an isoform of the cyclooxygenase enzyme family, along with COX-1 and COX-3, which are involved in the synthesis of prostanoids (eicosanoid sub-class) from an essential fatty acid, namely arachidonic acid (AA). AA is first released by the action of phospholipase A2 (PLA2) from plasma membranephospholipids, which acts at the sn-2 position of the phospholipid backbone (Engelking, 2015; Hanna and Hafez, 2018). PLA2 activity is stimulated by microbial products, thrombin, immunoglobulins, etc., whereas anti-inflammatory glucocorticoids are known to inhibit it (Engelking, 2015). Out of the 20 + different types of PLA2s known to occur, type IIA secretory PLA2 and type IV cytosolic PLA2 $\alpha$  have been shown to be coupled with COX-2 in different cell types. These two subclasses of enzymes have also exhibited cross-talk amongst themselves (Murakami et al., 1997; Balsinde et al., 1998; Bidgood et al., 2000; Sun et al., 2010). However, there are views that sufficient and conclusive data is still not present to establish a clear relationship between secretory PLA2 and eicosanoid signaling (Burke and Dennis, 2009).

Once AA is released, it is further metabolized by either enzymatic or non-enzymatic processes. Four different enzymatic pathways can act on AA: cyclooxygenase, lipoxygenase, anandamide, and cytochrome p450, resulting in different kinds of eicosanoids (**Figure 1**). Both COX-1 and COX-2 are part of the cyclooxygenase pathway, giving rise to prostanoids such as prostaglandin (PG) E<sub>2</sub>, PGF<sub>2α</sub>, PGD<sub>2</sub>, PGI<sub>2</sub> (prostacyclin), and thromboxane (TX) A<sub>2</sub>. Prostanoids are a part of vasoactive lipids that act as local hormones and play crucial roles in normal physiology as well as certain pathophysiological states. The COX enzymes were popularized in 1971 upon demonstrating that non-steroidal anti-inflammatory drugs (NSAIDs) exert their potent anti-inflammatory properties via inhibition of COX. Since then, a lot of research has been dedicated to this unique enzyme and the various roles it plays in human physiology. Now, it has been established that NSAIDs also affect many other molecules, but COX remains an important player in various conditions, including certain neuropathologies. Some of these pathologies are also found to be epigenetically regulated as faulty DNA hypermethylation causes transcriptional silencing of COX-2 gene (Kikuchi et al., 2002; Ma et al., 2004).

COX is an integral membrane glycoprotein that carries out the first two committed steps of the prostanoid synthesis pathway: cyclooxygenation and peroxidation. Thus, it's a bi-functional enzyme with a homodimeric structure and a single heme, involved in both the catalytic steps, situated in the middle of the two active sites of the enzyme (Rouzer and Marnett, 2009). In cyclooxygenation, two oxygen molecules are added to AA, forming the cyclic PGG<sub>2</sub> (Prostaglandin G<sub>2</sub>) and later PGH<sub>2</sub> (Prostaglandin H<sub>2</sub>) in the peroxidation step. PGH<sub>2</sub> is an unstable intermediate that is acted upon by specific synthases and isomerases giving rise to different PGs and TX in a cell-specific manner (Clària, 2003). The COX isoforms are encoded on different chromosomes and have a lot of differences in their structural and regulatory organization, although they share a 60% amino acid sequence homology in their respective proteins (Clària, 2003). COX-2 gene has many regulatory sequences, like a TATA box, two NF-κB sites, a NF-IL6 motif, a CRE motif, and an E box, among others, which are absent in COX-1 gene (Clària, 2003; Kang et al., 2007). Many studies have been conducted in this regard; for example, CREB and Ets family-proteins (Ets-1 and Elk-1) were found to upregulate COX-2 expression in pancreatic β-cells. A detailed account of the different transcriptional factors involved in COX-2 regulation in different cell types has been given by Kang et al. (2007). This is keeping in line with the fact that COX-1 is generally constitutively expressed (Minghetti, 2004; Hoozemans et al., 2008), whereas COX-2 is induced in response to inflammatory reactions (Clària, 2003). Thus, COX-1 is often associated with PG synthesis under normal physiological conditions leading to phenomena like platelet aggregation, renal perfusion maintenance, and gastric cytoprotection. However, it has been found that COX-2 is also expressed in the kidneys, brain, and testes under physiological conditions along with COX-1 (Minghetti, 2004; Hoozemans et al., 2008). Specifically, in the brain, COX-2 has been proposed to influence memory, sensory integration, and autonomic regulation in the central nervous

system (CNS) (Kaufmann et al., 1997). COX-3, on the other hand, is most populated in the cerebral cortex region of the brain and its enzymatic activity is inhibited by acetaminophen (Minghetti, 2004). However, much remains to be done to completely understand the functioning of COX-3. Both COX-2 and COX-1 are sources of pro-inflammatory prostanoids (Smyth et al., 2009); however, new evidence is fast emerging that also points to their role in resolution of inflammation (Williams et al., 1999; Fukunaga et al., 2005; Maskrey et al., 2011). Resolution is a complex process that kicks in once a sufficient inflammatory response has been mounted at the site of inflammation and is triggered by many cellular and molecular cues, such as macrophagic ingestion of apoptotic neutrophils (Ortega-Gómez et al., 2013).

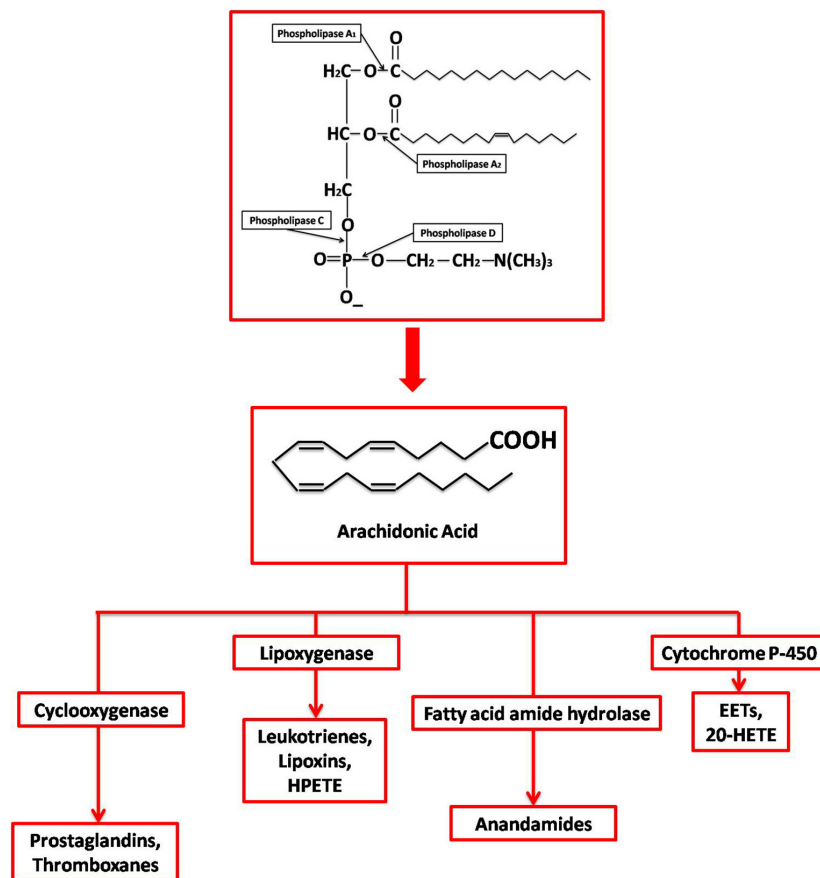

## MAMMALIAN/MECHANISTIC TARGET OF RAPAMYCIN (mTOR)

Rapamycin is a bacterial compound with anti-fungal, anti-cancer, and immunosuppressive properties, and thus, its target molecule, mTOR (mammalian/mechanistic target of rapamycin) has been implicated in processes such as aging, autophagy, and immune responses (Iglesias-Bartolome et al., 2012; Saxton and Sabatini, 2017) along with cellular pathways of proliferation, transcription, and translation (Shafei et al., 2017). The mTOR protein forms two complexes called mTORC1 and mTORC2, with a set of adaptor proteins. mTORC1 and mTORC2 are involved in different regulatory pathways and have different functions. The upstream regulatory components of mTOR include AMP-activated protein kinase (AMPK), glycogen synthase kinase (GSK3), insulin/insulin-like growth factor 1 (IGF-1), and phosphoinositide 3-kinase (PI3-K)/protein kinase B (Akt) while some of the major downstream regulators are 4E-binding proteins (4EBPs) and ribosomal protein S kinase (S6K) (Mueed et al., 2019; Papadopoulos et al., 2019).

## COX AND ALZHEIMER'S DISEASE

A lot of work has especially been dedicated to studying the role of COX-2 in neuroinflammatory and neurodegenerative conditions as its overexpression has been related to some of these pathologies (Minghetti, 2004). One of the prime targets of PGs includes the central and peripheral nervous system. The expression of COX-2 in certain types of mammalian neurons is "dynamically regulated" (Minghetti, 2004) by the synaptic activity of these neurons. Many *in vitro* as well as animal model studies have implicated the role of COX-2 in normal synaptic activity and plasticity (Hölscher, 1995; Kaufmann et al., 1997; Bazan, 2003), yet mice that had been genetically manipulated to knockout COX-2 gene exhibited a more or less normally functioning brain. However, in all these cases, accurate behavioral studies could not be performed as the mice suffered from renal failure very early in their lifespan (Dinchuk et al., 1995; Minghetti, 2004).

Alzheimer's disease (AD) is a progressive neurodegenerative disease and one of the most prevalent types of dementia

**FIGURE 1 |** Synthesis and metabolism of Arachidonic Acid. Different phospholipases act at different sites on membrane phospholipids generating various products, including free AA by PLA2. AA is then enzymatically metabolized by (1) Cyclooxygenases into prostaglandins; (2) Lipoxygenases into leukotrienes, lipoxins, and 8- 12- 15-hydroperoxyeicosatetraenoic acid (HPETE); (3) Cytochrome P450 into epoxyeicosatrienoic acid (EET) and 20-hydroxyeicosatetraenoic acid (20-HETE); and (4) Fatty acid amide hydrolase into endocannabinoid and anandamide.

worldwide (Mueed et al., 2019). It is pathologically marked by the presence of two specific types of deposits in the brain:  $\beta$ -amyloid plaques and neurofibrillary tangles (NFTs), leading to neuroinflammation, synaptic dysfunction, and eventually neurodegeneration. NFTs are mainly composed of hyperphosphorylated tau (a microtubule associated protein) (Grundke-Iqbal et al., 1986; Alonso et al., 2001) while  $\beta$ -amyloid plaques are formed due to self-aggregation of the hydrophobic A $\beta$  peptide produced upon cleavage of amyloid precursor protein (APP) (Luo et al., 2016; Mueed et al., 2019). The neuronal autophagy-lysosomal system is affected in AD pathology and results in low clearance of misfolded and damaged proteins, leading to aggregate formation (Shacka et al., 2008).

Epidemiological studies conducted on AD showed that populations which had a long history of NSAID use, were at a lower risk of AD (Breitner, 1996; Aisen, 2002; Minghetti, 2004; Hoozemans et al., 2008). This, along with other studies showing associations between COX-2 induction and neurodegeneration (Miettinen et al., 1997) as well as brain parenchymal amyloid plaque formation (Stewart et al., 1997), sparked interest, and subsequent research on potential effects of the COX enzymes and

their various pathways in AD progression as NSAIDs are known inhibitors of COX.

Additionally, it has also been shown that lipids and PGs play vital roles in AD (Bazan et al., 2002; Thomas et al., 2016). AA, which gives rise to PGs, also happens to be the second most abundant polyunsaturated fatty acid in the brain (Thomas et al., 2016). It was also found that free AA affects synaptic functions of the brain (Latham et al., 2007). Thus, the levels of free AA in the brain cells, along with a balance between enzymes converting it to other molecules like PGs and enzymes releasing free AA, is also an important factor in AD (Thomas et al., 2016). In spite of this buzz about involvement of COX in AD, clinical studies carried out with NSAIDs and selective COX-2 inhibitors did not show any significant effects in treatment of AD (Hoozemans et al., 2008). Thus, it can be inferred that the effects of COX enzymes are not as straightforward in the case of AD as previously thought and the exact mechanisms by which they influence AD progression are not yet known.

The amyloid plaques, a classical hallmark of AD, are associated with pro-inflammatory cells and proteins. These proteins are found in the brain throughout the various stages of AD

progression (Hoozemans et al., 2008). It is also speculated that inflammatory molecules may have dual role in AD as they exert both beneficial as well as detrimental effects based on their concentration and the stage of AD in which they are being expressed (Hoozemans et al., 2008). Along with this, epidemiological and genetic evidence also exist which points to the fact that inflammation is one of the key processes contributing to AD. However, due to failure of NSAIDs and selective COX-2 inhibitors against AD, alternate views are being considered which think of these drugs to perhaps have a preventive role with respect to AD and inflammation as merely a secondary phenomenon to clear off debris generated from more central underlying processes of AD (Wyss-Coray and Mucke, 2002; Hoozemans et al., 2006). It has also been reported that COX-2 expression in AD brains is correlated with altered expression of cell cycle proteins (Hoozemans et al., 2008). It was found that cell proliferation, adhesion, and differentiation genes were some of the most commonly upregulated ones along with PG synthesis genes in AD brains (Blalock et al., 2004).

COX-2 is constitutively expressed in certain cell populations of the brain, and additionally it is induced by inflammatory molecules such as cytokines, IL-1, IL-2, and TNF- $\alpha$  (Hoozemans et al., 2008). But, it is expressed in microglia (the local macrophages of the brain) only under very specific conditions, such as in chronic cases of cerebral ischemia (Tomimoto et al., 2000; Walsh et al., 2000). The expression of COX-2 is also absent in astrocytes (Pasinetti and Aisen, 1998; Hoozemans et al., 2001). COX-2 expresses differentially in different stages of AD and has pleiotropic functions in the brain (Hoozemans et al., 2008). In the early stages of the disease, COX-2 expression is increased (Ho et al., 2001; Hoozemans et al., 2001, 2002) and it is primarily expressed in pyramidal neurons (Braak and Braak, 1991). IL-1 levels also go up in AD due to association of neuritic plaques with microglial cells that express IL-1 (Blum-Degen et al., 1995). It is then reasonable to think that these IL-1 molecules perhaps induce higher expressions of COX-2. The expression of COX-2 has also been linked to cell cycle control (Xiang et al., 2002; Wu Chen et al., 2004), which may be involved in (re)generative pathways. However, these reasons are still controversial as the elevated expressions of COX-2 occur before the activation of microglia and astrocytes as shown by neuropathological studies (Hoozemans et al., 2002), whereas the expression has been found to reduce later on as the disease progresses and the number of neurons expressing COX-2 in severe cases of AD is very few (Hoozemans et al., 2004), which might be due to selective degeneration of neurons at these stages and a loss in the synaptic activity (Hoozemans et al., 2008).

It has even been observed that NSAIDs affected molecules and pathways involved in AD other than COX; for example peroxisome proliferator activated receptor  $\gamma$  (PPAR $\gamma$ ) is found to be up-regulated in AD and can be activated by NSAIDs (Kitamura et al., 1999). Activation of PPAR $\gamma$  leads to clearance of A $\beta$  deposits in neuronal as well as non-neuronal cells (Camacho et al., 2004). NSAIDs have also been found to lower A $\beta$  deposits by targeting the  $\gamma$ -secretase enzyme and inhibition of nuclear

factor- $\kappa$ B (NF- $\kappa$ B) pathway (Weggen et al., 2001; Morihara et al., 2002; Eriksen et al., 2003).

## ROLE OF mTOR IN AD

Recently, mTOR has also been found to be associated with AD pathology. Since AD is an age-associated disease, classical signs of aging like loss of proteostasis, mitochondrial dysfunction, altered intercellular communication, etc. can also be associated with mTOR (López-otín et al., 2013; Papadopoli et al., 2019). Since mTOR hinders autophagy, it promotes A $\beta$  deposition in brain (Uddin et al., 2018). Due to disruption of the autophagolysosomal pathway, immature autophagolysosomes give rise to autophagic vacuoles that are then populated by  $\beta$ -amyloid plaques (Mueed et al., 2019). Rapamycin, however, is known to lessen these numbers (Haung Yu et al., 2005). Normally, adults contain very few autophagic vacuoles in their neurons (Cuervo et al., 2005) while these go up significantly in the affected regions of an AD brain (Haung Yu et al., 2005). An opposite connection has also been reported where induction with A $\beta$  activates mTOR and its regulatory components (Bhaskar et al., 2009). Studies in both mouse models and humans have shown that the mTOR pathway is hyperactivated in AD (Perluigi et al., 2015). However, it has also been suggested that different neurons in an AD brain may have either upregulated or downregulated signaling cascades of mTOR based on how they react to AD stresses (Pei and Hugon, 2008).

Protein misfolding and subsequent aggregation is at the heart of Alzheimer's pathophysiology (Mueed et al., 2019). The mTORC1 complex has been reported to stimulate protein synthesis (Papadopoli et al., 2019). However, there have been contradicting reports in case of regulation of proteolysis, with some claims of mTOR suppressing protein degradation (Zhao et al., 2015; Rousseau and Bertolotti, 2016) and others of mTOR enhancing it (Papadopoli et al., 2019). Thus, mTOR can play a role in the aberrant proteostasis in AD patients. Tau is one of the proteins whose translational pathway involves mTOR-dependent signaling via a 5' top mRNA (Pei and Hugon, 2008). Thus, upregulated and continuous production of tau proteins in degenerating neurons is regulated by mTOR signaling via the P70S6K and 4EBP1 pathways (Pei et al., 2008).

Moreover, mTOR mediates tau synthesis and phosphorylation at specific sites and is found to co-localize with NFTs (An et al., 2003; Tang et al., 2013). This results in microtubule instability as tau is an essential microtubule associated protein and its hyperphosphorylation causes it to detach from microtubules (Mueed et al., 2019).

## COX-2 AND mTOR IN CELL METABOLISM AND SIGNALING CASCADES: IMPLICATIONS IN AD

Small metabolites are known to be able to cross the blood-brain barrier and are also affected by environmental and genetic cues. Aberrant levels of amino acids, lipids, certain neurotransmitters,

and other metabolites are found in both blood and brain in mouse models of AD (Pan et al., 2016). Many phospholipids have also been demonstrated to contribute to AD occurrence and progression (Li D. et al., 2016). Additionally, a general loss of protein homeostasis and glucose metabolism are characteristic of AD (Papadopoli et al., 2019).

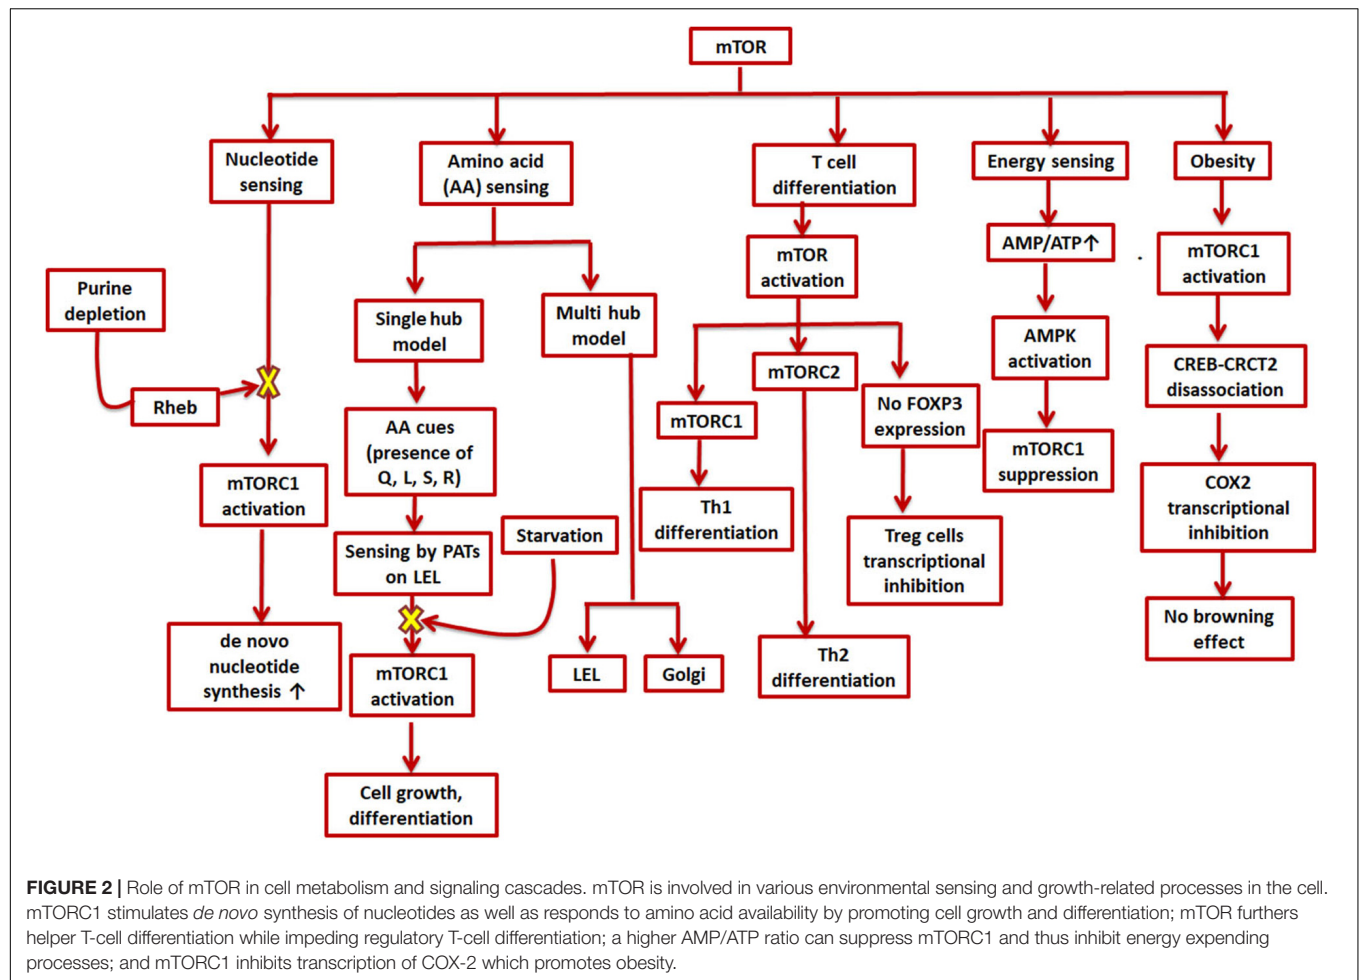

Along with growth factors, cellular energy levels, and oxygen levels, mTOR is also involved in sensing nutrients like amino acids and integrating these multitude of signals to produce a response according to the cell's need to further grow or differentiate (**Figure 2**; Howie et al., 2014; Goberdhan et al., 2016). Two models have been suggested to describe amino acid sensing by mTORC1 and the subsequent effector responses: a single hub, comprising of a single mTORC1 collecting all the micro-environmental cues to produce a variety of outputs; and a multi-hub model, where two different mTORC1 function in different parts of the cell (Jewell et al., 2015; Fan et al., 2016; Goberdhan et al., 2016). Many amino acid transporters, such as members of the proton-assisted transporters (PATs) family, are localized on the late endosomal and lysosomal (LEL) surfaces (Goberdhan et al., 2005; Goberdhan, 2010; **Figure 2**). Apart from the LELs, other possible amino acid sensing locations via mTORC1 have also been suggested such as the Golgi complex, supporting the multi-hub model of sensing. The entire process of amino acid sensing by mTORC1 has been divided into a priming step (sensitization of mTORC1 for the final activation) and an actual activation step. L-Glutamine, L-glycine, L-glutamic acid, L-serine, and L-arginine are some of the amino acids involved in priming whereas activation is majorly carried out by L-leucine and to some extent by L-methionine, L-isoleucine, and L-valine. L-Cysteine mostly impedes the priming step. Some of these amino acids (leucine, glutamine, serine, and arginine) are known to aid in autophagy inhibition by activating mTORC1 (Shafei et al., 2017). As previously mentioned, autophagy dysfunction is a key player in AD development (Saxton and Sabatini, 2017). Moreover, amino acids as well as enzymes metabolizing them in AD patients are also known to deter from their normal levels (Shafei et al., 2017). Lower levels of branched chain amino acids like valine, especially in later stages of life, have been associated with a higher risk of AD (Tynkynen et al., 2018). Cysteine has also been directly linked to AD and other neurodegenerative diseases as plasma levels of AD patients were found to have higher cysteine and sulfate ratio early in the morning. Higher cysteine implies higher thiol concentration in the cell, which could hinder with the functioning, confirmation, and synthesis of protein (Heafield et al., 1990). Glutamate is also known to regulate mTORC1 via glutamate dehydrogenase (GDH) and human branched chain aminotransferase (hBCAT) enzymes. Interestingly, glutamate, which is a neurotransmitter involved in excitatory functions, has also been found to be toxic and damaging to neurons when present in higher concentrations (Schubert and Piasecki, 2001).

Analogous to amino acid sensing, mTORC1 is also involved in nucleotide sensing in a cell (Hoxhaj et al., 2017). As mTORC1 promotes ribosome biogenesis, 60% of which consists of rRNA, it was found to boost *de novo* nucleotide (both purine and

pyrimidine) synthesis (Ben-Sahra et al., 2013; **Figure 2**). The pathway for *de novo* pyrimidine synthesis has been reported in an adult human brain, but whether or not mTORC1 has any role to play in it is not yet known. Moreover, the expression levels of several genes involved in synthesis of mRNAs (such as dihydroorotate dehydrogenase and uridine-cytidine kinase 2) for both the *de novo* as well as salvage pathways were found to be modified in case of AD patients (Pesini et al., 2019). The depletion of purines, specifically adenylates, was found to inhibit mTORC1 via the GTPase-activating protein (GAP) activity of TSC (Tuberous sclerosis complex) (Hoxhaj et al., 2017). The same study also reported mTORC1 inhibition on longer periods of guanylate-depletion due to degradation of Rheb. The TSC complex helps in maintaining Rheb in a GDP-bound state thereby inhibiting mTORC1 (Dibble et al., 2012). However, mTORC1 is also reported to be inhibited by guanylate depletion due to binding of Rheb-GTP and farnesylation (Emmanuel et al., 2017; **Figure 2**). Supplementation of uridine and other nutrients has positive effects in AD therapy (Engelborghs et al., 2014). In fact, uridine is also a part of the recipe for a rather popular medical supplement called Souvenaid®, known to support synaptic generation and function as a part of AD therapy (Ritchie et al., 2014).

The nutrient microenvironment inside a cell and sensing by mTOR is also closely related to T cell regulation, activation, and differentiation. While mTOR activation is needed for effector T cell proliferation and differentiation, it inhibits FOXP3 expression, the master transcription factor for regulatory T cells (Sauer et al., 2008; Delgoffe et al., 2010). Regulatory T cells are reported to be upregulated in an AD patient's blood (Sommer et al., 2017). It was also shown that mTORC1 promotes selective Th1 differentiation while mTORC2 Th2 differentiation (Lee et al., 2010). The potential role of adaptive immune cells in AD, however, is still unclear with reports of both an enhanced pro- and anti-inflammatory response (Sommer et al., 2017; **Figure 2**).

The COX-2/PG axis, in addition to its role in tissue inflammation, also mediates insulin secretion in adipose tissue and differentiation of adipocytes (Fjaere et al., 2014). Epidemiological studies have linked diabetes and obesity with dementia (Ferreira et al., 2018). In fact, a lot of recent studies have highlighted the common cellular pathways underlying both diabetes and AD, thereby coining the term “type-3-diabetes” or “brain diabetes” to refer to AD (Xu et al., 2019). Anti-diabetic drugs are being explored as potential candidates of anti-AD therapy (De Felice, 2013). PGs have been reported to exert both pro- as well as anti-obesogenic effects (Madsen et al., 2008). Beige adipocytes play important roles in counteracting obesity and other related disorders like diabetes and cardiovascular diseases (Boström et al., 2012; Harms and Seale, 2013; Cohen et al., 2014; X. Zhang et al., 2018). The inter-communications between adipose tissue and CNS puts obese people at a higher risk of developing cognitive and other mental disorders (Fornly-Germano et al., 2019). Interestingly, mTORC1 is also hyperactivated in adipose tissues of obese rodents and its enhanced expression in fact gives rise to adiposity as well as obesity (Um et al., 2004; Khamzina et al., 2005; Polak et al., 2008; Laplante and Sabatini, 2012). Most groups have reported

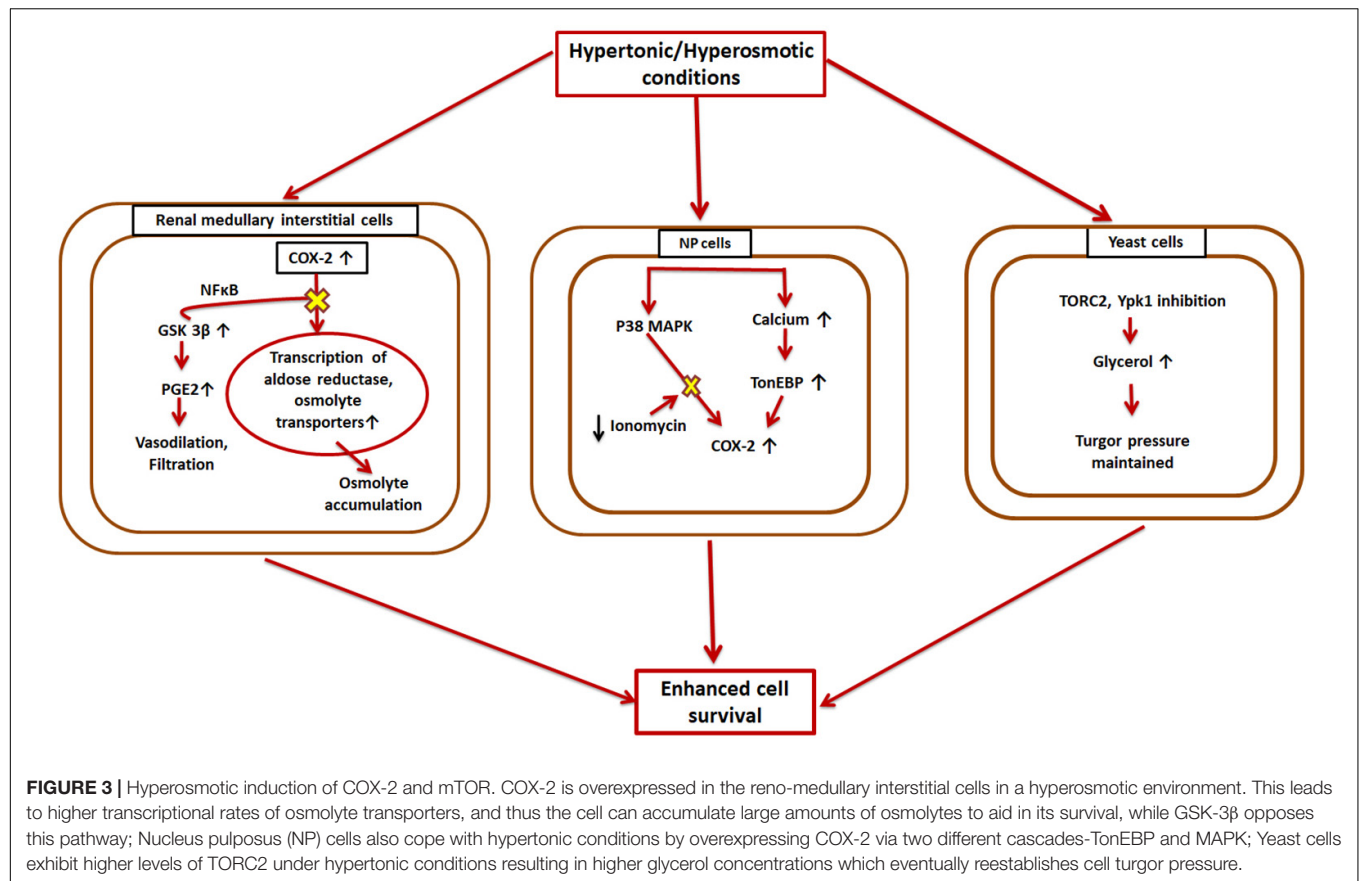

that mTORC1 is inhibitory for thermogenesis and “browning effect” (conversion of white adipose tissue to brown/beige adipocytes), which help tackle obesity by inducing enhanced energy consumption processes (M. Um et al., 2004; Polak et al., 2008; Liu et al., 2014; Wada et al., 2016). Nevertheless, there have been a few studies which have shown that inactivation of mTORC1 also compromises thermogenesis (D. Liu et al., 2016; Tran et al., 2016). While exposure to cold is also known to induce browning effect in mammals, it has been found to modify pathways involved in AD in a study carried out in mice models (Xu et al., 2019). Since mTOR and COX-2 have been found to operate together directly or indirectly in various other disorders or conditions, it can also be speculated that they may affect each other in this particular case. In one such study, mTORC1 inactivation in the mice adipose tissue causes COX-2/PG pathway induction, sending off a paracrine signal to initiate browning effect (Zhang et al., 2018), whereas when mTORC1 is activated, it phosphorylates a serine residue (Ser<sup>136</sup>) in CREB-regulated transcription coactivator 2, preventing its efficient association with CREB and subsequently CREB binding with COX-2 promoter (Zhang et al., 2018). As CREB binding enhances COX-2 promoter activation (Reddy et al., 2000; Yang and Bleich, 2004), mTORC1 activation eventually leads to

transcriptional inhibition of COX-2, thereby preventing beige adipogenesis (Figure 2).

## COX-2 AND mTOR IN OSMOPROTECTION

For normal cell functioning it is essential that the cellular volume, electrolytes, and other solute concentrations be maintained. Changes in the extracellular tonicity results in accompanying changes in the intracellular environment to ensure the cell maintains its normal volume (Macknight, 1988). The kidneys are one of those mammalian organs wherein cells are subjected to extreme concentrations of solutes like urea and NaCl (Burg et al., 2007). However, many diseases are known to be caused by the hyperosmotic stresses faced by non-renal tissues (Brocker et al., 2012). Cells deal with these conditions using certain small organic molecules, called osmolytes, that are dissolved in the cellular as well as extracellular fluids (Wijayasinghe et al., 2017). These organic osmolytes have been found to be accumulated in the renal medullary cells in situations of osmotic stress (Wijayasinghe et al., 2017). COX-2 and mTOR are involved in different kinds of osmoprotective pathways in different cell types (Figure 3).

Both COX-1 and COX-2 are expressed in different parts of the kidney (Y. Harris et al., 1994; Guan et al., 1997) with different regulatory mechanisms. While COX-2 exhibits expression based on the surrounding tonicity, COX-1 does not follow any such pattern (Briggs, 1999). Thus, there were speculations that COX-2 might have an osmoprotective function in the kidneys. Treatment with NSAIDs and COX-2 specific inhibitors in the reno-medullary interstitial (RMI) cells reduces osmolyte accumulation induced by hypertonic conditions in these cells and affects their survival (Moeckel et al., 2003). It was found that COX-2 causes this effect by transcriptional regulation of osmolyte transporters. Later on, it was also shown that GSK-3 $\beta$  kinase is a key player in this process and affects COX-2 via a signaling pathway involving NF- $\kappa$ B (Rao et al., 2004). The increased hypertonic conditions upregulate GSK-3 $\beta$  activity in the RMI cells, which increases their apoptotic rate (Rao et al., 2004). Thus, GSK-3 $\beta$  works as an antagonist of COX-2. TonEBP/NFAT5, a master transcription factor of osmoprotective genes (Favale et al., 2007), has also been found to enhance COX-2 mRNA levels in osmotically stressed RMI cells (Favale et al., 2009). MAPK family members and Src kinases are other known enzymes that are implicated in hypertonicity-induced COX-2 regulation (Burg et al., 2007; Yang et al., 2000; **Figure 3**).

Another part of the body that experiences higher and a constantly changing osmolarity is the inner core of vertebral disc, called nucleus pulposus (NP) (Choi et al., 2018). Therefore,

the NP cells have mechanisms to adapt to these hyperosmotic microenvironments, which involve up-regulation of COX-2. This upregulation is intracellular calcium-dependent, but rather than the calcineurin signaling pathway, it occurs through TonEBP (Choi et al., 2018). It was found that TonEBP overexpression resulted in enhanced COX-2 promoter activity while its silencing resulted in diminished COX-2 promoter activity (Choi et al., 2018). TonEBP silencing also causes COX-2 enzyme levels to fall in iso-osmotic conditions (Choi et al., 2018). Additionally, p38 MAPK pathway also induced elevated expression of COX-2 under hyperosmotic conditions in NP cells. However, ionomycin treatment nullified this effect (Choi et al., 2018). This COX-2 overexpression eventually aids in (NP) cell survival under osmotic stress (**Figure 3**).

Additionally, in case of yeasts, mTORC2 (referred to as TORC2 in this case) has been demonstrated to be involved in osmotic-homeostasis maintenance (Eltschinger and Loewith, 2016; **Figure 3**). Ypk1 and Ypk2, homologs of Akt, are two important downstream substrates of TORC2. Hypertonic conditions inhibit TORC2 and Ypk1, which eventually results in increased glycerol concentrations in the cell and reestablishes the turgor pressure.

Osmolytes are reported to play corrective roles in many human pathologies caused by protein misfolding, although nothing specifically for AD (Kim et al., 2006). Meanwhile, a typical AD brain is marked by misfolded proteins that keep

getting accumulated and result in autophagic and lysosomal dysfunction as well as amyloid and tau aggregate formation (Efeyan et al., 2013). In fact, hypertonicity is one of the many causes of protein damage in cells (Hahr, 2015).

## COX-2 MODULATION OF mTOR

Both COX-2 and mTOR have been extensively studied individually and in combination with other speculated regulators of AD in the disease's progression (Hoozemans et al., 2008; Pei and Hugon, 2008; Tang et al., 2015; Thomas et al., 2016; Mueed et al., 2019). The exact role COX-2 plays in the various stages of the disease is still debated, with reports claiming both beneficial as well as detrimental effects of the enzyme in the various AD associated pathologies (Minghetti, 2004; Hoozemans et al., 2008). However, mTOR is mostly known to be hyperactivated in AD and causes excessive phosphorylation of tau protein and formation of A $\beta$  plaques and NFTs (Figure 4). Both have been implicated in development of synaptic plasticity under physiological conditions (Minghetti, 2004; Papadopoulos et al., 2019). Interconnected signaling and working of COX-2 and mTOR has been the subject of many studies in the case of various types of cancer (Chuang et al., 2019; Lipskar et al., 2009; Rouzer and Marnett, 2009; Li H. et al., 2016), but no such studies have yet been conducted for AD. Both cancer and AD have a faulty DNA damage repair mechanism at their core that causes uninhibited growth and neuronal loss, respectively (Behrens et al., 2009). Rapamycin has been found to exert anti-tumor and anti-angiogenic effects by inhibiting neovascularization (Guba et al., 2002; Phung et al., 2006). It can do this via either an mTOR-dependent or independent pathway. In case of the mTOR-independent pathway, the phosphorylation of downstream effectors of mTOR remains unchanged and other molecules including COX-2 are instead involved (Jung et al., 2003; Lipskar et al., 2009). Moreover, cancer and AD have been shown to manifest an inverse relationship via many cellular pathways and signaling molecules such as p53 and cAMP and hormones like estrogen, growth factors, neutrophins, etc (Shafi, 2016).

In yet another study carried out on endometrial cancer (EMC) on mouse models and human cell lines, it was established that both COX-2 and mTORC1 work cooperatively to reduce tumor load and exacerbate the cancer. This common signaling pathway also involved Akt as both COX-2 and mTORC1 are downstream targets of Akt (Gadducci et al., 2008; Jae et al., 2009; Slomovitz and Coleman, 2012; Figure 4). Although these studies have been limited to mostly cancer models, similar pathways could exist in case of AD as well. If the presence of such a connection between COX-2 and mTOR could be established in AD, it could be exploited as a therapeutic strategy.

As mentioned in previous sections, mTOR controls T-cell activation and innate immune responses. mTOR is also known to modulate COX-2 expression in immune reactions. An *in vitro* study conducted on enhancement of immunomodulatory effects of human bone marrow mesenchymal stem cells showed elevated levels of COX-2 and higher phosphorylation of kinases, GSK-3 $\beta$ ,

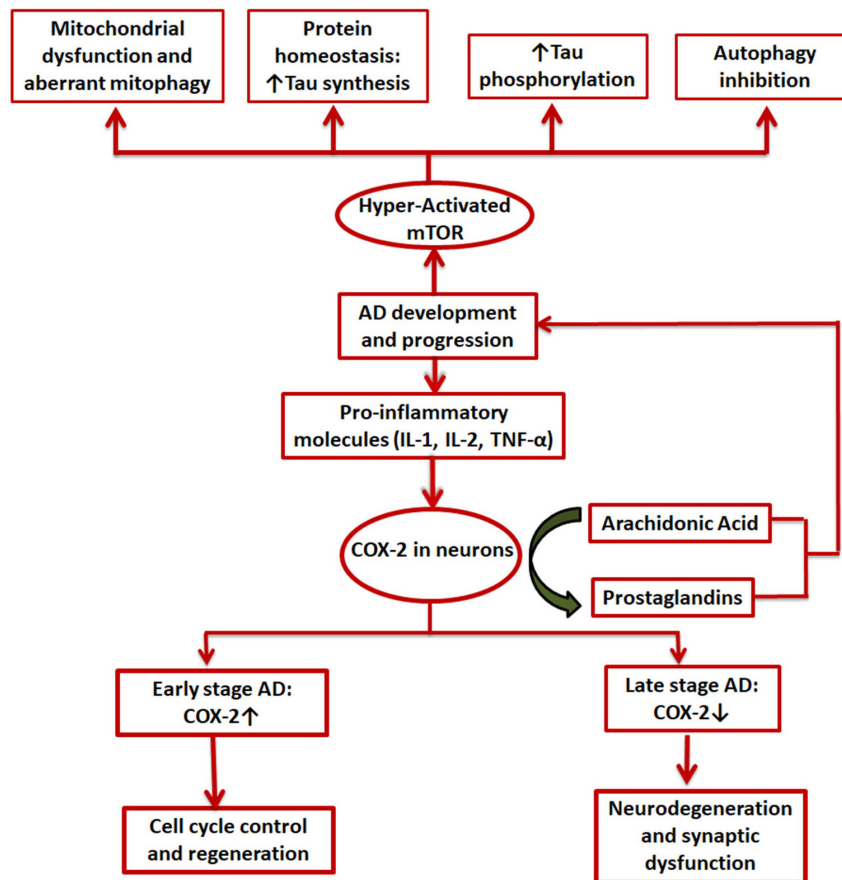

and Akt, upon mTOR inhibition by short-term (4 h) rapamycin treatment (Wang et al., 2017; Figure 4). However, COX-2 is significantly downregulated on longer rapamycin treatments. PGE<sub>2</sub>, which plays important roles in immunosuppression by inhibition of NK (natural killer) cell cytotoxicity, dendritic cell maturation, and T cell proliferation (Spaggiari et al., 2008; Wang et al., 2017), was also found to be upregulated (Figure 4). Apart from COX-2 being overexpressed during inflammatory reactions including AD and cancers, it is also known to resist apoptosis (Tsujii and DuBois, 1995). Similar to COX-2, mTOR is also thought to be involved in apoptosis and activation of cell cycle in post mitotic neurons (Pei and Hugon, 2008; Figure 4). Thus, NSAIDs and selective COX-2 inhibitors induce apoptosis. Two pathways have been suggested for this: stimulation of ceramide (a death signal) production by availability of higher amounts of AA (Chan et al., 1998), and downregulation of Bcl-2 (X. Liu et al., 1998; Sheng et al., 1998). Alternatively, a selective COX-2 inhibitor, celecoxib, is thought to induce apoptosis by selectively blocking Akt pathway (Hsu et al., 2000). However, the mechanism behind this remains elusive as celecoxib does not significantly affect the major kinase, PI-3K, or the phosphatase, protein phosphatase 2A, involved in the activation of Akt (Hsu et al., 2000). Interestingly, this might indicate another possible pathway by which COX-2 modulates mTOR signaling as Akt is one of the major upstream regulators of mTOR.

## COX-2 AND mTOR-BASED THERAPIES

As discussed earlier, NSAIDs were found to be associated with a lower vulnerability to AD due to lowering levels of A $\beta$ <sub>42</sub> as well as reducing inflammation. A lot of studies have been conducted in this regard exploring different aspects of the disease development and progression. Various therapeutic approaches for AD have also been reviewed previously (Mueed et al., 2019).

It was found that selective COX-2 inhibitors could restore long term potentiating which was lost due to incubation with external A $\beta$ <sub>42</sub> in studies carried out in rat hippocampal slices, while inhibition of only COX-1 failed to produce any such effects (Kotilinek et al., 2008). The same study also reported regarding restoration of memory in Tg2576 mice over-expressing APP by both selective COX-2 inhibitors as well as non-selective NSAIDs. However, these beneficial effects of COX-2 inhibition were lost on addition of exogenous PGE<sub>2</sub> but not by inflammatory cytokines like IL-1 $\beta$ , TNF- $\alpha$ , or even A $\beta$ . Thus, the authors proposed an alternative mechanism of NSAID action on AD: preventing PGE<sub>2</sub> response at synapses due to blockage of COX-2.

As previously stated, mTOR is known to be hyperactivated in an AD brain and exerts its effects by affecting key cellular processes such as nucleotide synthesis, protein synthesis, and modifications, mitochondrial dynamics, lipid metabolism and the cellular autophagic system. Therapies against AD and other neurodegenerative disorders have thus also targeted mTOR. Inhibition of mTOR using rapamycin and its analogs has shown reduction in the amounts of amyloid and tau deposits in early stage-AD-affected brains of mice and improved their cognitive abilities (Spilman et al., 2010; Majumder et al., 2011).

**FIGURE 4 |** Involvement of COX-2 and mTOR in AD. Pro-inflammatory molecules induce COX-2 expression in certain brain cells. It is upregulated in the initial stages of AD and is expected to be involved in cell cycle control and regenerative pathways while in the later stages a decline in COX-2 levels is seen, mainly due to degeneration of neurons by the disease; mTOR, on the other hand, is always hyperactivated in case of AD and exerts its effects in mainly 4 ways: mitochondrial dysfunction, aberrant proteostasis, tau hyperphosphorylation, and inhibition of autophagy.

In fact, humans who were administered with a rapamycin analog, everolimus, in order to elicit immunosuppression after a heart transplant also showed better memory skills than the control group (Papadopoli et al., 2019). mTOR overexpression has been routinely linked to intracellular tau accumulation and translocation. Its inhibition via rapamycin or silencing by mutation leads to lower tau levels in the cell (Tang et al., 2015). This has implications across various tauopathies and presents a potential therapeutic approach. mTOR inactivation has proved to be helpful in reducing microglial-inflammatory responses in the brain. Some of these studies have also shown a possible COX involvement in the process as rapamycin treated microglia also resulted in lower levels of COX-2 (Dello Russo et al., 2013).

COX-2 is also implicated in a variety of cancers (Hwang et al., 1998; Pandey et al., 2008; Greenhough et al., 2009; Alexanian et al., 2014; Mattsson et al., 2015) and its inhibition can also be used as one of the ways for cancer therapy. Tuberous sclerosis complex (TSC) caused as a result of mutations in any of the two tumor suppressor genes, *TSC1* and *TSC2*, leads to formation of localized tumor masses in multiple organs (Borkowska et al., 2011; Kwiatkowski and Manning, 2014; Schepis, 2016). mTORC1

is known to be hyperactivated by loss of TSC2 in TSC tumors (Moavero et al., 2015; Li H. et al., 2016). This leads to downregulation of COX-2 activity via activation of STAT3 (signal transducer and activator of transcription 3). It was also found that IL-6 is a downstream target of COX-2 in cells with loss-of-Tsc2 mutation and thus reduced activity of COX-2 inhibits IL-6 which limits cellular proliferation (Li H. et al., 2016). Rapamycin and celecoxib, together, were found to be most useful against TSC in Tsc2 negative cells, than either individually (Li H. et al., 2016).

## CONCLUSION AND FUTURE PERSPECTIVES

COX-2 is involved in diverse cellular functions in the human body such as PG synthesis, insulin secretion, adipogenesis, CNS autonomic regulation, etc., and thus, any structural or functional aberrations in the enzyme will have varied repercussions across many pathways. Many inflammatory and neoplastic disorders are related to COX-2 expression levels and activity. Similarly, mTOR affects central cellular activities such as growth,

transcription, and translation. It has also been found to play a vital role in inflammatory and age-related diseases. COX-2 and mTOR operate in a number of overlapping pathways such as nutrient sensing, obesity, apoptosis, immune reactions, osmoprotection, etc.

Alzheimer's is one of the world's leading types of dementia and a neuro-inflammatory disease. COX-2 has been classically implicated in AD and much research has been done to develop therapies against AD based on blocking or deleting COX-2. However, it has been known for some time now that neither the cause of AD nor the role COX-2 plays in its occurrence and progression is as it was traditionally considered. There have been many views rejecting the amyloid as well as tau hypotheses to be at the heart of AD. Also, COX-2 is now thought to have pleiotropic effects in the brain and AD pathophysiology as the enzyme exhibits different expression levels during different stages of the disease with elevated levels in the early stages and a gradual fall later on. Moreover, other molecular targets of NSAIDs rather than the COX enzymes are being considered as possible key players in AD. Thus, in order to effectively tackle AD, it has to be considered in its entirety and not as isolated underlying pathways.

mTOR entered the AD picture as a molecule of interest quite recently but it has since been well established in AD pathology. It is supposedly overexpressed in AD, promotes amyloid- as well as tau-deposition, and is also involved in their targeting to various cell organelles to a certain extent. Inhibition of mTOR *in vitro* and *in vivo* models of AD has demonstrated improved memory and other cognitive abilities which are compromised in the disease.

The main aim of this review was to explore the biphasic nature of relationship between COX-2 and mTOR in key cellular processes, some of which have direct roles in AD progression. This suggests a very strong possibility that their relationship could be exploited in order to develop an effective counter for AD. Moreover, their actions have already been found to be inter-dependent in the case of a number of cancers, and anti-cancer therapies targeting the two of them are underway. However, dedicated studies in this direction in the case of AD are still, to the best of our knowledge, non-existent. The possible future prospective in this direction would include exploring in detail selected targets of interest, such as Akt, and all their associated pathways which may provide specific answers as to if and how COX-2 and mTOR co-operate in AD and if drugs targeting either or both of these would be helpful in combating the disease.

## AUTHOR CONTRIBUTIONS

AT wrote the manuscript. NP made the background of the manuscript and finalized the manuscript. MK gave valuable comments and help in writing the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by Enhanced Seed grant EF/2019-20/QE04-02 to NP from Manipal University Jaipur, Rajasthan, India is gratefully acknowledged.

Alzheimer disease (AD) has an insidious onset and heterogeneous clinical symptoms. The well-accepted biomarkers for clinical diagnosis of AD include  $\beta$ -amyloid (A $\beta$ ) deposition and pathologic tau level within cerebral spinal fluid (CSF) and imaging AD pathology such as positive emission tomography (PET) imaging of the amyloid-binding agent Pittsburgh compound B (PET-PiB). However, the high expense and invasive nature of these methods highly limit their wide usage in clinic practice. Therefore, it is imperious to develop less expensive and invasive methods, and plasma biomarkers are the premium targets. In the current study, we utilized a single-blind comparison method; all the probable AD cases met the core clinical National Institute on Aging and Alzheimer's Association (NIA-AA) criteria and validated by PET-PiB. We used ultrasensitive immunomagnetic reduction (IMR) assays to measure plasma A $\beta$ <sub>42</sub> and total-tau (t-tau) levels, in combination with different variables including A $\beta$ <sub>42</sub>  $\times$  t-tau value, Montreal Cognitive Assessment (MoCA), and Mini Mental State Examination (MMSE). We used logistic regression to analyze the effect of all these variables in the algorithm. Our results showed that (1) plasma A $\beta$ <sub>42</sub> and t-tau are efficient biomarkers for AD diagnosis using IMR platform, whereas A $\beta$ <sub>42</sub>  $\times$  t-tau value is more efficient for discriminating control and AD; (2) in the control group, A $\beta$ <sub>42</sub> level and age demonstrated strong negative correlation; A $\beta$ <sub>42</sub>  $\times$  t-tau value and age demonstrated significant negative correlation; (3) in the AD group, t-tau level and MMSE score demonstrated strong negative correlation; (4) using the model that A $\beta$ <sub>42</sub>, A $\beta$ <sub>42</sub>  $\times$  t-tau,

and MoCA as the variable to generate receiver operating characteristic (ROC) curve, cutoff value = 0.48, sensitivity = 0.973, specificity = 0.982, area under the curve (AUC) = 0.986, offered better categorical efficacy, sensitivity, specificity, and AUC. The multifactor model of plasma A $\beta$ 42 and t-tau in combination with MoCA can be a viable model separate health and AD subjects in clinical practice.

**Keywords:** Alzheimer disease,  $\beta$ -amyloid, tau, Montreal Cognitive Assessment, ultrasensitive immunomagnetic reduction

## INTRODUCTION

Alzheimer disease (AD) is a neurodegenerative disease with latent initiation and progressive course, which is the most common cause of dementia and the fourth cause of mortality in the elder population (Katzman, 2008). Growing evidences have shown the early diagnosis, before massive neuron loss and dementia occur, is crucial to AD treatment (Jack et al., 2013; Dubois et al., 2016). IWG 2016 and the National Institute on Aging and Alzheimer's Association (NIA-AA) research framework are aligned on the key issue that although AD is currently defined as a biological event throughout the course, the combination of abnormal  $\beta$ -amyloid (A $\beta$ ) and tau biomarkers is conclusive enough to define AD regardless of cognitive symptoms (Jack et al., 2018).

A $\beta$  level in cerebral spinal fluid (CSF) and A $\beta$  accumulation measured by positive emission tomography (PET) imaging of the amyloid-binding agent Pittsburgh compound B (PET-PiB) have been validated as viable AD biomarkers. Absolute sensitivity of amyloid PET is comparable to the gold standard of autopsy (Roberts et al., 2017). However, the high expense and limited availability of the amyloid PET and the invasive nature of CSF collection highly limit its wide used in clinic practice (Villemagne et al., 2013; Vos et al., 2013; Sperling et al., 2014; Baird et al., 2015). Therefore, it is imperious to develop less expensive and invasive methods, and plasma biomarkers are the premium targets. Moreover, blood biomarkers such as plasma total tau (t-tau) have shown promising potential to identify neurodegenerations, whereas plasma A $\beta$ 42 was shown to be a high-performance biomarker for AD (Dage et al., 2016; Ovod et al., 2017; Nakamura et al., 2018). However, the sensitivity and specificity of blood biomarkers detection will determine the future of their clinical application, thus needing further clinical validation.

Currently, many technologies have been developed for detecting plasma A $\beta$ 42, t-tau: ELISA, CLIA, ultrasensitive immunomagnetic reduction (IMR), and so on. Immunomagnetic reduction has shown far better sensitivity than others, with clinical validation (Chiu et al., 2012, 2013; Chen et al., 2019; Lue et al., 2019a). But more clinical validation is needed to determine the reliability of IMR in AD diagnosis.

In our study, 97 cases of volunteers were discretely screened and diagnosed by experienced neurologists, to guarantee the quality for selected subjects. Through cognitive psychophysiology evaluation analysis and confirmed by PET-PiB neuroimaging analysis, all the AD patients met the core clinical NIA-AA criteria.

We used IMR technology measuring plasma A $\beta$ 42 and t-tau, in combination with other factors, and thus comprehensively evaluated the sensitivity and specificity of AD diagnosis, which paved the avenue of potential using IMR technology for AD early diagnosis.

## MATERIALS AND METHODS

### Participants

Alzheimer disease group: 40 AD patients were recruited from the neurology department of PLA hospital between August 2017 and June 2018. All the patients underwent cognitive psychology scale evaluation and neuroimaging measurement and confirmed by PET-PiB examination. All probable AD patients met the core clinical NIA-AA criteria (Jack et al., 2011), without family history.

Normal control (NC) group: 57 healthy volunteers were recruited. All the subjects have normal cognitive function by neuropsychology evaluation, also without severe heart, liver, kidney, or other systematic diseases; mental illness; surgery; and injury history or other major disease history, without dementia patients in the family.

Consensus agreements were signed by patients himself/herself or custodians and provided blood samples; the entire process met human rights, humanity, and medical ethical standard.

### Methods

Sample collection: 5 mL non-fasting venous blood sample (K2 EDTA tube) was drawn from every subject. The blood samples were centrifuged at  $2,500 \times g$  for 15 min within 3 h of collection, and plasmas were aliquoted into cryotubes (1 mL per tube) and stored at  $-80^{\circ}\text{C}$ . Each sample was assigned an identification number following reception. The laboratory staffs handling the sample processing were blind to the clinical status and the demographic data of the subjects.

The Mini Mental State Examination (MMSE) (Li et al., 2016) and Montreal Cognitive Assessment (MoCA) Beijing version<sup>1</sup> (Lu et al., 2011) evaluation were performed by the same doctor for the entire study: in the normal age range (score > 1.5 standard deviation), age- and education-matched normal recipient, and CDR = 0. Every patient underwent magnetic resonance imaging (MRI) and PET-PiB imaging scan examination. A $\beta$ 42 and t-tau concentration were measured using IMR technology for all the collected plasma samples.

<sup>1</sup>www.mocatest.org

Reagents: Calibrator60 (A $\beta$ 42 standard), MagQu, CA-DEX-0080; tau IMR Reagent, MagQu, MF-tau-0060; tau Solution-L (standard L), MagQu, CL-tau-000T; tau Solution-H (standard H), MagQu, CL-tau-050T; A $\beta$ 42 IMR Reagent, MagQu, MF-AB2-0060; A $\beta$ 42 Solution-M (standard M), MagQu, CL-AB2-020T; 6  $\times$  50 mm sample analysis tubes, MagQu, MQ-TUB-0100; disposable vacuum blood collection tube (K2 EDTA tube), Jiangsu Yuli Medical Instrument Co. Ltd., Y30983502; Cryo tube, CORNING, 430659.

**Immunomagnetic reduction measurements:** Details of the mechanism and technology of IMR have been previously reported (Nasreddine et al., 2005; Lee et al., 2016; Yang et al., 2017b). The reagents used to determine plasma A $\beta$  and t-tau protein levels in this study consisted of dextran-coated Fe<sub>3</sub>O<sub>4</sub> nanoparticles functionalized with antibodies. The percentage reduction in an alternating current (ac) that reflects the magnetic susceptibility (Xac) of a reagent due to the interactions of functionalized magnetic nanoparticles and target proteins. The percentage reductions of immunomagnetic signals are then converted to target protein concentrations using the standard curves of the respective analyses. The selection of the antibodies conjugated to the IMR reagents was based on epitopes, affinity to antigens, ability to be conjugated onto nanoparticles, and the ability to provide linearity of standard curves quantified by magnetic signal reduction. For t-tau assay, 40  $\mu$ L of plasma sample was mixed with 80  $\mu$ L IMR reagents at room temperature, and for A $\beta$ 42 assay, 60  $\mu$ L of plasma sample was mixed with 60  $\mu$ L of IMR reagent.

## Statistical Analysis

Data were expressed as means  $\pm$  SD or an absolute number with a proportion for descriptive statistics. Spearman correlation analysis was applied to examine the correlations between plasma A $\beta$  measures and cerebral uptake values of <sup>11</sup>C Pittsburgh Compound B PET, <sup>11</sup>C-PiB PET in different brain regions. Significant correlations were validated using non-parametric Spearman rank-order correlations. Correlation analysis was also used to evaluate the correlations between the plasma A $\beta$  measures, <sup>11</sup>C-PiB PET SUVRs and each parameter of the demographic data, clinical characteristics, and cognitive tests. Multiple linear regression analysis was used to further evaluate the associations between plasma A $\beta$  measures and <sup>11</sup>C-PiB PET binding after controlling for age. A *P*-value of 0.05 was defined as the threshold of statistical significance in each test. To elucidate the AD-related tests, the current study used statistical analysis with SPSS for data analysis; considering the data do not obey Gaussian distribution, we used Spearman correlation analysis, to describe the level and direction of the correlation of two variables (*r* > 0 represents positive correlation, *r* < 0 represents negative correlation, the closer *r* value to 1, the stronger correlation is, and *P* < 0.05 represents a significant difference). Within the final prediction model, binary logistic regression analysis demonstrated the result of (*P*<sub>MoCA</sub>, *P*<sub>A $\beta$  42</sub>, and *P*<sub>A $\beta$  42  $\times$  t-tau</sub>) < 0.05, whereas (*P*<sub>MMSE</sub> and *P*<sub>t-tau</sub>) > 0.05. Considering the stability of using this model, we decided to

choose A $\beta$ 42, A $\beta$ 42  $\times$  t-tau and MoCA these three variables as prediction factors.

## RESULTS

### Patients Selection

Ninety-seven volunteers aged between 54 and 78 years (mean = 68.0  $\pm$  9.3) were recruited, of which 57.7% were females. The control group had 57 subjects; the AD group had 40 subjects, with an average age of 67.9  $\pm$  9.5 and 68.1  $\pm$  9.0 years, respectively. Average MMSE value was 28.25  $\pm$  3.36 in control group and 12.67  $\pm$  9.21 in AD group; Average MoCA value was 26.25  $\pm$  4.61 in control group and 10.69  $\pm$  7.33 in AD group, therefore, both MMSE (*P* = 1.41  $\times$  10<sup>-19</sup>) and MoCA (*P* = 8.81  $\times$  10<sup>-22</sup>) showed highly significant difference between control and AD group (Table 1).

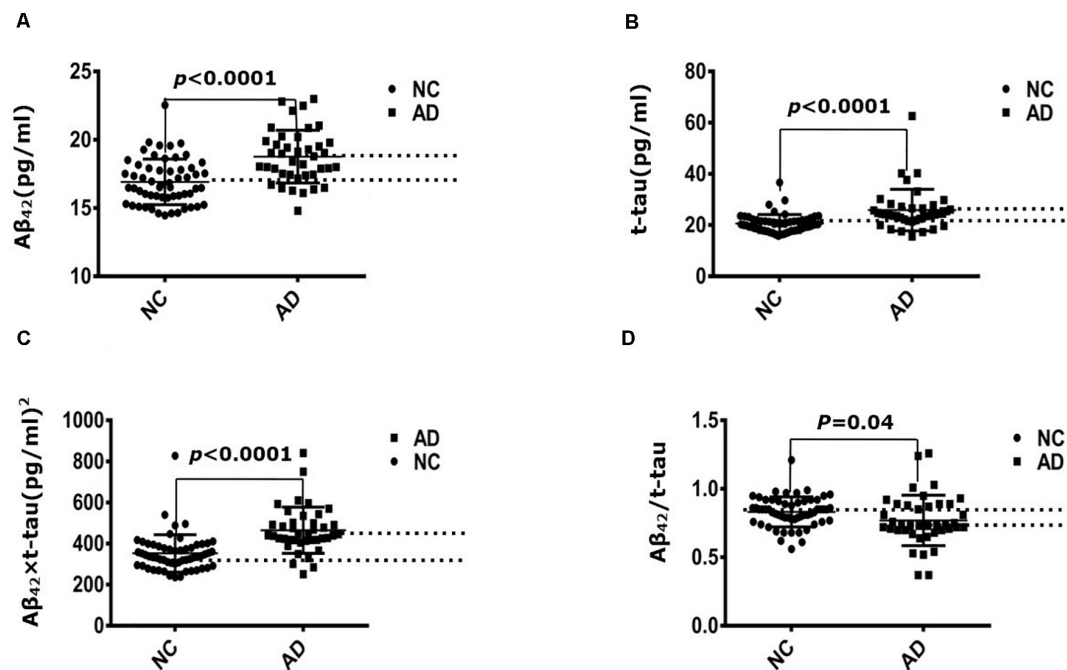

### IMR Measurement of Plasma A $\beta$ 42 and T-tau Levels

Immunomagnetic reduction technology was used to measure the human plasma A $\beta$ 42 and t-tau levels. Table 1 demonstrated that the mean value of t-tau concentration was 20.65  $\pm$  3.52 pg/mL in the control group and 25.9  $\pm$  8.12 pg/mL in the AD group; the difference was strongly significant (*P* = 3.42  $\times$  10<sup>-5</sup>). Mean value of A $\beta$ 42 concentration was 16.92  $\pm$  1.67 pg/mL in the control group and 18.77  $\pm$  1.93 pg/mL in the AD group; the difference was strongly significant between control and AD group (*P* = 2.31  $\times$  10<sup>-6</sup>). Mean value of A $\beta$ 42  $\times$  t-tau was 352.53  $\pm$  90.88 pg/mL in the control group and 490.44  $\pm$  190.48 pg/mL in the AD group; the difference was strongly significant (*P* = 7.03  $\times$  10<sup>-6</sup>). Mean value of A $\beta$ 42/t-tau concentration was 0.83  $\pm$  0.11 in the control group and 0.77  $\pm$  0.18 in the AD group; the difference was strongly significant (*P* = 0.04). Figure 1 demonstrates that all the differences between two groups were strongly significant.

Clinical characters, mean  $\pm$  SD. AD, Alzheimer disease; NC, normal control; MMSE, Mini-Mental State Examination; MoCA, Montreal Cognitive Assessment.

**FIGURE 1** | Immunomagnetic reduction measurement of plasma A $\beta$ 42 and t-tau protein levels. **(A)** A $\beta$ 42 concentration of NC and AD group; **(B)** t-tau concentration of NC and AD group; **(C)** A $\beta$ 42  $\times$  t-tau value of NC and AD group; **(D)** A $\beta$ 42/t-tau value of NC and AD group. NC: normal control ( $n = 57$ ); AD, Alzheimer disease ( $n = 40$ ).

## Receiver Operating Characteristic Curve Analysis

Receiver operating characteristic (ROC) curve analysis demonstrated that the cutoff value of A $\beta$ 42 concentration between control and AD group was 17.22 pg/mL, sensitivity was 0.650, specificity was 0.719, and area under the curve (AUC) was 0.689 (**Figure 2A**). The cutoff value of t-tau concentration between control and AD group was 21.30 pg/mL, sensitivity was 0.625, specificity was 0.667, and AUC was 0.659 (**Figure 2B**). The cutoff value of A $\beta$ 42  $\times$  t-tau between control and AD group was 403.72 (pg/mL)<sup>2</sup>, sensitivity was 0.825, specificity was 0.842, and AUC was 0.883 (**Figure 2C**); The cutoff value of A $\beta$ 42/t-tau between control and AD group was 0.74, sensitivity was 0.775, specificity was 0.386, and AUC was 0.558 (**Figure 2D**). The values were summarized in **Table 2**. A biomarker combination of A $\beta$ 42  $\times$  t-tau has the highest sensitivity, specificity, and AUC.

## Spearman Correlation Analysis

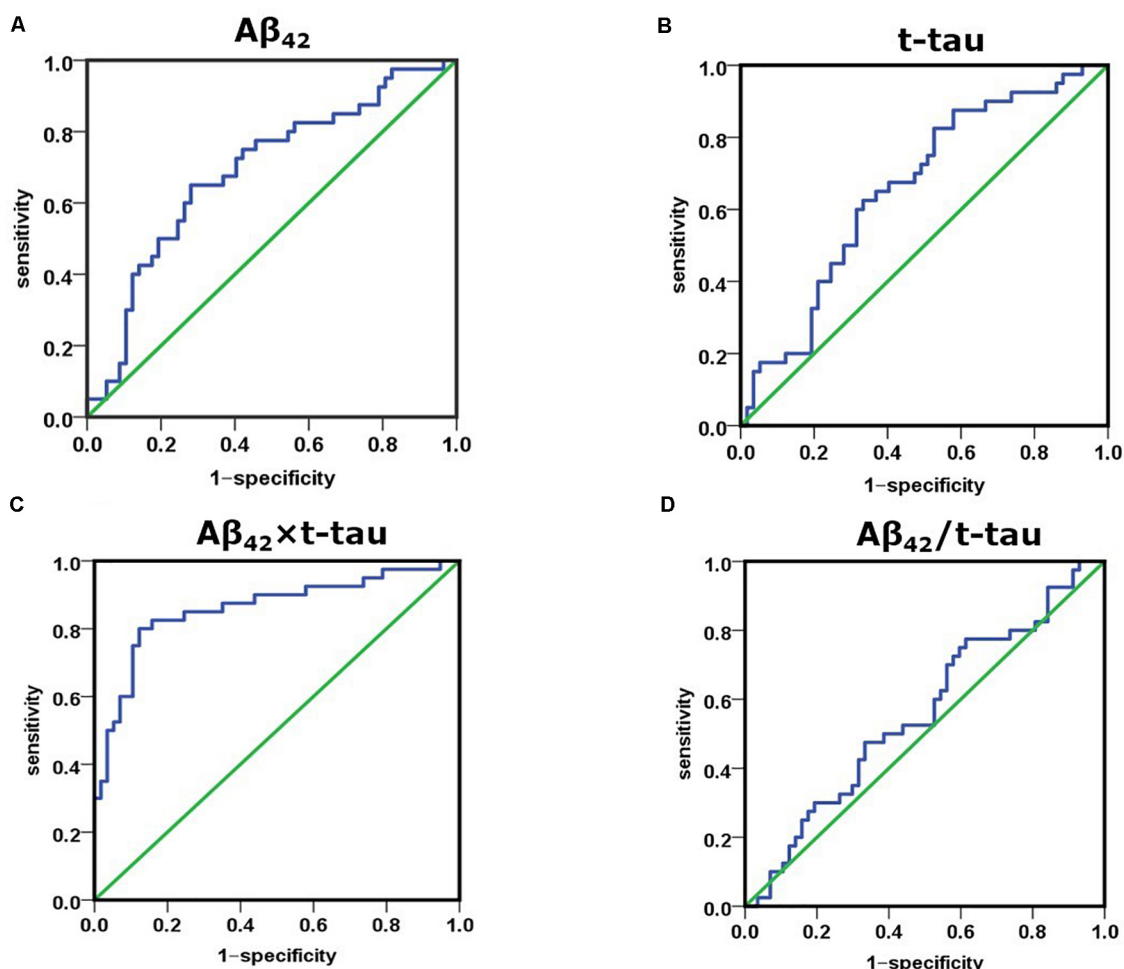

Spearman correlation analysis in the control group showed that A $\beta$ 42 concentration and age demonstrated a strong negative correlation ( $r = -0.365$ ,  $P = 0.005$ ); A $\beta$ 42  $\times$  t-tau value and age demonstrated significant negative correlation ( $r = -0.266$ ,  $P = 0.046$ ) (**Table 3**). In the AD group, t-tau concentration and MMSE score demonstrated a strong negative correlation ( $r = -0.579$ ,  $P = 0.006$ ) (**Table 4**). This thus suggests that in AD patients, the lower MMSE value is, which represents the severity of the disease, the higher is the plasma t-tau protein level.

## Logistic Regression Analysis

To further study the relationship between plasma biomarker and brain A $\beta$  deposit, we utilized SPSS software performing logistic regression analysis. We combined different variables to establish a disease prediction model (i.e., practical clinical diagnosis) and predicted if the individual is AD or NC who met the entry criteria (i.e., clinical diagnosis). Our model introduced the variables A $\beta$ 42, t-tau, A $\beta$ 42  $\times$  t-tau, MMSE, and MoCA predicted as shown in **Table 5**. This model has the prediction accuracy of 98.2% for the control groups and 97.3% for the AD group, an overall prediction percentage of 97.8%. Further variable logistic analysis concluded that A $\beta$ 42, A $\beta$ 42  $\times$  t-tau, and MoCA also had statistical significance in the model ( $P < 0.05$ ), as the prediction accuracy of these three variables shown in **Table 6**. This three-variable model has a prediction accuracy of 98.2% for the control groups and 94.6% for the AD group, an overall prediction percentage of 96.7%. Using the prediction values of A $\beta$ 42, A $\beta$ 42  $\times$  t-tau, and MoCA as variable, with PET-PiB as standard, the ROC curve is shown in **Figure 3**, as cutoff value = 0.48, sensitivity = 0.973, specificity = 0.982, AUC = 0.986. The results demonstrated the prediction model of A $\beta$ 42, A $\beta$ 42  $\times$  t-tau, and MoCA have a significant correlation with clinical probable AD diagnosis.

## DISCUSSION

As all we know, the early diagnosis and treatment of AD may benefit to improve symptoms and decelerate the course

**FIGURE 2 |** Receiver operating characteristic curve analysis for discriminating between NC and AD subjects using A $\beta$ 42 level, t-tau level, A $\beta$ 42  $\times$  t-tau value, and A $\beta$ 42/t-tau value as diagnostic parameters. **(A)** AUC of A $\beta$ 42 concentration between NC and AD group; **(B)** AUC of t-tau concentration between NC and AD group; **(C)** AUC of A $\beta$ 42  $\times$  t-tau value between NC and AD group; **(D)** AUC of A $\beta$ 42/t-tau value between NC and AD group. and also alleviate the burden of the family and society (Andreasen et al., 2001; Kim et al., 2010). Therefore, it is crucial to define the disease with a clear biological foundation including clinical and preclinical phases. The NIA-AA Research Framework focuses on biomarker discovery in living people for AD diagnosis, including biomarkers for A $\beta$  deposition, pathologic tau, neurodegeneration, and so on (Jack et al., 2018). CSF AD-specific pathological protein test and PET

have become internationally recognized biomarker diagnoses in living patients (Prestia et al., 2013; Toledo et al., 2014; Vos et al., 2015). Especially, the absolute sensitivity of amyloid PET relative to an autopsy gold standard has been assessed (Roberts et al., 2017); its sensitivity and accuracy are higher than neuropsychological evaluation, computed tomography and MRI. However, CSF biomarker analysis related lumbar puncture

is an invasive procedure and poor in repeatability, and the assessment is not always feasible and difficult to be accepted by patients in some countries, especially in the elderly patients. Meanwhile, brain imaging biomarkers (amyloid-PET, tau-PET) also have their disadvantages: the assay cost is too expensive, and it requires sophisticated technologies and equipment, which are not accessible in regular clinical settings, which limit the widespread application of these two types of biomarkers. Therefore, compared with all above, analyzing pathologic A $\beta$  and tau in peripheral blood, which have great advantages, including blood samples being easy to access, the procedure is non-invasive or minimally invasive, with reasonable cost-effective and good replication rate. More and more studies show that blood biomarkers have promising prospects (Kaneko et al., 2014; Mattsson et al., 2016; Nabers et al., 2018; Nakamura et al., 2018).

Immunomagnetic reduction technology for AD-associated plasma biomarkers has been developed in the last few years (Lue et al., 2019a). In a recent study, plasma A $\beta$ 42 level was assayed by IMR in European Caucasian AD subjects (Teunissen et al., 2018). However, pathologic A $\beta$  and t-tau levels are under

gene regulation; there are interracial discrepancies of these gene expressions (Huynh and Mohan, 2017). Thus, directly using the data from the European population in the Chinese population will have great limitations. Currently, there are many studies assessed the potential of A $\beta$ 40, A $\beta$ 42, and t-tau measured by IMR in discriminating AD in China Taiwan area (Chiu et al., 2012, 2013; Yang et al., 2017a; Fan et al., 2018). These studies used the same methods but obtained different cutoff values, which may be caused by race, regions, living habit differences, and so on. Therefore, a larger sample size from mainland China is needed for establishing accurate cutoff value for the Chinese population. In this study, we used IMR technology to measure plasma A $\beta$ 42 and t-tau protein levels and for the first time verified the reliability of the multiparameter model of plasma A $\beta$ 42 and t-tau in combination with MoCA for diagnosing probable AD confirmed by PET-PiB, which provides sensitive and reliable discrimination between control and AD subjects in a Chinese population.

In this single-blind test, we discovered plasma A $\beta$ 42, t-tau, and A $\beta$ 42  $\times$  t-tau levels are significantly higher in AD subjects compared to the control subjects. Further ROC curve analysis demonstrated that plasma A $\beta$ 42  $\times$  t-tau as a combinational biomarker yielded better discrimination between control and AD subjects than that of plasma A $\beta$ 42 or t-tau concentration alone. Using Spearman correlation analysis, we found A $\beta$ 42 level is negatively correlated with age ( $r = -0.365$ ,  $P = 0.005$ ), and the value of A $\beta$ 42  $\times$  t-tau is negatively correlated with age ( $r = -0.266$ ,  $P = 0.046$ ) in the control group. These findings suggest that A $\beta$ 42 level as well as A $\beta$ 42  $\times$  t-tau value decreases according to age growth in healthy subjects, which agree with those of Lue et al. (2019b), who showed that plasma A $\beta$ 42

decreased as age increased in cognitively normal subjects. These relationships provided evidence that A $\beta$ 42 may be involved in the pathophysiology of aging and could act as plasma biomarkers in aging-associated disease. In our study, in AD patients whose MMSE/MoCA value is less than 10, the t-tau level is strongly negatively correlated with MMSE value ( $r = -0.579$ ,  $P = 0.006$ ). Our findings suggest that, in AD patients, the lower the MMSE value is, the higher plasma the t-tau protein level is, which is consistent with the discovery from clinical studies that showed MMSE score is negatively correlated with plasma t-tau concentration (Mattsson et al., 2016). That reveals the severity of AD is positively correlated with the level of t-tau.

To establish the valid prediction model, we initially started with a five-variable model, including A $\beta$ 42, t-tau, A $\beta$ 42  $\times$  t-tau, MMSE, and MoCA. Our prediction model can distinguish AD subjects from control subjects with an accuracy of 98.2 and 97.3%, respectively, and the overall prediction rate is 97.8%. To further simplify our model, we tried different combinations, and discovered three variables, A $\beta$ 42, A $\beta$ 42  $\times$  t-tau, and MoCA, are sensitive enough to yield similar prediction accuracy in comparison to a five-variable prediction model (98.2% for the control group, 94.6% for AD group and the overall 96.7%). Moreover, MoCA is a superior screen tool for the identification of mild cognitive impairment compared to MMSE (Li et al., 2018; Pinto et al., 2019). Therefore, the three-variable model is optimal for predicting early stage AD with MoCA as its neuropsychological measurement. Further ROC curve analysis showed using a three-variable model offered better categorical efficacy, sensitivity, specificity, and AUC compared with using A $\beta$ 42  $\times$  t-tau alone. We think that the prediction model established by plasma biomarkers has a significant correlation with clinical diagnostics. Lue et al. (2017), using the IMR assay, found that the regression model incorporating age and tau level has 81 and 96% accuracy for identifying probable AD in Banner Sun Health Institute (BSHRI) and National Taiwan University Hospital (NTUH) cohorts, respectively; incorporating age with the products of A $\beta$ 42 and tau in BSHRI and NTUH cohorts have 84 and 95% accuracy, respectively. At a 382.68 (pg/mL)<sup>2</sup> cutoff value, the product of A $\beta$ 42 and tau achieved 92% accuracy with 96% sensitivity and 90% specificity in identifying AD in the combined cohorts. Compared to this study, we relied on PET-PiB, a gold standard for AD in living patients, as one of the criteria for the recruitment of AD patients, and created a new prediction model of AD. This model obtained different cutoff values from the United States and China Taiwan area, and the sensitivity and specificity are more than 95%. The strength of the study is the predictive value of the combination of different parameters. In AD, A $\beta$  and tau proteins are the core biomarkers. Significant increases in A $\beta$ 42 and t-tau levels in plasma have been found in early AD patients (Chen et al., 2019; Lue et al., 2019a). Our attempt of combining these two pathological proteins with neuropsychological measurement offers a new avenue of enhancing sensitivity and specificity for diagnosing with plasma biomarkers only, thus overcoming the limitation of plasma biomarkers, as described by Chen et al. (2019) for plasma A $\beta$ 42 and t-tau correlate with cognitive decline in amnesic MCI patients.

Although the current study has plausible results, it does have certain limitations. First, the volunteer number included in the study is rather small, thus requiring to expand sample size for further validation of our data and model. Second, the current study is a retrospective study; a further prospective longitudinal study will be extremely valuable.

In conclusion, our study introduced variables A $\beta$ 42, t-tau, A $\beta$ 42  $\times$  t-tau, MMSE, and MoCA into the model and performed analysis; analyzed the role of each variable in the model via logistic regression; further determined using A $\beta$ 42, A $\beta$ 42  $\times$  t-tau, and MoCA for companion diagnosis for AD; compared with previous using a single biomarker; and greatly enhanced the efficacy and stability of the diagnosis. Moreover, as blood samples are more accessible than CSF in community hospitals, plasma biomarkers for early diagnosis of AD can be promoted and popularized. Although early screening and diagnosis of AD are unlikely to rely on a single biomarker or a combination of biomarkers in blood, this information may serve a crucial role for companion diagnosis, so as to give early warning and early intervention for AD for clinicians.

## DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article/supplementary material.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Medical Ethics Committee of Chinese People's Liberation Army General Hospital. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

LW and HS designed the study strategy. YW, SZ, YG, WD, HZ, and LL recruited the participants and collected their information and blood samples. FJ, FY, YW, and JR performed the experiments. FJ, FY, and YG performed the data analysis, data management, and reference collection. FJ, FY, and JR wrote the manuscript. All authors reviewed the manuscript.

## FUNDING

This work was supported by the Military Special Health Care Project (Grant No. 15BJZ38).

## ACKNOWLEDGMENTS

We are very grateful to all the participants of the study. This work was supported by the Department of Nuclear Medicine in Chinese PLA General Hospital and we deeply appreciate all the work done by clinicians in the Department of Nuclear Medicine.

Diabetes and Alzheimer's disease (AD) place a significant burden on health care systems in the world and its aging populations. These diseases have long been regarded as separate entities; however, advanced glycation end products (AGEs) and the receptors for AGEs (RAGE) may be a link between diabetes and AD. In our study, mice injected with AGEs through stereotaxic surgery showed significant AD-like features: behavior showed decreased memory; immunofluorescence showed increased phosphorylated tau and APP. These results suggest links between diabetes and AD. Patients with diabetes are at a higher risk of developing AD, and the possible underlying molecular components of this association are now beginning to emerge.

**Keywords:** advanced glycation end products, RAGE, Alzheimer's disease, diabetes, PI3K

## INTRODUCTION

Accumulated evidence suggests that sporadic cases account for more than 95% of the total cases of Alzheimer's disease (AD; Levin, 2019). AD is a neurodegenerative disease with progressive memory cognitive dysfunction as the main clinical manifestation. The hallmark lesions observed in the brain of patients with AD result from the formation of numerous neurofibrillary tangles (NFTs) and senile plaques (SPs) composed of hyperphosphorylated tau and A $\beta$ , respectively (Lane et al., 2018). Studies have implicated diabetes mellitus (DM) as a strong risk factor for the development of AD (Jayaraj et al., 2020). DM shares pathological features with AD, such as impaired insulin signaling, increased oxidative stress, increased amyloid-beta (A $\beta$ ) production, tauopathy, and cerebrovascular complications (Shinohara and Sato, 2017), and therefore appears to be closely related to AD.

Glycosylation is an important non-enzymatic reaction between reducing sugars and amines (Singh et al., 2018). Lysine or arginine residues of proteins and glucose, moving towards the Schiff-base, convert themselves to the more stable aminomethyl ketone by the Amadori rearrangement and finally result in the formation of advanced glycation end (AGE) products (Bunn and Higgins, 1981; Hartog et al., 2007; Rabbani and Ahn, 2019). The synthesis of AGEs is irreversible, and although the process of cell death is slow and insignificant, the non-enzymatic saccharification process accompanied by neuron metabolism seriously affects the normal functioning of the nervous system (Kamynina et al., 2018).

Therefore, AGEs and the receptor for advanced glycation end-products (RAGE) may play an important role in disease pathogenesis. Many studies have shown that the accumulation of AGEs is a major factor in the incidence and development of several diabetic complications and neuropathies (Hammes et al., 1999; Negre-Salvayre et al., 2009; Singh et al., 2014; Nowotny et al., 2015; Yamagishi et al., 2015; Hashimoto et al., 2016; Kumar Pasupulati et al., 2016), and the accumulation of AGEs under *in vivo* conditions is associated with secondary complications related to diabetes in hyperglycemic environments (Garay-Sevilla et al., 2005). Furthermore, AGEs are closely linked to amyloid-based neurodegenerative diseases (Vicente Miranda and Outeiro, 2010; Li et al., 2012; Simó et al., 2017). Salahuddin et al. (2014) showed that disrupting the AGE-RAGE interaction can effectively prevent the development of AD, and AGEs are therefore considered promising drug targets for AD. Studies also show that the formation of AGEs will pass through and interfere with H1, H2A, and H3 histones by causing structural changes. The normal functioning of serotonin affects chromatin structure and function, leading to secondary complications which in turn aggravates the diabetic condition (Ashraf et al., 2014, 2015a, Ashraf et al., 2015b). The above evidence reveals that AGEs have a role in both diabetes and AD in humans as well as in disease models.

Studies also have found that AGEs induce oxidative stress in neurons, promoting the release of neuroinflammatory cytokines and A $\beta$  (Yan et al., 1996; Baig et al., 2018). At the same time, extracellular AGEs can also affect neuronal function through RAGE. Studies have shown that RAGE also interacts with and mediates the cytotoxicity of A $\beta$  (Wang et al., 2018). For example, the combination of RAGE and A $\beta$  can activate the inflammatory signaling pathway, release ROS to produce oxidative stress, and cause neuroinflammation, cause mitochondrial and neuronal dysfunction (Deane et al., 2008), and affect the mitogen-activated protein kinase signaling pathway (Deane, 2012). RAGE also accelerates the absorption and transport of A $\beta$ , which causes A $\beta$  to pass through the blood-brain barrier and into the central nervous system by endocytosis (Deane et al., 2003), causing cerebrovascular dysfunction and eventually leading to neurovascular inflammation and subsequent increase in synaptic toxicity (Deane and Zlokovic, 2007), which in turn affects the normal functioning of the central nervous system (Zhang et al., 2011; Galasko et al., 2014; Wang et al., 2014; Cai et al., 2016; Fang et al., 2018). The elevated expression of RAGE activates the nuclear transcription factor NF- $\kappa$ B, resulting in a positive feedback effect on inflammation (Wan et al., 2015; Fang et al., 2018). A $\beta$  activation of RAGE increases the expression of proinflammatory cytokines such as TNF- $\alpha$ , interleukin-6, and macrophage colony-stimulating factor (Dukic-Stefanovic et al., 2003), which accelerates the occurrence and development of AD. The RAGE signaling pathway also plays an important role in AGE-induced tau phosphorylation and spatial memory impairment. In SK-N-SH cells, primary hippocampal neurons, and rats, AGEs induce tau hyperphosphorylation *via* the RAGE/GSK-3 pathway (Li et al., 2012; Son et al., 2012). AGEs also block the BDNF-TrkB signaling pathway in rat brain and

N2A cells (Li et al., 2012), activate the GSK-3 $\beta$  kinase at Ser9, phosphorylate GSK-3, and induce tau hyperphosphorylation (Wu et al., 2019). Also, the deposition of AGEs activates microglia and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, resulting in the release of ROS and the formation of peroxynitrite, which oxidizes proteins, lipids, and DNA (Nam et al., 2012), eventually causing neuronal death. Co-immunoprecipitation studies have found that almost all AGE-immunoreactive neurons contain phosphorylated tau protein (Qi et al., 2017), which indicates that AGEs play an important role in tau protein hyperphosphorylation. As compared to AD mice, the phosphorylation levels of tau were increased in the offspring mouse model of diabetes and AD hybridization (Pdx1<sup>+/-</sup>/APP/PS1); furthermore, the production of A $\beta$  was increased and the clearance of A $\beta$  was inhibited (Guo et al., 2016). More and more evidence shows that DM is also a causative factor of AD; therefore, AD is also called type III diabetes (Luchsinger et al., 2001; Huang et al., 2014; Ahmed et al., 2015; Sridhar et al., 2015). As the RAGE signaling pathway may be an important therapeutic target in AD, computer-aided drug design has especially emerged as an efficient means of developing candidate drugs for the treatment of AD. The above observations suggest that the signal pathways mediated by AGEs/RAGE are implicated in AD-like learning and memory impairment, trigger neuroinflammation, and promote A $\beta$  deposition and tau hyperphosphorylation.

Immunohistochemical evidence also suggests that AGEs were co-located with NFTs and SPs, indicating that AGEs can induce AD symptoms (Takeda et al., 2011). AGEs are prooxidant factors that induce oxidative stress, causing neuronal dysfunction or death. It has been reported that GSK-3 $\beta$  is a potential link between diabetes and AD; the excessive activation of GSK-3 $\beta$  can cause hyperphosphorylation of tau (Zhang et al., 2018). LiCl is an inhibitor of GSK-3 (Kurgan et al., 2019), which has been reported to alleviate the hyperphosphorylation of tau proteins caused by AGEs to a certain extent. While AGEs may play an important role in the development of AD, the mechanism remains unclear.

In hyperglycemia and diabetes, the body produces large amounts of AGEs, which accelerate and aggravate the symptoms of diabetes and its complications, such as AD (Simó et al., 2017). AGEs are elevated in AD brains where they stimulate A $\beta$  production and colocalize with NFTs and SPs, suggesting that AGEs play an important role in the pathogenesis of AD (Cai et al., 2016). Studies have found that diabetes can aggravate the decline of tau protein lesions and spatial learning memory in the AD model. Due to advances in clinical treatment, the lifespan of diabetic patients can be further extended, with a higher global incidence of diabetes-associated AD (Ahmed et al., 2015).

AGEs play a central role in the development of AD and link neurodegenerative disease and diabetes. The stage during which AGEs impact AD and how AGEs influence tau proteins and A $\beta$  are still unclear. The effects of increased AGEs on spatial learning and memory, as well as the effects of early inhibition of AGEs production on the behavior and pathophysiology of the AD model, have not yet been reported. Therefore, elucidating

the mechanism of AGEs is important to show the association between diabetes and AD.

In previous studies, the main focus was on the mechanism of AGE-RAGE signaling in neurodegenerative diseases (Juranek et al., 2015; Batkulwar et al., 2018). The purpose of our research is to study the common target (RAGE) between diabetes and AD, and then establish the links between diabetes and AD to RAGE, and further carry out the related mechanism research. We not only studied the mechanism of RAGE in AD, but it's also more important to link diabetes to AD through RAGE.

To explore the role of AGEs in AD and diabetes, we injected AGEs in mice and found that they showed obvious symptoms of AD; behavioral studies showed that memory was impaired, immunofluorescence and western blot showed increased APP and p-Tau levels, and PET and qPCR confirmed this increase in A $\beta$  and Tau levels. Immunofluorescence revealed elevated RAGE, Tau, and APP levels in ZDF rats as well. Therefore, through these experiments, we demonstrated that AGEs-RAGE may be a potential link between AD and diabetes.

## MATERIALS AND METHODS

### Animals

C57BL/6 mice and ZDF rats were housed in specific pathogen-free (SPF) rooms with a 12-h light-dark cycle and sufficient water and food. All animal handling protocols were approved by the Animal Ethics Committee of Fudan University (No. 20171732A680).

### Morris Water Maze

Three days before the experiment, we placed the mouse into the behavioral room to adapt to the environment. A water tank measuring 122 cm in diameter was placed into the water labyrinth and instrument collection area. The tank was filled with water and bleaching powder to make the water turbid. The camera software that measured water maze behavior was adjusted for clarity, light, and brightness using a graphic mark placed approximately 0.1 m from the bottom of the tank. On the first day, a platform was placed above the surface in a single position in the water tank. The mouse was released into the water from the east, west, south, and north directions, and the time until the mouse found the underwater platform and climbed onto it was recorded. On days 2–5, the platform was placed 1 cm below the level of the liquid. Similar to day 1, the mouse was placed in the water from four different orientations. The time until the mouse found the platform hidden under the water and climbed onto it was recorded. If the mouse did not locate the platform within 60 s, the time was recorded as 60 s. On day 6, the platform was removed and the mice were allowed to move freely in the tank for 10 min. The time spent in each quadrant was determined, with a focus on the time the mouse was in the quadrant where the platform was previously located, each quadrant was marked by a different shape on the wall.

### Y-Maze

The mice were placed in a behavioral room to adapt to the environment 3 days before the experiment. Different

geometric figures were attached to the three arms of the Y-maze as visual markers. The three arms of each Y-maze were randomly divided into new arms, starting arms, and other arms. The Y-maze device was placed in the behavioral camera capture area to adjust for camera clarity, light brightness, and to set up the software. Blocking the new arm, the starting arm and the other arm were opened, allowing the mice to explore for 5 min. Subsequently, all three arms were opened and the mice were allowed to explore freely for 5 min; the time the mice spent exploring the new arm was recorded.

### Open Field

The mice were placed in a behavioral room to adapt to the environment 3 days before the experiment. A 120-cm long and wide-field camera equipment was set up in the behavioral acquisition area to adjust the camera sharpness, brightness, and set up the software. The mice were placed in the open field and allowed to move freely for 10 min. The time the mice spent in the central and surrounding areas was recorded.

### Protein Extraction

The mice were anesthetized with 2% sodium pentobarbital, and the mouse brain was quickly excised and placed in ice-cold PBS. The mouse hippocampus was isolated in frozen PBS. The hippocampus was placed in a tissue lysis buffer containing protease inhibitors. The tissue was lysed by thorough grinding on ice, was kept on ice for 2 h, and then 500  $\mu$ g of the hippocampal slurry was centrifuged at 4°C for 10 min. The supernatant was transferred to a new sterile 1.5-ml Eppendorf tube.

The sample was centrifuged again at 13,000 g for 20 min under the same conditions. The supernatant was aspirated into a new sterilized EP tube. Each sample received 5 $\times$  SDS buffer mixed with  $\beta$ -mercaptoethanol and was heated at 99°C for 15 min, immediately followed by a 3 min incubation on ice. The samples were then centrifuged for 3 min and used immediately or stored at –80°C until use.

### Western Blot Analysis

The percent SDS PAGE gels were determined according to the molecular weight of the target protein with a 5% separating gel. Protein ladder (1  $\mu$ l) and protein samples (10  $\mu$ l) were loaded onto the gel, and the gels were run at 80 V/30 min or 120 V/1.5 h. Afterward, the samples were transferred to a membrane by wet transfer. After the transfer, the membrane was blocked with 5% BSA (diluted in PBS) for 1 h, followed by incubation with the primary antibody (diluted in PBS) overnight at 4°C. The primary antibody was then aspirated off the membrane, which was washed five times with PBST for 5 min. The membrane was incubated with the fluorescent secondary antibody for 1 h at room temperature. The membrane was then washed three times with PBST for 5 min each and then scanned with the Odessey system (LI-COR, Lincoln, NE, USA).

### Immunohistochemistry

The brain tissue of the mice treated with AGEs, BSA, and AGEs+LiCl was taken from the 80°C freezer, rinsed three

times with 1× PBS for 5 min each time, and incubated in PBS+0.1% TritonX-100 for 30 min at room temperature to permeate the cell membrane. The sections were then rinsed three times with 1× PBS for 5 min before adding 5% BSA-PBS for 2 h at room temperature to block non-specific binding. The blocking solution was then aspirated, and the primary antibody diluted in 1% BSA-PBS was added [APP (1:1,000, Thermo Fisher Scientific, Waltham, MA, USA), or P-TAU (1:100, Santa Cruz Biotechnology, Santa Cruz, CA, USA)] to the sections, which were incubated at 4°C overnight. The following day, the sections were washed three times in 1× PBS for 5 min each. A fluorescent secondary antibody (1:500) diluted in 1× PBS was added in the dark and incubated for 2 h at room temperature. The secondary antibody was removed, and DAPI (1:1,000) diluted in 1× PBS was added to the sections for 5 min at room temperature. The DAPI was discarded, and the sections were washed three times in 1× PBS for 5 min each. The slides were photographed using a confocal microscope.

## RNA Extraction and Reverse Transcription and Real-Time Quantitative PCR (qPCR)

The hippocampus of the mice treated with AGEs, BSA, and AGEs + LiCl was extracted. Total RNA was extracted using Promega's total RNA extraction kit following the manufacturer guidelines. The concentration of RNA was determined by measuring the absorbance at 260 nm, and 2 µg of RNA was used for first-strand cDNA synthesis using Takara's reverse transcription kit. The mixture of cDNA samples and the indicated primers (Table 1) was subjected to at least three replicate qPCR amplification using YEASEN's SYBR Green qPCR mix. Relative gene expression was calculated by comparing the CT value of the gene of interest with the CT value of the internal reference gene *GAPDH*.

The qPCR primer sequences of the human genes (*APP*, *TAU*, *GAPDH*) required for the experiment were found in the Primer Bank, as shown in Table 1.

## Immunofluorescence

Rat brain slices were washed three times with 1× PBS for 5 min each, treated with 0.2% Triton-X100 (diluted in PBS) for 30 min, and then blocked with 5% BSA for 1 h. Next, the sections were incubated with RAGE, tau, and APP primary antibodies (diluted in PBS) at 4°C overnight. The following day, the sections were washed three times with 1× PBS for 5 min each and then incubated with secondary antibodies for 1.5 h. Finally, DAPI was incubated for 10 min. After washing with PBS, the plate was mounted with a fluorescent mounting plate. The expression of RAGE, tau, and APP was observed on confocal microscopy.

**TABLE 1** | List of the primers used for qPCR.

Gene	Primer Sequence (5' to 3')
Tau	Forward Primer: TGGGGAACATTCGGTATGAGG
	Reverse Primer: CAGAAGCCATAACCCCTTGGG
APP	Forward Primer: AACCGACTCCAGGATGACTATG
	Reverse Primer: TCTGGGGTTCCATGTAAAGC
GAPDH	Forward Primer: TGGATTGGACGCATTGGTC
	Reverse Primer: TTTGCACTGGTACGTGTTGAT

## RESULTS

### Behavioral Experiments Reveal Abnormal Behavior in AGE-Treated Mice

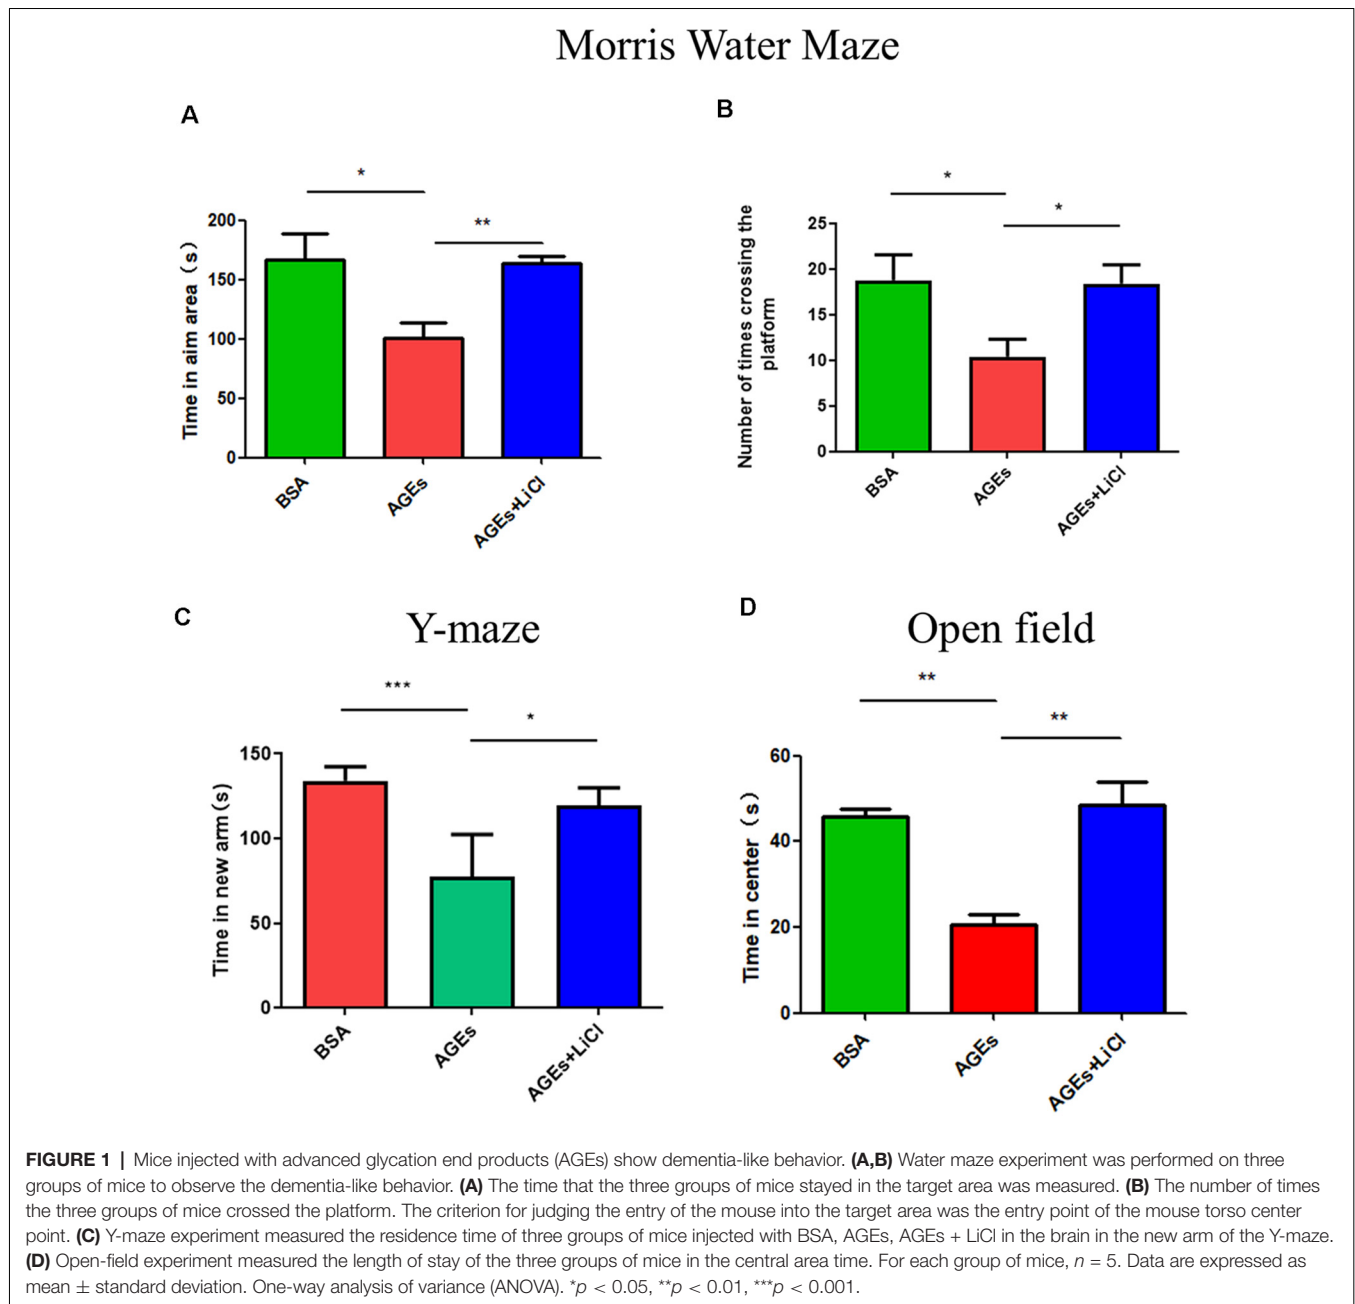

To investigate whether behavior changes develop in mice after the injection of AGEs, we studied the behavior of mice using the Morris Water Maze, Y-maze, and open field experiments. In the water maze test, compared with the control group, the AGE mice stayed in the target area for significantly lesser time, indicating that AGEs impair memory in mice. However, when treated with LiCl, the time spent in the target area significantly increased compared to that of AGE mice, indicating that LiCl can mitigate memory impairment (Figure 1A). Similarly, the number of times AGE mice crossed the platform decreased compared with that of the control group; however, when AGE mice were treated with LiCl, the number of times the mouse crossed the platform significantly increased compared to that of AGE mice (Figure 1B). This indicated that AGEs impair the memory of mice, while LiCl can alleviate the damage of AGEs.

Y-maze is an effective way to assess short-term memory in mice (Kraeuter et al., 2019). In the Y-maze experiment, compared with the control group, AGE mice stayed in the new arm for significantly lesser time. However, treatment with LiCl increased the time spent in the new arm, indicating that AGEs damage the memory capacity of mice, while LiCl can alleviate the damage of AGEs (Figure 1C). In the open field experiment, compared with the control group, AGE mice stayed in the central area for a significantly shorter time. When AGE mice were treated with LiCl, however, the time spent in the central area significantly increased. This indicated that AGEs increased the anxiety behavior of mice, while the addition of LiCl eased the anxiety behavior (Figure 1D).

### P-tau and APP Increased in the Hippocampus of AGE Mice

To investigate whether mice injected with AGEs develop AD symptoms, we analyzed the expression of P-tau (Phospho-Tau-S356 Rabbit pAb) and APP in the hippocampus of the mice by immunofluorescence, Western blot, and qPCR. The results showed that compared with the BSA control group, the expression of P-tau was significantly up-regulated in AGE mice, while it was not significantly changed in AGE mice treated with LiCl (Figure 2A). Compared with the control group, the mRNA expression of tau was significantly up-regulated in AGE mice, while it was not significantly changed in AGE mice treated with LiCl (Figure 2B). The same results were verified by immunoblotting (Figures 2C,D). Compared with the BSA control group, in AGE mice, the expression of APP protein was significantly up-regulated, while it was not changed in AGE mice treated with LiCl (Figure 2E). At the mRNA level, compared with the control group, the mRNA expression of APP in the AGE mice was significantly up-regulated, with no effect of LiCl (Figure 2F). This indicated that, compared with the control, the AGE mice successfully developed AD symptoms, which were mitigated when treated with LiCl.

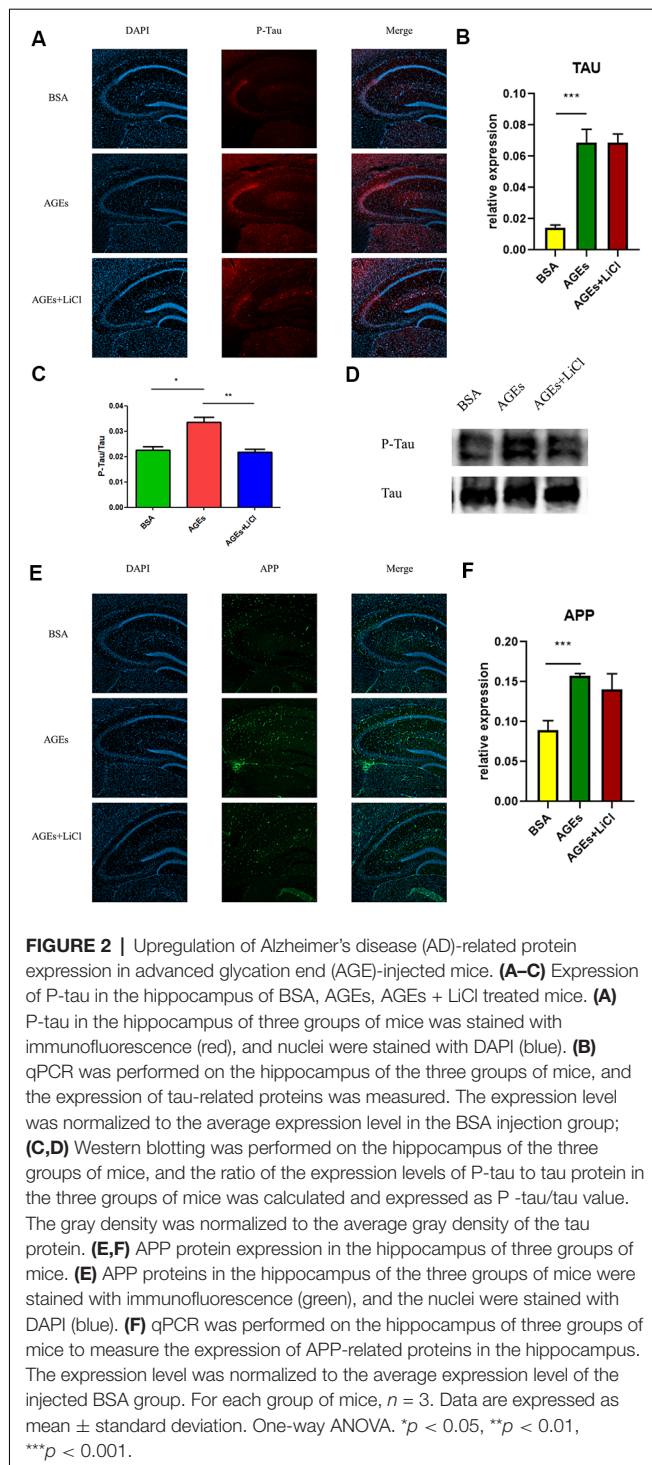

At the same time, the increase in tau and A $\beta$  in living mice was further verified by PET (**Figures 3A,B**). AV45 and PBB3 injections, respectively, showed that tau and A $\beta$  in AGE mice increased significantly, but were relieved when treating with LiCl. This result further demonstrates that AGEs can promote the occurrence of AD symptoms.

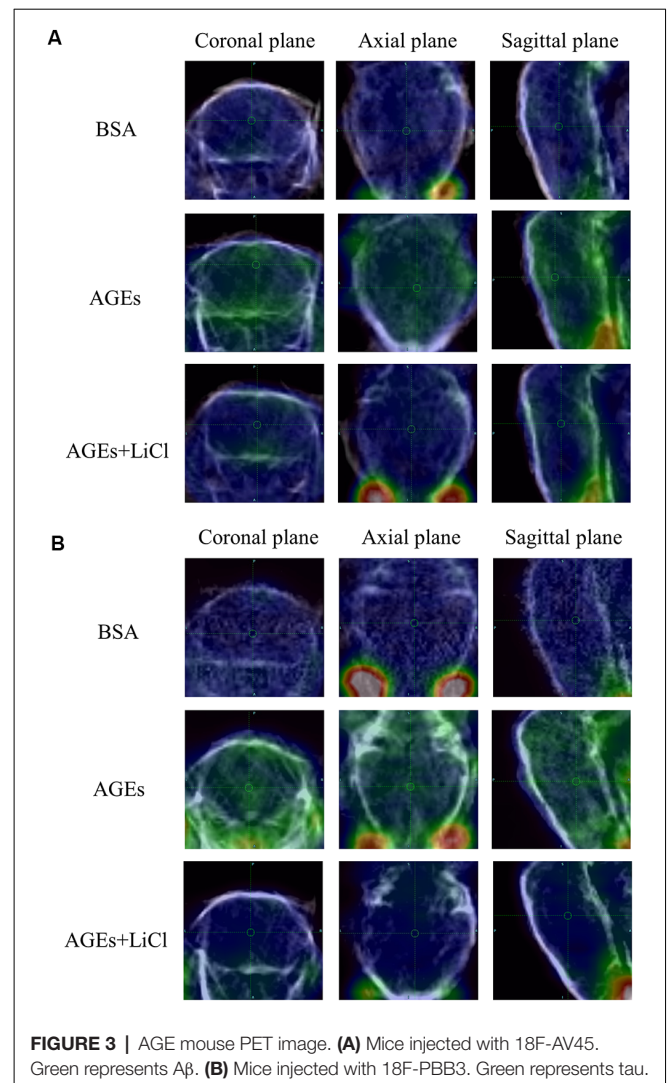

### AGEs Increase Tau Phosphorylation *via* the PI3K Signaling Pathway

Many studies have shown that increased phosphorylation of tau is closely related to the PI3K signaling pathway (Wang et al., 2018, 2019; Wei et al., 2019; Zhao et al., 2019).

Activation of the PI3K signaling pathway can reduce the over-phosphorylation of tau (Xiong et al., 2020). Therefore, we speculated whether AGEs cause increased tau phosphorylation by affecting the PI3K signaling pathway. To verify our conjecture, we detected the changes in the expression of PI3K protein and its downstream SRC and ERK proteins in the hippocampus of AGE and AGE+LiCl mice. Compared with controls, AGEs significantly down-regulated the protein expression of PI3K in the hippocampus of mice. However, this was up-regulated again after treatment with LiCl, indicating that AGEs may affect the memory of mice through the PI3K signaling pathway and LiCl may alleviate the damage of AGEs to brain function to some

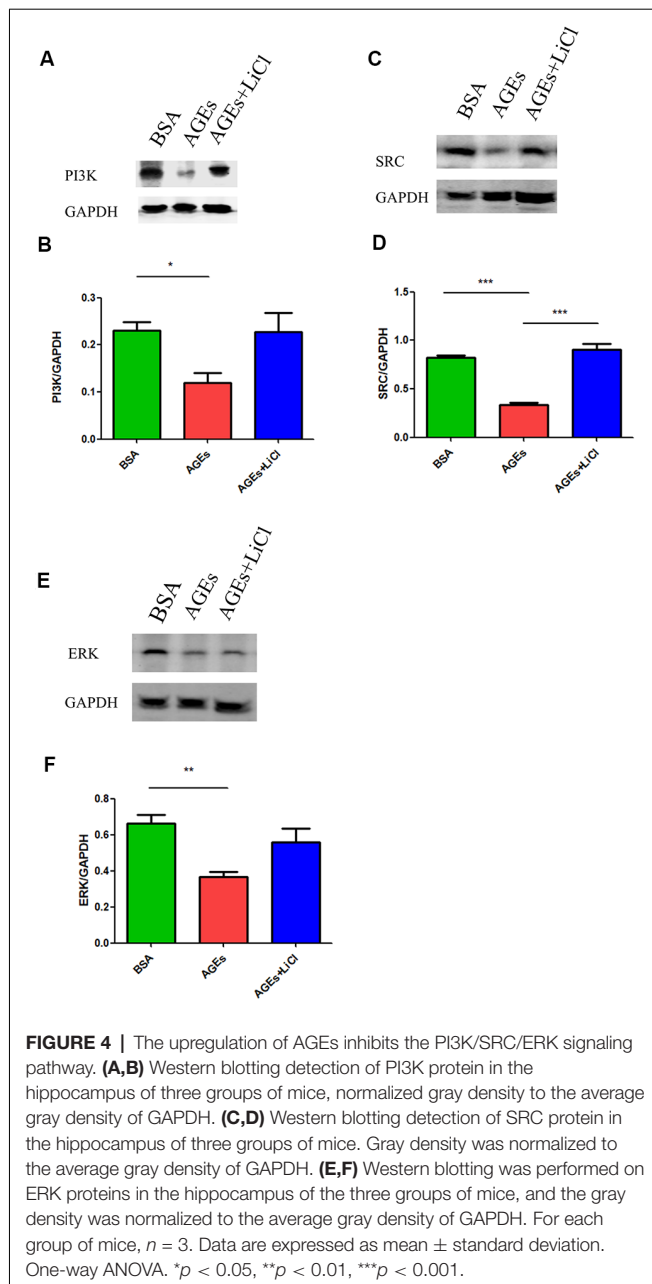

extent (Figures 4A,B). Moreover, the protein expression of SRC in the hippocampus of AGE mice was significantly down-regulated, while it was significantly up-regulated again when treated with LiCl, indicating that the down-regulation of PI3K resulted in a decrease in SRC (Figures 4C,D). Furthermore, the expression of ERK protein in the hippocampus of AGE mice was significantly decreased. LiCl, however, had no significant effect

on the expression of ERK. There was an upward trend of ERK, indicating that AGEs ultimately lead to a decrease in ERK protein through the PI3K signaling pathway, which may be the main signaling pathway leading to phosphorylation of tau protein, and the addition of LiCl can effectively inhibit the action of AGEs (Figures 4E,F).

## ZDF Rats Show Increased RAGE, APP, and Tau

To further verify the changes of RAGE in diabetes, we investigated whether there is a link between diabetes and AD by detecting changes in APP and tau in ZDF rats. Using immunofluorescence, we found that compared with normal wild rats, RAGE expression in the CA2–CA3 region significantly increased and was aggregated (Figures 5A,B). RAGE expression in the CA1 and DG regions was similar (Figure 5C). When comparing the expression of tau protein, we found that tau expression in wild SD rats was evenly distributed in the hippocampus, while tau expression in ZDF rats showed an aggregated state (Figures 5D–F). Similarly, we found that APP

showed a clear upward regulation in the hippocampus of ZDF rats (Figures 5G–I). These results indicate that RAGE expression is up-regulated in diabetic rats and that AD-like symptoms (increased tau aggregation and APP expression) occur in the hippocampus of diabetic rats, confirming that there is indeed an association between diabetes and AD.

## DISCUSSION

This study investigated the association between diabetes and AD through the treatment of mice with AGEs. First, memory dysfunction in AGE mice was verified by behavior (Figure 1). Next, immunofluorescence, qPCR, and Western

blotting confirmed an increase in P-tau and APP in the hippocampus of AGE mice (Figures 2, 3). We then speculated that AGEs may cause tau protein hyperphosphorylation through the PI3K signaling pathway (Figure 4). At the same time, LiCl improved these symptoms caused by AGEs. Finally, it was confirmed by immunofluorescence experiments in ZDF rats that diabetic rats develop AD symptoms (Figure 5). Therefore, our data illustrate the close relationship between diabetes and AD.

When diabetic patients are in a state of hyperglycemia for a long time, glucose will form covalent compound AGEs with plasma. AGEs not only form intracellular and cellular diplomatic links with proteins but also form crosslinks with other endogenous key molecules including lipids and nucleic acids, thereby promoting the development of diabetic complications (Singh et al., 2014). Cognitive dysfunction has been documented as one of the complications of diabetes, suggesting a close link between diabetes and AD (Jash et al., 2020). One of the main symptoms of AD is impaired memory (Sharma et al., 2020); therefore, to test whether the memory is altered in mice after the injection of AGEs, we conducted the Morris Water Maze, Y-maze, and open field tests and found that the memory of AGE mice decreased significantly and anxiety behavior increased, which is consistent with previous AD research (Tian et al., 2019; Du et al., 2020). Subsequently, to further study whether the brain of AGE mice can develop AD symptoms, we assessed the expression of AD-related proteins such as P-tau and APP, which were significantly increased in the hippocampus of AGE mice. This indicates that AGEs promote the occurrence of AD symptoms.

Much research has been done on the relationship between diabetes and AD. Some researchers have proposed that insulin can affect the phosphorylation of tau protein through the GSK-3 signaling pathway (Jash et al., 2020) and that LiCl is an inhibitor of GSK-3 (Kurgan et al., 2019). Therefore, when treated with LiCl, AGEs were not able to phosphorylate tau in large amounts, thereby improving AD symptoms in AGE mice. However, our results did not show that AD symptoms in AGE mice were significantly improved after treatment with LiCl; therefore, we speculate that the GSK-3 signaling pathway is only one of the links between diabetes and AD and other mechanisms have not been studied. Therefore, through AGEs, we speculate that there is a complex relationship between diabetes and AD, and its specific molecular mechanism requires further study.

A previous study reported that AGEs/RAGE interactions can stimulate the activation of multiple signaling cascades, including PI3K, and reduce the mRNA expression of downstream proteins of PI3K signaling pathways, such as AKT2 (Abdelmageed et al., 2019). These data indicate that AGEs/RAGE interactions occur through the PI3K signaling pathway. Furthermore, studies have shown that normal activation of the PI3K signaling pathway can reduce tau hyperphosphorylation (Xiong et al., 2020). Our previous experimental results showed that the proportion of phosphorylated tau protein increased in the hippocampus of mice when AGEs were injected. We further explored whether this is caused by the PI3K signaling pathway. We found that when mice were injected with AGEs, the expression of PI3K, SRC, and ERK proteins in the hippocampus were decreased, and

**FIGURE 5 |** ZDF rats show AD symptoms. **(A–C)** Staining rat hippocampus with RAGE antibody (red) and the nuclei with DAPI (blue). **(D–F)** Staining rat hippocampus with tau antibody (green) and the nuclei with DAPI (blue). **(G–I)** Staining rat hippocampus with APP antibody (green) and the nuclei with DAPI (blue).

the expression of PI3K and SRC increased again after injection of its inhibitor LiCl (**Figure 3**). The class III PI3K/Beclin-1 pathway has certain autophagic activity to promote autophagy clearance of tau (Chen et al., 2020), suggesting that blocking of PI3K-related pathways will hinder tau clearance. AGEs can induce tau hyperphosphorylation in SK-N-SH cells, primary hippocampal neurons, and in SD rats through the RAGE/GSK-3 pathway (Li et al., 2012; Son et al., 2012). The deposits of AGEs will activate microglia and NADPH oxidase, affecting PI3K-related pathways, leading to ROS synthesis and release, and further leading to oxidative stress (Nam et al., 2012; Zhou et al., 2020). In turn, this leads to the deposition of tau, suggesting that blocking the PI3K-related pathways will result in tau deposition. We speculate that AGEs promote the increase in tau phosphorylation by blocking the PI3K signaling pathway and down-regulating the expression of its downstream proteins, while LiCl has a certain relieving effect. However, its specific mechanism remains to be further studied.

Finally, we performed experiments on a diabetic rat model to verify whether symptoms similar to AD would occur in the diabetic model. We found that RAGE expression in the hippocampus of ZDF rats was increased significantly. At the same time, tau and APP expression were also increased, which is similar to the phenotype observed in the AD mouse model (Gallardo and Holtzman, 2019), further illustrating the relationship between diabetes and AD.

In conclusion, mice injected with AGEs showed significant AD-like features including decreased memory and increased phosphorylated tau and APP expression. These results suggest links between diabetes and AD. Patients with diabetes are at a higher risk of developing AD, and the possible underlying

molecular components of this association are now beginning to emerge.

## DATA AVAILABILITY STATEMENT

All datasets presented in this study are included in the article.

Wan M, Xia R, Lin H, Qiu P, He J, Ye Y, Tao J, Chen L and Zheng G (2020) Volumetric and Diffusion Abnormalities in Subcortical Nuclei of Older Adults With Cognitive Frailty. *Front. Aging Neurosci.* 12:202. doi: 10.3389/fnagi.2020.00202

**Background:** Cognitive frailty (CF) is defined as the simultaneous presence of physical frailty and cognitive impairment among older adults without dementia. Previous studies have revealed that neuropathological changes may contribute to the degeneration of subcortical nuclei in the process of cognitive impairment. However, it is unclear in CF. The aim of this study is to investigate the changes in subcortical nuclei in older adults with CF and their relationship with cognitive decline and physical frailty.

**Methods:** A total of 26 older adults with CF and 26 matched healthy subjects were enrolled. Cognitive function and physical frailty were assessed with the Montreal Cognitive Assessment (MoCA) scale (Fuzhou version) and the Chinese version of the Edmonton Frailty Scale (EFS). Volumetric and diffusion tensor imaging (DTI) parameters of subcortical nuclei were measured with structural and DTI brain magnetic resonance imaging (MRI) and compared between groups. Partial correlation analysis was conducted between subcortical nuclei volumes, MoCA scores, and physical frailty indexes.

**Results:** Significant volume reductions were found in five subcortical nuclei, including the bilateral thalami, left caudate, right pallidum, and accumbens area, in older adults with CF ( $P < 0.05$ ), and the bilateral thalami was most obvious. Decreased fractional anisotropy and relative anisotropy values were observed only in the left thalamus in the CF group ( $P < 0.05$ ). No group differences were found in apparent diffusion coefficient (ADC) values. The MoCA scores were positively correlated with the volumes of the bilateral thalami, right pallidum, and accumbens area ( $P < 0.05$ ). Negative correlations were found between the physical frailty index and the volumes of the bilateral thalami, caudate, pallidum, and right accumbens area ( $P < 0.05$ ).

**Conclusion:** Microstructural changes occur in the subcortical nuclei of older adults with CF, and these changes are correlated with cognitive decline and physical frailty. Therefore, microstructural atrophy of the subcortical nuclei may be involved in the pathological progression of CF.

**Keywords:** cognitive frailty, subcortical nuclei, diffusion tensor imaging, volume, correlation

## INTRODUCTION

Cognitive frailty (CF) was first defined in 2013 by the International Academy on Nutrition and Aging (I.A.N.A.) and the International Association of Gerontology and Geriatrics (I.A.G.G.; Kelaiditi et al., 2013). Cognitive frailty has a heterogeneous clinical manifestation characterized by the simultaneous presence of both physical frailty and cognitive impairment among older adults without dementia. Epidemiological surveys based on community people estimated the prevalence rate of CF to be 1.0% to 22.0% (Shimada et al., 2016; Feng et al., 2017), whereas in the clinical setting, the figure was much higher at 10.7% to 40% (Malek et al., 2019). Cognitive frailty has been identified to be associated with an increased risk of severe adverse events in older people, such as dementia and disability and even mortality. Therefore, CF is recognized as an important threat to healthy aging. With the growing understanding of CF as an important clinical syndrome, identifying biomarkers of pathophysiological changes has become paramount. Furthermore, it is helpful to map its biological markers for the development of secondary preventive treatments for this disorder.

Clinically, the judgment of CF is typically established using tests of physical and mental status, including the Clinical Dementia Rating (CDR) and Montreal Cognitive Assessment (MoCA) or Mini-Mental State Examination (MMSE; Won et al., 2018). With the development of morphometric magnetic resonance imaging (MRI) technology, robust imaging biomarkers for some diseases related to brain damage have reduced the potential for clinical impact. For example, MRI studies based on voxel-based morphometry analysis have established the association of cognitive impairment and morphometric changes in the brain. Previous studies have reported reductions in the volumes of the whole hippocampus, medial temporal lobe, and entorhinal cortex in the brains of older adults with cognitive impairment compared to healthy subjects (Anatürk et al., 2018; Gu and Zhang, 2019). Cortical gray matter atrophy first occurs in the temporal cortex and is followed by occipital, parietal, and frontal atrophy along a temporospatial gradient with the progression of cognitive decline (Fennema-Notestine et al., 2009). Considering that microstructural changes likely precede macrostructural changes, studies have revealed that the degeneration of subcortical nuclei also contributes to neuropathological changes in the process of cognitive impairment (Tentolouris-Piperas et al., 2017). However, compared to macroscopic measurements, the underlying microstructural changes seem complicated and heterogeneous (Gong et al., 2017).

Diffusion tensor imaging (DTI) can be used to quantify microscopic white/gray matter integrity not detectable on conventional MRI and is sensitive for detecting microstructural volumetric impairment through the intrinsic properties of water diffusion (Mori and Zhang, 2006). DTI has helped to explain neuropathological mechanisms for different neuropsychiatric conditions (Cherubini et al., 2010). Several studies have used DTI to explore the microstructural changes in subcortical nuclei in conditions associated with cognitive decline (Eustache et al.,

2016; Mak et al., 2017). Moreover, few studies have focused on CF. However, there have been reports of different patterns of degeneration that were compatible with either mild cognitive impairment or physical frailty. The aim of the present study was to investigate microstructural volumetric changes in brain DTI indexes in older adults with CF and to compare their trajectories with those of healthy older adults.

## MATERIALS AND METHODS

### Participants

Twenty-six older adults with CF and 26 matched healthy controls (HCs) participated in this study. All participants were right-handed native Chinese speakers. The CF participants were all recruited from the communities in Fuzhou City, Fujian Province, China, and the HC participants were recruited from the same communities. Written informed consent was obtained from all participants before data collection. This study was approved by the ethics committee of the Second People's Hospital affiliated with Fujian University of Traditional Chinese Medicine. All CF participants met the following inclusion criteria: (1) Chinese version of Edmonton Frailty Scale (EFS)  $\geq 5$  points; (2) Fuzhou version MoCA score  $\leq 26$  points; (3) age  $\geq 60$  years old; and (4) CDR score = 0.5 (i.e., did not meet the criteria for dementia). The controls did not have CF syndrome, which was confirmed using the assessment of EFS and MoCA scale. Individuals who met the following conditions, which were assessed based on medical records, were excluded: (1) had hypertension and uncontrollable blood pressure (systolic blood pressure  $> 160$  mm Hg or diastolic blood pressure  $> 100$  mm Hg after taking drug); (2) had a history of alcohol and drug abuse; (3) had a history of mental illness (such as personality disorder, schizophrenia, etc.), severe depression (Baker Depression Scale  $> 10$  points), severe aphasia and audiovisual impairment, severe organ failure, cerebral hemorrhage, cerebral infarction, history of myocardial infarction, history of coronary heart disease, musculoskeletal disease, and other sports contraindications; (4) had metal implants (such as fixed metal dentures, pacemakers, etc.); and (5) were not suitable for MRI scans.

### MRI Data Acquisition

The structural MRI and diffusion tensor MRI data for all participants were collected at Fujian Province Rehabilitation Hospital. MRI scans were acquired with a Siemens Prisma 3.0-T magnetic resonance scanner (Siemens Medical System, Erlangen, Germany) and a Siemens 64-channel head-neck joint coil. The subject lay back on the scanning bed, his/her head was properly fixed, and rubber earplugs were used to reduce the noise impact of the machine. High-resolution structural images were acquired by using a three-dimensional T1-weighted magnetization-prepared rapid acquisition of a gradient echo sequence with the following parameters: repetition time (TR) = 2,300 ms, echo time (TE) = 2.27 ms, flip angle =  $8^\circ$ , slice thickness = 1.0 mm, field of view (FOV) =  $250 \times 250$  mm, matrix =  $256 \times 256$ , voxel size =  $0.98 \times 0.98 \times 1$  mm<sup>3</sup>, and number of slices = 160. For DTI, the following parameters were used: TR = 8,000 ms, TE = 64 ms, FOV =  $224 \times 224$  mm, slice

thickness = 2.0 mm, gap = 0 mm, slice number = 75, and slice order = interleaved.

## Image Processing

The original data from the magnetic resonance image machine were transformed from DICOM format to nifti format file and classified into T1 images and DTI images by MRIconvert software (version 2.0 Rev. 235<sup>1</sup>). T1 image analysis was carried out with FreeSurfer software (version 6.0.0<sup>2</sup>). DTI analysis was carried out with FSL software (version 5.0.10<sup>3</sup>).

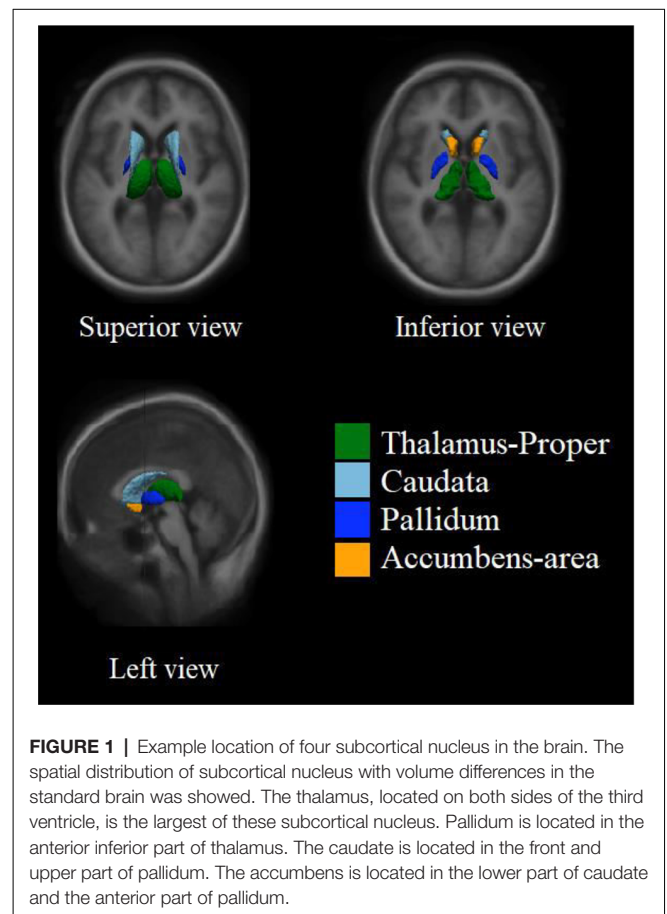

## Volumes of the Subcortical Nuclei Analysis

The T1 image preprocessing procedure included image format conversion, image quality check, Talairach transformation (this computes the affine transform from the original volume to the MNI305 atlas), intensity normalization, skull stripping, segmentation of gray and white matter, tessellation of the gray and white matter boundary, automatic subcortical segmentation, automatic topology fixer, and smoothing.

For comparisons of the volumes of the subcortical structures between the groups, the automatic extraction technology of FreeSurfer was used. FreeSurfer segments the brain into several regions that have a unique id. Through the segmentation id, we could identify the nuclei of interest and extract their information. The volumes of the subcortical nuclei, including the thalamus, caudate, putamen, pallidum, hippocampus, amygdala, and accumbens area of both sides, were extracted.

## Diffusion Parameters of the Subcortical Nuclei

The DTI image data preprocessing procedure included image format conversion, image quality check, eddy current and motion correction, skull stripping, DTI tensor [including fractional anisotropy (FA), apparent diffusion coefficient (ADC), relative anisotropy (RA)] construction, registration of low b images to the same-subject anatomical used affine registration and deformed registration, and map FA to Talairach space to obtain DTI parameters of the subcortical nucleus in the same space with volume extraction. Then, the same subcortical nuclei segmentation id was used as the last step to extract the FA, ADC,

**FIGURE 1 |** Example location of four subcortical nucleus in the brain. The spatial distribution of subcortical nucleus with volume differences in the standard brain was showed. The thalamus, located on both sides of the third ventricle, is the largest of these subcortical nucleus. Pallidum is located in the anterior inferior part of thalamus. The caudate is located in the front and upper part of pallidum. The accumbens is located in the lower part of caudate and the anterior part of pallidum.

and RA values of subcortical nuclei with volume differences between the two groups.

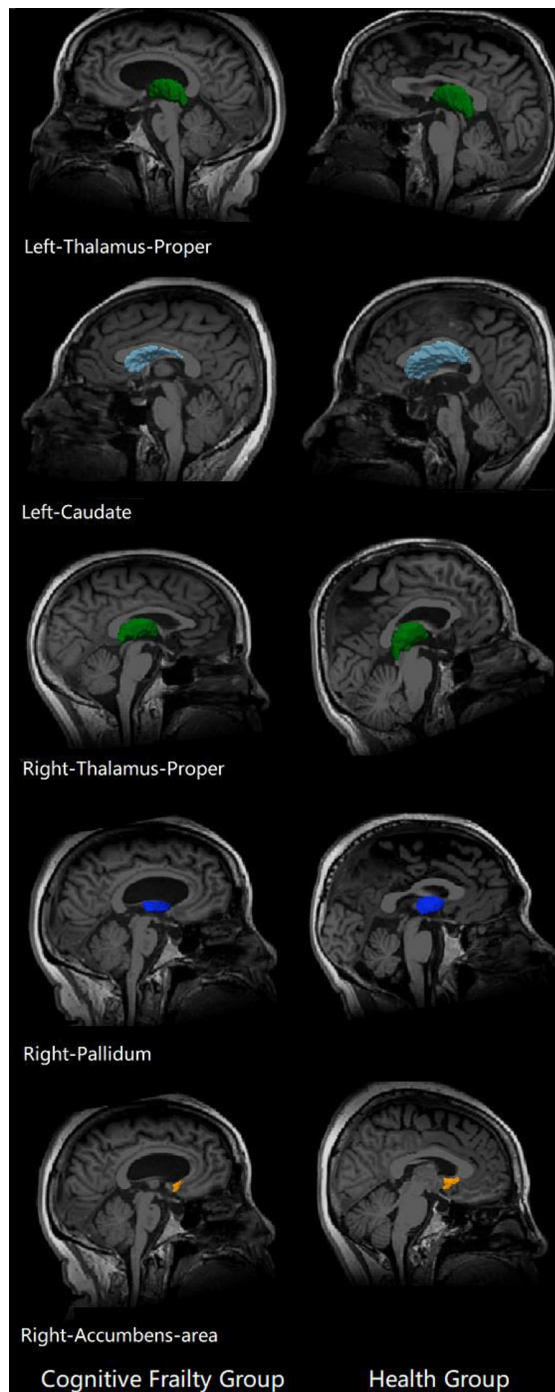

## Statistical Analysis

Statistical analysis was performed using the Statistical Package for Social Sciences for Windows version 21.0 (IBM Corp., Armonk, NY, USA), and *P* < 0.05 was considered significant. Continuous variables were expressed using the mean and standard deviation for the normal distribution or median and its interquartile range for a nonnormal distribution and were analyzed using Student *t*-test or Mann–Whitney *U* test, respectively. Categorical

<sup>3</sup><https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/>

**FIGURE 2 |** Subcortical nuclei with differences in the two groups. Brain structural changes associated cognitive frailty. Cognitive frailty group showed a decrease in the volume of subcortical nucleus compared with health group.

variables were described as frequencies and were analyzed using the  $\chi^2$  test.

Volumetric and DTI parameters of subcortical nuclei in the two groups were compared by independent-sample *t*-tests. To identify brain structural changes related to the frailty index and MoCA, we assessed nuclei volume differences between groups

using partial correlation analysis. Age, sex, education years, and Beck Depression Inventory scores were also entered as covariates.

## RESULTS

### The Baseline Characteristics of the CF Participants and Healthy Controls

The average MoCA score in the CF group was significantly lower than that in the healthy control group. The frailty index in the CF group was significantly higher than that in the healthy control group. There were no significant differences between the two groups in gender, age, years of education, or Beck Depression Inventory scores ( $P < 0.05$ ; **Table 1**).

### Subcortical Nuclei Volume

Compared to the healthy control group, the CF group showed decreased volume in five brain nuclei, including the left thalamus, left caudate, right thalamus, right pallidum, and right accumbens area ( $P < 0.05$ ), and there was the most obvious volume difference in the thalamus (**Figures 1, 2, Table 2**).

### DTI Parameters

Decreased FA and RA values were observed in the left thalamus in the CF group compared to the healthy control group ( $P < 0.05$ ). No group significance was found in the ADC values of any subcortical nuclei ( $P > 0.05$ ; **Figure 3, Table 3**).

### Correlation Between Subcortical Nuclei Volumes, MoCA Scores, and Frailty Index Scores

After adjusting for age, sex, and education, the volumes of the left and right thalamus proper, right pallidum, and right accumbens area were positively correlated with the MoCA scores ( $P < 0.05$ ); the volumes of the left and right thalamus proper, left and right caudate, left and right pallidum, and right accumbens area were negatively correlated with the frailty index scores ( $P < 0.05$ ; **Figure 4, Table 4**).

## DISCUSSION

Cognitive frailty is a clinical condition characterized by the simultaneous presence of both physical frailty and cognitive impairment but without concurrent Alzheimer disease or other dementia. However, there may be some extent of association with physical frailty or cognitive impairment through some common mechanisms. However, the underlying mechanisms of CF remain unclear. In the present study, we investigated the brain structural characteristics in the subcortical nuclei between adults with CF and matched healthy older adults by using DTI technology. The findings of this study showed that there was an obvious decrease in the volume of five brain subcortical nuclei, including the bilateral thalami, left caudate, right pallidum, and right accumbens area in older adults with CF compared to HCs. Furthermore, the volumes of more than five subcortical nuclei were negatively correlated with the frailty index, whereas the volumes of the bilateral thalami, right pallidum, and accumbens

were positively correlated with MoCA scores. We also found that those with CF showed decreased FA and RA values in the left thalamus compared to the HCs. These findings suggest that structural atrophy or impairment in some subcortical nucleus areas may be a potential mechanism for CF.

Previous studies have confirmed that the frailty index had significant relationships with subcortical and cortical atrophy but not with changes in white matter in older adults with cognitive decline (Del Brutto et al., 2017; Gallucci et al., 2018). As an important subcortical nucleus, the thalamic nucleus adjacent to the third ventricle connects to its cortex, subcortex, and cerebellum. The thalamic nucleus is a key node in the neural network of hippocampal and cortical structures and is a fundamental substrate for human cognitive functions, especially the formation of memory, information processing, and executive function (Minagar et al., 2013; Fama and Sullivan, 2015; Dolleman-van der Well et al., 2019). Abnormal thalamic macrostructure, microstructure, or neural connectivity is widely associated with some clinical manifestations, such as cognitive impairments, motor deficits, and physical frailty (Fama and Sullivan, 2015). Studies of multimodal MRI have demonstrated that changes in the thalamus, including volume shrinkage, microstructural degradation, and integrity and connectivity decline, are associated with cognitive decline in elderly individuals (Hughes et al., 2012). In addition, a study reported that shrinkage of thalamic volume was positively correlated with gait speed and grip strength in frail populations, such as those with human immunodeficiency virus infection (Kallianpur et al., 2016). The present study found that the volumes of the bilateral thalami were highly correlated with cognitive function and the frailty index, especially the right thalamus, in older adults with CF. Our findings were in line with previous studies. Brain microstructure, tissue quality, and fiber integrity can be assessed with DTI by measuring the magnitude and orientation of water diffusion within the image volume unit (Jones et al., 2013). Fractional anisotropy and RA are two of the most commonly used scalar measurement methods of anisotropy in DTI. Published studies have shown that FA has superior noise immunity relative to RA (Hasan et al., 2004). Fractional anisotropy may assess the integrity of white matter

fibers by the orientation of water diffusivity (Truong et al., 2014). Moreover, this modality of FA could also be used to assess the microstructure of gray matter because it likely reflects the

**FIGURE 3** | Fractional anisotropy (FA), apparent diffusion coefficient (ADC), relative anisotropy (RA) map comparison between two groups. The mean values of FA, ADC and RA were computed within thalamus, caudate nucleus, globus pallidus and nucleus accumbens for individual subjects.

Group CF, cognitive frailty group; group HC, healthy group; FA, fractional anisotropy; ADC, apparent diffusion coefficient; RA, relative anisotropy. Value of FA, ADC and RA was presented by mean ± standard deviation.

integrity of the neuronal cell wall and intercellular membranes (Whitwell et al., 2010). ADC mapping can quantitatively evaluate changes in brain water diffusivity and improve the performance of automatic morphological diagnosis. Our results showed that cognitive decline and physical frailty were highly correlated with the FA and RA values of the thalamus after adjustment for age and some other factors, but we did not find significant differences in the ADC mapping of the subcortical nucleus between the two groups. This might be attributed to the different compartmentalization and impact of diffusion time on the ADC of different molecules under limited diffusion conditions (Kan et al., 2012). Nevertheless, it is possible that thalamic microstructural damage and atrophy may be predictors of CF.

The current study also found that the caudate volume in the CF group was lower than that in the healthy control group, and the caudate volume, especially the left caudate, had a negative correlation with physical frailty. The caudate and putamen constitute the neostriatal nucleus that receives projections from the cerebral cortex and sends them to the brain stem and spinal cord, which play a complex role in the function of the motor regulation system (Jane, 2020). A previous study reported that the caudate nucleus importantly contributed to body and limb posture, as well as the accuracy and speed of directed movements (Villablanca, 2010). These findings may explain why volume changes in the caudate nucleus are related to the frailty index and not cognitive impairment in the current study. Another study reported that the caudate nucleus may play a significant role in brain processing of muscle pain (Maeda et al., 2011), which could be related to physical frailty. In addition, the abnormal functional connection between the caudate nucleus and prefrontal lobe was involved in motor inhibition related to obsessive-compulsive disorder, which also showed the importance of the caudate nucleus in motor control (Fineberg et al., 2018).

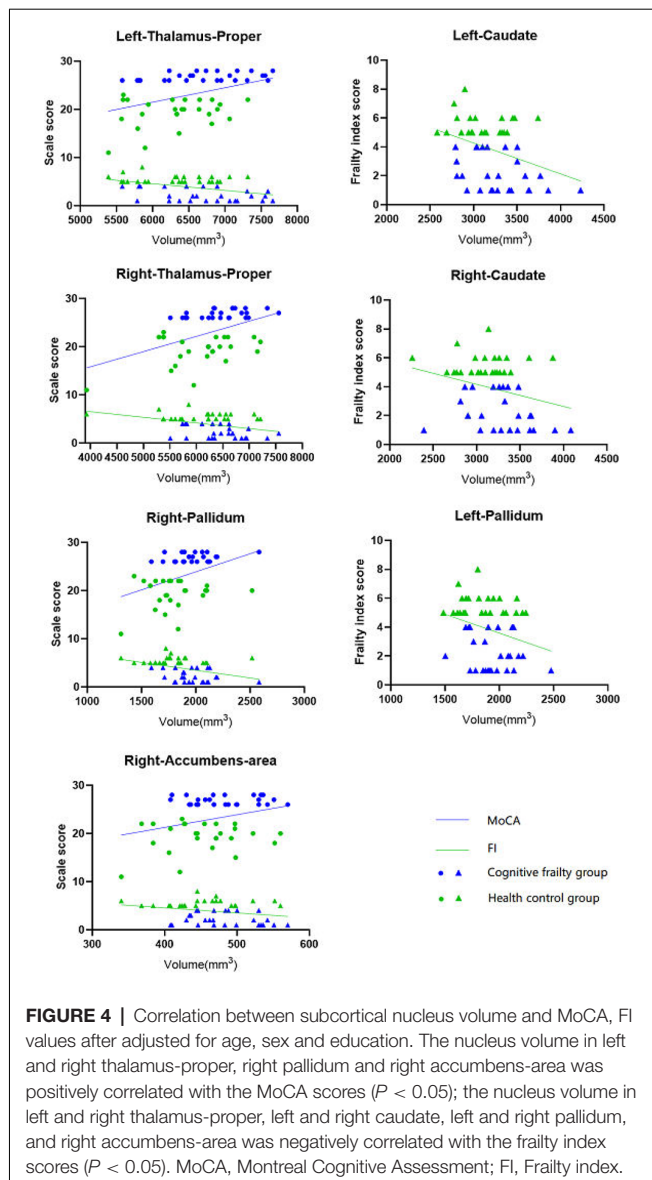

The globus pallidus is a principal component of the basal ganglia. The globus pallidus contains a rich concentration of neuropeptides and endogenous cannabinoids, which are important neural signaling molecules that affect brain function, including motivation, cognition, and action and are related

to nervous system diseases (Chen et al., 2020; Jakimovski et al., 2020). A study in patients with first-episode psychosis showed that worse cognitive performance was associated with decreased gray matter in the right globus pallidus (Dempster et al., 2017). The globus pallidus plays an important role in the pathogenesis of cognitive and behavioral disorders associated with Huntington disease (Singh-Bains et al., 2016a). Moreover, Nombela et al. (2019) reported that patients with Parkinson disease were treated with deep brain stimulation of the globus pallidus, and improvements in motor function were observed at the 2- to 3-month follow-up. The present study found that the pallidal volume in older adults with CF was lower than that in HCs and was correlated with cognitive decline and physical frailty. These findings were consistent with previous studies, indicating that the globus pallidus plays an important role in regulating cognition and movement. In this study, we also found that volume of the right accumbens area in older adults with CF was smaller than that in HCs and was related to both physical frailty and cognitive impairment, which might indicate that the accumbens area may participate in the regulation of cognitive and physical frailty together with the thalamus, caudate, and pallidum. According to Singh-Bains et al. (2016b), the globus pallidus and nucleus accumbens contribute to “limbic-motor integration” together by transforming the marginal motor signal into motor output. Therefore, the volume atrophy of the globus pallidus and accumbens could also be related to this. In fact, the human nucleus accumbens is an important structure in maintaining normal cognition, motivation, and emotional processes and is involved in some neuropsychiatric disorders (Cartmell et al., 2019). There was also a negative correlation between cognitive function and accumbens volume (Mavridis et al., 2011).

## LIMITATIONS

Our study had several limitations. First, the sample size in this study was relatively small. Although we implemented methodological approaches to minimize small sample effects by

matching patients and controls in age, sex, and education, it was possible not to detect group differences in certain tracts because of the lack of statistical power. In the future, a study with a larger sample size is needed to replicate our findings. Second, this study was a cross-sectional design, which limits causal and temporal inferences. Longitudinal follow-up studies will be required to better assess the relationship of neuroimaging changes and CF. Third, this study focused only on the main subcortical gray matter nuclei and excluded the cortex and white matter, but in fact, the realization of brain function is a reflection of the overall structure. Fourth, the volume of those subcortical nuclei was inevitably influenced by their part surrounding structure, because of lack of partial volume correction in image data processing. Even so, our current findings provide new insights into the pathological progression of CF.

**TABLE 4 |** Correlation of between the volumes of subcortical nuclei and MoCA, frailty index scores.

	MoCA		Frailty Index	
	R	P	R	P

\* $P < 0.05$  significant correlation coefficients.

## CONCLUSION

The present study shows that microstructural atrophy of the subcortical nuclei occurs in the brains of older adults with CF compared to those of healthy subjects, and the atrophy was correlated with the degree of cognitive decline and physical frailty. These findings demonstrate the involvement of subcortical nuclei in the pathological progression of CF.

## DATA AVAILABILITY STATEMENT

The datasets used and/or analyzed during the current study are available from the corresponding author upon request.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the second people's hospital affiliated to Fujian University of Traditional Chinese Medicine. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

GZ and LC conceived and designed the study. JT was in charge of coordination and direct implementation. MW and RX wrote the manuscript. MW, RX, HL, PQ, JH and YY managed the recruitment and the follow-up. All authors read and approved the final manuscript.

## FUNDING

This study is supported by the National Natural Science Foundation of China (<http://www.nsf.gov.cn>, No. 81574045).

## ACKNOWLEDGMENTS

We thank the participants and staff at the communities and hospitals for their work in this project, including Fujian University of Traditional Chinese Medicine Subsidiary Rehabilitation Hospital.

in Vascular Cognitive Impairment  
Raises the Possibility of Mixed  
Pathology With Lewy Body Disease.  
*Front. Neurosci.* 14:781.  
doi: 10.3389/fnins.2020.00781

**Objectives:** Tremor is common in patients with Lewy body disease (LBD) and not rare in normal individuals. Prevalence of tremor in patients with vascular cognitive impairment (VCI) and its association with other comorbidities are seldom studied. The aim of this study was to investigate the patient characteristics of VCI associated with tremor and to evaluate the possibility of mixed pathology with LBD in these patients.

**Methods:** Retrospective analysis of a large population with VCI registered in the database of a regional healthcare system was performed. VCI patients were divided into tremor and non-tremor groups. The associated characteristics including demographics, clinical features in motor and non-motor domains, vascular risk factors, and neuroimaging features were compared between the tremor group and the non-tremor group.

**Results:** Among 1337 patients with VCI, 292 (21.8%) had tremor, while 1045 (78.2%) did not have tremor. The tremor group had significantly higher prevalence of all motor and non-motor LBD clinical features than the non-tremor group. The tremor group also demonstrated more severe neuropsychiatric symptoms. Among patients with tremor, patients having tremor onset earlier than stroke onset showed significantly higher prevalence of rapid eye movement sleep behavior disorder. All comparisons were adjusted for age and severity of dementia.

**Conclusion:** Tremor is a common comorbidity of VCI. VCI patients with tremor had a higher prevalence of motor and non-motor LBD features. These findings raised the possibility of VCI patients with tremor having high possibility of mixed pathology with LBD.

**Keywords:** tremor, vascular cognitive impairment, Lewy body disease, risk factors, neuroimaging

## INTRODUCTION

Tremor is a common symptom/sign in patients with neurological as well as systemic disorders, and it occurs primarily during action or at rest (Bhatia et al., 2018). Tremor at rest is among one of the most important clinical features of Lewy body disease (LBD) including Parkinson's disease (PD) and dementia with Lewy bodies (DLB) (Postuma et al., 2015; McKeith et al., 2017). However, prevalence of resting or kinetic tremors in patients with vascular cognitive impairment (VCI) and their association with the comorbidities are seldom studied. A previous study showed that movement disorders were uncommon in stroke patients and only 1% of the stroke patients developed movement disorders after acute stroke (Ghika-Schmid et al., 1997). Atypical tremors are observed more commonly after acute stroke than typical action or resting tremors (Ghika-Schmid et al., 1997; Handley et al., 2009). Locations of brain lesions in tremor resulting from acute stroke were varied and included the cortical, subcortical, and cerebellar regions (Handley et al., 2009). Stroke in the midbrain, basal ganglia, or chronic small vessel cerebrovascular disease can result in acute onset of PD-like movement disorders or parkinsonism. This condition is termed "vascular parkinsonism" (van Zagten et al., 1998; Handley et al., 2009). A study of vascular parkinsonism revealed that one or more parkinsonian signs were observed in 36% of the patients with small vessel cerebrovascular disease, and clinically, 11% of those patients had parkinsonism (van Zagten et al., 1998). Despite the clinical presentation and association of VCI with vascular parkinsonism that has been documented, very few studies have focused on the comorbidity of tremor in VCI. A previous study on parkinsonian features including tremor among patients with mild cognitive impairment (MCI), vascular MCI, and subcortical vascular dementia revealed that prevalence of tremor was not different among these groups (Frisoni et al., 2002). Tremors as a comorbidity of stroke with or without cognitive impairment are not typical features of vascular parkinsonism. The predominant clinical feature in most cases of vascular parkinsonism is gait impairment rather than tremor (Korczyn, 2015). Therefore, according to the current evidence, the underlying mechanism of tremor associated with VCI is still unclear and deserves further investigation and clarification.

Mixed dementia have traditionally focused on the coexistence of Alzheimer's disease (AD) and CVD in the same demented patient (Langa et al., 2004; Custodio et al., 2017). However, pathological study did show that in persons with dementia, over 50% had multiple diagnoses including AD, PD/LBD, or CVD (Schneider et al., 2007). Validation studies on DLB consensus criteria have provided evidence with high specificity based on the characteristic clinical Lewy body features by comparing the pathological findings (Nelson et al., 2010; Skogseth et al., 2017). A study on AD with typical AD pathology also showed that Lewy-type synucleinopathy influences motor and non-motor clinical findings in AD patients (Savica et al., 2019). Multiple pathological processes are common in dementia patients, and they can affect the clinical presentations (Woodward et al., 2010). Based on these findings showing a high association of clinical Lewy body features

with Lewy body pathologies in LBD as well as in non-LBD patients, we proposed that the presentation of tremor should raise the possibility of co-existing LBD pathophysiology in patients with VCI (Postuma et al., 2015; McKeith et al., 2017; Bhatia et al., 2018). Therefore, the present study aimed to investigate the prevalence of tremor and the characteristics of VCI patients in various cognitive states for exploring the possibility of co-existing pathophysiology of LBD by observing and comparing the prevalence of clinical Lewy body features among patients with and without tremor.

## MATERIALS AND METHODS

### Database

This retrospective study selected participants registered in a dementia database of a healthcare system in Taiwan. From 2015/10/1 to 2019/9/30, a total of 6353 participants were registered in the database, and those who met the diagnosis of VCI ( $n = 1337$ ) were selected and analyzed. Normal elderly ( $n = 573$ ), patients with non-vascular MCI ( $n = 766$ ), AD ( $n = 1867$ ), DLB ( $n = 456$ ), PD ( $n = 334$ ), PD dementia ( $n = 309$ ), essential tremor ( $n = 311$ ), normal pressure hydrocephalus ( $n = 180$ ), frontotemporal dementia ( $n = 84$ ), other or undetermined dementia ( $n = 1475$ ) were excluded from the study. Only the patients who had undergone at least a cerebral computed tomography scan or cerebral magnetic resonance imaging (MRI) and a set of blood screening tests for ruling out other possibilities of cognitive decline that could be analyzed were included in the study. The following information recorded in the database was used in this study:

1. Age, gender, education, duration of motor dysfunction and cerebrovascular disease (CVD), subtypes of CVD, and current medication at the time of entry.
2. Dementia severity according to Clinical Dementia Rating Scale (CDR) (Morris, 1993).
3. A structured questionnaire including motor features (resting tremor, postural/action tremor, bradykinesia, rigidity, postural instability, asymmetric onset, and easily falling tendency) and non-motor features [cognitive fluctuation, parkinsonism, visual hallucinations (VHs), rapid eye movement (REM) sleep behavior disorder (RBD), severe neuroleptic sensitivity (SNS), depression, apathy, delusions, urinary frequency, incontinence, and constipation] for the diagnosis of DLB (Chiu et al., 2019).
4. Assessment of activities of daily living according to the Instrumental Activities of Daily Living (IADL) scale (Lawton and Brody, 1969).
5. Cognitive performance according to the Cognitive Abilities Screening Instrument, Chinese version (CASI C-2.0) (Lin et al., 2002) and the Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005).
6. Neuropsychiatric symptoms according to the 12-item version of the Neuropsychiatric Inventory (NPI) on the basis of observations within the past month (Cummings, 1988).

7. Clinically relevant vascular risk factors (VRFs) including hypertension, arrhythmia, coronary artery disease, diabetes, hyperlipidemia, and cerebrovascular disease (history of stroke/transient ischemic attack or the diagnosis of vascular encephalopathy in brain imaging).
8. A set of blood screening tests including complete blood count, COT, GPT, BUN, creatinine, total cholesterol, TG, LDL, ac glucose, HbA1c, TSH, free T4, RPR, vitamin B12, and folic acid.

## Assessment of Disease Severity and Subtypes

VCI in this database was diagnosed according to the criteria for probable vascular dementia, possible vascular dementia, and vascular MCI in the 2011 American Heart Association/American Stroke Association criteria for VCI (Gorelick et al., 2011). A diagnosis of DLB and its core clinical features was made according to the revised consensus criteria for probable DLB developed by the fourth report of the DLB consortium (McKeith et al., 2017). Fluctuation was diagnosed when a Mayo Fluctuation Composite Score (MFCS) > 2 (Ferman et al., 2004) was present. VHs were diagnosed when a clinical history of recurrent complex VHs were present. RBD was diagnosed when the minimal criteria for REM sleep behavior disorder according to the International Classification of Sleep Disorders, revised (American Academy of Sleep Medicine, 2001) was met. SNS was diagnosed when a clinical history was established for both the usage of neuroleptic drugs and an obvious association of adverse events with the neuroleptic drugs. Depression, apathy, and delusions were diagnosed by NPI. Urinary frequency, incontinence, and constipation were diagnosed according to chart recording. Cognitive tests of all patients were performed by a trained neuropsychologist. Severity and subtypes of dementia were diagnosed by a consensus meeting composed of neurologists, neuroradiologists, nuclear medicine doctors, and neuropsychologists.

## Data Analysis

The Chinese version of SPSS 22.0 for Windows (IBM SPSS Statistics, IBM Corp., Armonk, NY, United States) was used for statistical analyses. Comparisons of the demographic data including CDR, clinical features, IADL, CASI, MoCA, and composite scores (frequency vs. severity) of the NPI were performed between the tremor and the non-tremor VCI groups using the independent *t*-test and odds ratios (ORs) were adjusted for age and dementia severity according to CDR. VCI subtypes and CVD subtypes were analyzed using the chi-squared test. Clinical history of VRFs, current use of antipsychotics, and current use of antiparkinsonian drugs were analyzed using the chi-squared test and all ORs were adjusted for age and dementia severity according to CDR. To compare the associations of clinical motor and non-motor features and neuroimaging variables between the tremor group and the non-tremor group, all ORs were adjusted for age and dementia severity according to CDR.

## Ethical Considerations

The participants were selected from a dementia database of Show Chwan Healthcare System. The study design was retrospective and the data were analyzed anonymously. The Committee for Medical Research Ethics of Show Chwan Memorial Hospital reviewed the project and the Data Inspectorate approved the study.

## RESULTS

Among 1337 patients with VCI, 292 (21.8%) had tremor, while 1045 (78.2%) did not have tremor. In the tremor group, 48 (16.4%) had isolated resting tremor, 99 (33.9%) had isolated postural/action tremor, and 145 (49.7%) had resting as well as postural/action tremors. The tremor group had lower educational levels (4.1 vs. 5.0 years, OR = 0.95,  $p = 0.004$ ), longer duration of motor dysfunction (4.2 vs. 2.6 years, OR = 0.95,  $p < 0.001$ ), and more severe neuropsychiatric symptoms (NPI scores: 11.6 vs. 8.3, OR = 1.03,  $p < 0.001$ ) than the non-tremor group. Gender, duration of CVD, IADL, CASI, MoCA, VCI subtypes, and CVD subtypes showed no significant difference between the tremor group and the non-tremor group. Cognitive domains of CASI as well as MoCA were compared between tremor and non-tremor groups and showed no significant difference. Comparisons of the demographic data are summarized in **Table 1**.

The comparison of Lewy body clinical motor features revealed that the tremor group had significantly higher prevalence of all motor features ( $p < 0.001$  for bradykinesia, rigidity, postural instability, hypotonic/monotonic speech, and easily falling tendency) than the non-tremor group after adjustment for age and disease severity according to CDR. The comparison of Lewy body non-motor features showed that the tremor group had significantly higher prevalence of all non-motor features ( $p < 0.001$  for fluctuation of cognition, VHs, RBD, SNS, depression, urinary frequency, constipation, and incontinence) than the non-tremor group after adjustment for age and disease severity according to CDR. Patients in the tremor group also demonstrated significantly higher prevalence of delusions ( $p = 0.001$ ) and apathy ( $p = 0.015$ ). Clinically, At least two DLB core features and/or indicative biomarkers are essential for the diagnosis of probable DLB. Our analysis and comparison between the two groups showed that the tremor group had significantly higher probable DLB standard compliance than the non-tremor group (OR = 5.36,  $p < 0.001$ ) (**Table 2**).

**Table 3** demonstrates the comparisons of the relationship of CVD and dementia, VRFs, and current medication between the tremor group and the non-tremor group. After adjustment for age and dementia severity according to CDR, the tremor group had significantly higher prevalence of all VRFs including hypertension, diabetes, hyperlipidemia, and heart disease (all  $p$  values  $\leq 0.001$ ). Comparison of current medications revealed that the tremor group showed higher consumption of antiparkinsonian drugs ( $p < 0.001$ ) and antipsychotics ( $p = 0.002$ ) than the non-tremor group.

age and dementia severity according to CDR is demonstrated in Table 4. None of the MRI variables including Fazekas scale, global atrophy scale, medial temporal lobe atrophy scale, or microbleeds showed significant difference between the groups. The comparison of TRODAT variables also showed no significant difference in striatal background ratio, caudate putamen ratio, or rates of abnormal uptake between the groups.

We further compared clinical features between resting tremor group (*n* = 193) and isolated postural/action tremor group (*n* = 99). The results showed that no significant different between two groups in most of the motor and non-motor features except for bradykinesia (67.9 vs. 51.5%, OR = 2.01, *p* = 0.006) after adjustment for age and CDR. Motor features were also compared according to tremor onset asymmetry or not and the asymmetric group demonstrated significantly higher prevalence of bradykinesia (70.7 vs. 56.8%, OR = 1.87, *p* = 0.014), rigidity (62.1 vs. 47.7%, OR = 1.90, *p* = 0.009), postural instability (81.0 vs. 67.6%, OR = 2.08, *p* = 0.011), and easily falling (28.4 vs. 14.8%, OR = 2.39, *p* = 0.004). Besides, we also analyzed the clinical features among patients with tremor. Patients were divided into groups according to the temporal sequence of tremor and CVD. The results showed that the group showing tremor

## DISCUSSION

The present study has several important findings. A relatively high prevalence of resting and/or postural/action tremors (21.8%) was found in patients with VCI. This finding was not consistent with the findings of previous studies, which reported that the association of movement disorders and stroke was uncommon and only 1% of the patients developed movement disorders after acute stroke (Ghika-Schmid et al., 1997). This discrepancy in the results was probably due to the fact that motor deficit due to acute stroke tends to improve after the development of abnormal movement (Handley et al., 2009). However, our study investigated CVD patients with cognitive impairment without restricting the investigation to acute CVD. Therefore, the present study population was different from that in the previous studies. Moreover, tremors might have started before CVD and persisted without improving. The comparison of VCI patients in the tremor group and those in the non-tremor group showed no difference in the subtype of VCI (MCI or dementia stages) or in the location of CVD (cortical, subcortical, mixed location, infarct, or hemorrhage). These findings indicated that tremor in VCI patients was probably not simply caused by vascular disease itself. Instead, degenerative process might have contributed the most to the pathophysiology or the etiology of tremor. Furthermore, rather than atypical tremors related to acute stroke (Ghika-Schmid et al., 1997; Handley et al., 2009), VCI patients presented high prevalence of typical (resting and postural/action) tremors, which are traditionally regarded as tremors of neurodegenerative disorders (Zappia et al., 2013; Postuma et al., 2015; McKeith et al., 2017). Therefore, mixed vascular and degenerative pathologies were also implicated in this group of VCI patients with typical tremor. The longer duration of motor dysfunction in the tremor group compared to the non-tremor group represented a higher percentage of early onset of motor dysfunction (before the onset of CVD or VCI). In other words, among patients with tremor, movement disorders were diagnosed before the

diagnosis of CVD or VCI. Besides, the much higher prevalence of motor and non-motor diagnostic features of LBD in the tremor group provided further evidence of the possibility of the prevalence of mixed pathologies with LBD being higher in the tremor group. High percentage of abnormal dopamine transporter imaging studies and no difference in striatal uptake is reported between patients with and without tremor. We proposed that structure damage in the striatal region might probably contribute to the impairment of uptake of the dopamine transporter imaging. Besides, patients with clinical pictures of mixed Parkinson's disease were prone to have a dopamine transporter imaging. Therefore, abnormal uptake in both groups were relatively high in this study (44.3% in tremor and 58.7% in non-tremor group).

The higher prevalence of vascular risk factors (VRFs) including hypertension, diabetes, hyperlipidemia, and heart diseases in the tremor group were interesting and novel findings in VCI patients. Previous studies on the association between VRFs and VCI revealed that these factors contributed to the cardio-vascular diseases (CVD) attack or to the occurrence of cognitive impairment/dementia (Jeng et al., 1994; MacKnight et al., 2002; Schulz and Rothwell, 2003; Gorelick, 2004; Sahathevan et al., 2012; Staals et al., 2014). Besides, most of the midlife VRFs have been associated with increased neurodegenerative or vascular disorders and cognitive impairment as a comorbidity in late life (Kivipelto et al., 2001; Whitmer et al., 2005; Barnes et al., 2012). The contribution of VRFs has been well studied in patients with movement disorders. Patients with PD are associated with lower prevalence of VRFs or CVD (Scigliano et al., 2006). CVD and VRFs show significant association with motor and cognitive dysfunction in PD (Papapetropoulos et al., 2004; Malek et al., 2016). Therefore, these research findings might help explain our results of higher prevalence of VRFs in VCI patients with tremor. Furthermore, we proposed that VRFs contributed not only to the incidence of CVD and cognitive impairment but also to the incidence or progression of tremor-related movement disorders like LBD. For better clarification, we further analyzed the motor composite questionnaire (MCQ) (total score 6, **Table 2**) as well as the non-motor composite questionnaire (NMCQ) (total score 10, **Table 2**) in the present study and found that in the current VCI population, MCQ and NMCQ were higher in the hypertension group compared to the non-hypertension group (MCQ:  $2.0 \pm 1.8$  vs.  $1.5 \pm 1.7$ ,  $p < 0.001$  and NMCQ:  $2.8 \pm 2.4$  vs.  $2.2 \pm 2.3$ ,  $p < 0.001$ ); higher in the diabetes group than in the non-diabetes group (MCQ:  $2.1 \pm 1.8$  vs.  $1.6 \pm 1.8$ ,  $p < 0.001$  and NMCQ:  $3.0 \pm 2.4$  vs.  $2.3 \pm 2.4$ ,  $p < 0.001$ ); higher in the hyperlipidemia group than in the non-hyperlipidemia group (MCQ:  $2.1 \pm 1.8$  vs.  $1.6 \pm 1.8$ ,  $p < 0.001$  and NMCQ:  $2.9 \pm 2.3$  vs.  $2.3 \pm 2.4$ ,  $p < 0.001$ ); and higher in the heart diseases group than in the group with no heart diseases (MCQ:  $2.3 \pm 1.8$  vs.  $1.7 \pm 1.8$ ,  $p < 0.001$  and NMCQ:  $3.3 \pm 2.4$  vs.  $2.4 \pm 2.4$ ,  $p < 0.001$ ). In addition to age and dementia severity, we further adjusted gender, antiplatelet, and Fazekas scale, and the results were still the same as our original ones. Based on these findings, we may conclude that each VRFs could have contributed to the

presentation of motor as well as non-motor Lewy body features in patients with VCI.

Finally, it deserves attention that in this study, more than 80% of patients in the tremor group present parkinsonism, but only 16.4% were treated with antiparkinsonian drugs, indicating that neurologists mostly consider this neurological condition as a vascular parkinsonism, probably preventing patients from having a possibly effective treatment. Careful and detailed clinical assessment of associated symptoms in VCI patients with tremor to find out the possible comorbidity with PD or DLB should always be in mind.

The present study has some limitations. It was a retrospective study without pathological confirmation of the diagnosis. Therefore, the findings and the speculations were based only on clinical observations and neuroimaging. Clinical presentations in the present study were recorded based on a structured questionnaire, and though the interrater reliability test showed good reliability, accuracy and completeness of the clinical data needs to be verified. Only 10% of the participants in the study had received dopamine transporter imaging. Therefore, the reported contribution of LBD to VCI was based only on the clinical features. Further prospective studies based on biomarkers for LBD (CSF/plasma  $\alpha$ -synuclein and/or dopamine transporter imaging) are necessary to clarify the probability and the contribution of Lewy body pathology to VCI with tremor.

In conclusion, tremor is a common comorbidity of VCI. VCI patients with tremor had a higher prevalence of all motor and non-motor Lewy body clinical features and more severe neuropsychiatric symptoms. These findings raised the possibility of mixed pathology with LBD in VCI patients with tremor. Importantly, VCI patients with tremor showed higher prevalence of VRFs including hypertension, diabetes, hyperlipidemia, and heart diseases. However, causal relationship of VRFs in VCI with parkinsonism needs further study to be clarified.

Impairment Based on Eye Movement  
Parameters in an Aging  
Chinese Population.  
*Front. Aging Neurosci.* 12:221.  
doi: 10.3389/fnagi.2020.00221

**Background:** The pathogenesis of dementia often starts several years prior to clinical onset during which the individual is asymptomatic. Existing strategies for the accurate diagnosis of early dementia are limited by high cost and the invasive nature of the procedures. Eye movement parameters associated with cognitive functions may be helpful in the early identification of dementia and in the development and evaluation of preventive and therapeutic strategies.

**Objective:** We aimed to assess differences in eye movement parameters between healthy elderly individuals and patients with mild cognitive impairment (MCI). Furthermore, we examined the correlations between eye movement parameters with cognitive functions and specific hemispheric region and neural structures in individuals with MCI.

**Method:** Eighty individuals with MCI without dementia (based on DSM-IV criteria) identified by community screening and 170 healthy controls were administered Chinese versions of MoCA and NTB, and a long (20 min) or short (5 min) version of a visual paired comparison (VPC) task. Two weeks later, 44 MCI patients and 107 healthy controls completed a retest of the VPC task, 44 MCI patients and 43 healthy controls among them administered a MRI. At the end of 1-year follow-up, a subset of 26 individuals with MCI and 57 healthy controls were administered the long version of VPC task and MoCA test again. Eye movement parameters and the relationship of eye movement parameters with cognitive functions and with changes in neural structures were compared between groups.

**Results:** Patients with MCI were older, had less education, and had lower scores on cognitive tests than healthy controls. After adjustment for age and level of education, patients with MCI had lower novelty preference scores on the VPC than healthy controls. Using the logistic regression model, the amount of time that subjects focused on these novel images could predict MCI patients from normal elderly with an out of sample area

under the receiver operator characteristic curve of 0.62. Furthermore, the cognition score of subjects whose novelty preference score was low decreased more remarkably in 1 year. For both the patient and control groups, VPC novelty preference was significantly correlated with verbal fluency and delayed and short-term memory function. Novelty preference score was also significantly correlated with the cortical thickness of several structures in the right hemisphere.

**Conclusion:** Eye movement parameters are stable indicators to distinguish patients with MCI and cognitively normal subjects and are not affected by different testing versions and numbers. Additionally, the patients' cognitive deficits and eye movement indices were correlated. Future longitudinal studies should further explore the clinical utility of eye movement parameters as early markers of MCI.

**Keywords:** mild cognitive impairment, preclinical diagnosis, dementia, eye-tracking assessment, magnetic resonance imaging

## INTRODUCTION

The pathogenesis of dementia is mostly asymptomatic and begins many years before the onset of clinical symptoms. Patients with mild cognitive impairment (MCI) can still perform independent living activities and functions relatively well; however, they have declining verbal memory, visuospatial, and executive capacity (Petersen et al., 1999; Vega and Newhouse, 2014). Previously, MCI was assumed to be an intermediate state between normal aging and dementia that increased the risk of progression to Alzheimer's disease (AD). However, not all aging processes lead to cognitive impairment. Currently, MCI is regarded as a pathological condition of aging that requires better diagnostic strategies (Petersen, 2004; Galimberti and Scarpini, 2012).

Currently, there are several methods for predicting the progression of MCI, such as structural magnetic resonance imaging (MRI; Wood, 2016), functional imaging techniques (Jessen and Dodel, 2014), and analysis of biomarkers in the cerebrospinal fluid and peripheral blood (Hermida et al., 2012). However, these methods are limited by their high costs and invasive nature; furthermore, they are considered too restrictive for subdiagnosis among the MCI population (Vega and Newhouse, 2014).

The visual paired comparison (VPC) task is a nonverbal recognition task that can sufficiently challenge an individual's cognitive system, especially the memory. VPC has been shown to have high sensitivity and specificity for distinguishing normal elderly individuals and patients with the MCI. In the VPC task, an item is initially presented briefly, and after a specified time, the subjects are presented with the previously seen item together with a new item. The amount of time spent observing the new item, compared to that spent on the old item, is recorded and the preference for the new item is calculated as the novelty preference (NP) score (Zola et al., 2000; Lagun et al., 2011). Healthy controls tend to concentrate disproportionately more on the novel aspects of the environment (Haque et al., 2019; Jiang et al., 2019; Oyama et al., 2019). In the VPC tasks, the expected normal performance is that the subjects spend more time looking at new pictures than the old ones. In contrast,

memory impairment may be characterized by roughly equal amount of time spent reading fiction and familiarizing with pictures, which indicates an impaired declarative memory of previously observed images.

We aimed to establish a baseline pattern of association between cognitive function and eye-tracking parameters in patients with MCI. We primarily aimed to determine whether the NP score could distinguish patients with MCI from cognitively normal elderly individuals. As a secondary objective, we aimed to determine the correlation of eye movement parameters with various specific cognitive regions. Furthermore, we assessed whether eye movement parameters could indicate underlying regional brain dysfunction and help in the identification of underdiagnosed MCI in subsequent follow-up visits.

## MATERIALS AND METHODS

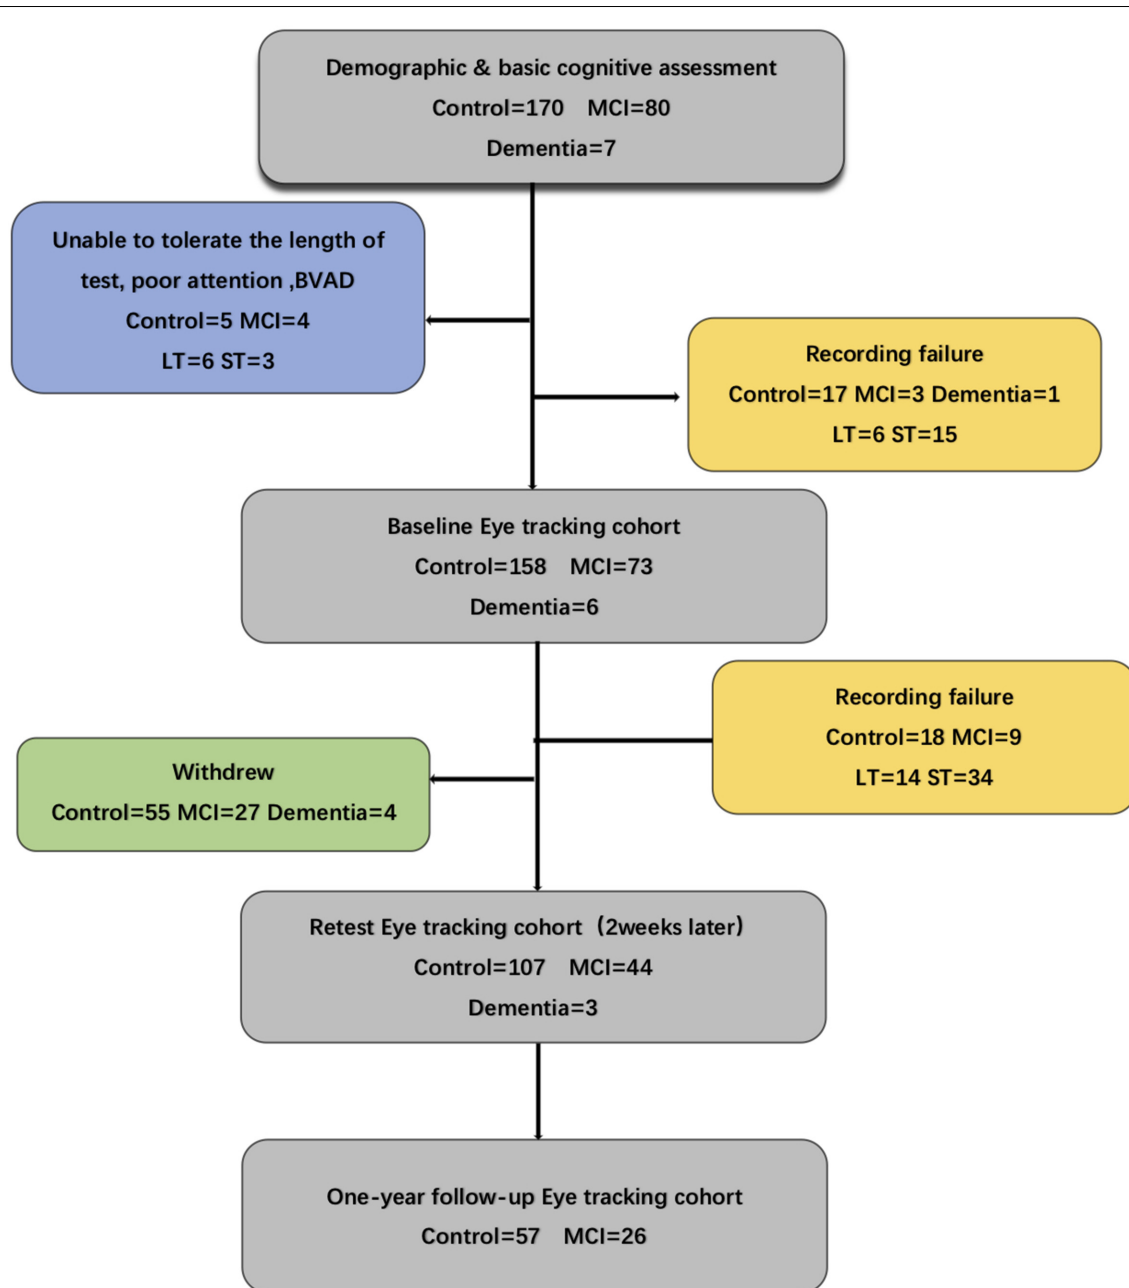

### Subjects and Clinical Classification

In this study, we recruited two groups of participants aged 65–80 years from four different communities in Shanghai and stratified them into MCI ( $n = 80$ ) and healthy ( $n = 170$ ) groups. One-hundred and fourteen participants completed the 12-month follow-up. We excluded subjects with other psychiatric illness; neurological, ophthalmological, or hearing impairment disorders; or inability to sit comfortably because of severe physical illness (Figure 1).

### Diagnostic Procedures

All clinical diagnoses were established by three different geriatric psychiatrists according to the results of standardized assessment and review. Clinical diagnosis of MCI required evidence of definite decline in memory (MoCA scores of  $>1.5$  SD of age-appropriate norms or abnormal memory function for age) and additional possible impairment of other cognitive domains, severity of symptoms or consequent functional limitation not meeting the DSM-IV dementia standard; a diagnosis of NC was made if participants demonstrated no evidence of cognitive decline as compared to their baseline cognitive functions on clinical interview and assessment. Exclusion criteria included

**FIGURE 1 |** Flow chart for the eye-tracking study indicating recording failure or problems with tolerance to the procedure. Several of the eye-tracking cohorts failed to complete the whole test. MCI, mild cognitive impairment; BVAD, binocular visual acuity differences; LT, long task: eye moving type sets of 30 min; ST, short task: eye moving type sets of 5 min.

a history of substance abuse, learning disability, dementia, and neurological (stroke, tumor, etc.) or psychiatric illness. Moreover, because the VPC task involves visual memory, subjects were excluded if: (1) the eye-tracking equipment could not record adequate pupil and corneal reflection because of physiological constraints or visual problems (such as droopy eyelid, cataracts, detached retinas, glaucoma, extremely small pupils, etc.); and/or (2) participants could not complete the eye-tracking calibration procedure (American Psychiatric

Association, 1990). Then, a detailed medical, social, and family history was obtained from each participant; they completed the following subtests: C-MoCA (Chinese Version of Montreal Cognitive Assessment) and C-NTB (Chinese Version of neuropsychological test battery) including WMDS (Wechsler Memory digit span), WMVis-I (Wechsler Memory Scale visual immediate), WMVis-D (Wechsler Memory Scale visual delayed), CFT (Category Fluency Test), COWAT (Controlled Word Association Test), RAVLT-I (Rey Auditory Verbal Learning

Test immediate), and RAVLT-D (Rey Auditory Verbal Learning Test delayed). This study was approved by the Institution Review Board of the Shanghai Mental Health Center. Written informed consent was obtained from all the participants or their representatives.

## Assessment of MR Image Acquisition and Processing

MRI scanning was performed using a Siemens Magnetom Verio 3.0T scanner (Siemens, Munich, Germany). We acquired T1-weighted images with 176 sagittal slices using the 3D magnetization-prepared rapid gradient-echo acquisition sequence with the following parameters: TR = 2,300 ms; TE = 2.98 ms; flip angle = 9°; and spatial resolution, 1 mm × 1 mm × 1.2 mm (Lin et al., 2018).

Reconstruction of cortical surfaces and cortical thickness measurements was performed using the automated reconstruction function in the FreeSurfer version 6.0 software as described by Dale et al. (1999).

## Assessment of Visual Exploration

The VPC task requires participants to sit comfortably in front of a monitor and keep their heads positioned on a chinrest to maintain their viewing position. During task performance, all participants' eye movements were recorded using an Applied Science Laboratories (ASL) Model 5000 remote pan/tilt camera system continuously. A ring of filtered, near-infrared light-emitting diodes illuminated the eye; a high-speed, near-infrared, sensitive charge-coupled device camera captured the pupil and corneal reflection. The gaze angle was determined by the relative positions of the corneal and pupil centers with an accuracy of  $\pm 0.75^\circ$ . The sampling frequency was 60 Hz, with a temporal resolution of 16 ms and linearity of less than 10%. The participants were seated approximately 26 inches from a 19-inch flat panel computer screen that displayed the stimuli. No physical constraints other than a chinrest were used. The eye position was calibrated for each subject using an infrared eye-tracker instrument for 1–2 min. Calibration for each subject was accomplished using a 9-point array. Data of eye fixation and eye movement were recorded with the ASL EYEPOS software. In our present study, we used the dispersion-based fixation detection algorithm from Crutcher MD. The duration threshold was set to 100 ms, and the dispersion threshold was set to five points in eye tracker units ( $2^\circ$  of visual angle). The eye fixation and movement data were all recorded with ASL EYEPOS software system. All acquired black and white pictures were high contrast measuring 4.4 inches wide and 6.5 inches high. Unique pictures were used for each trial (Crutcher et al., 2009). System parameters were adjusted until the subject's fixations were accurately mapped onto the calibration points. Subjects were informed preemptively that images would begin to appear on the computer screen before the test and were instructed to look at the images as if they were watching television. The subjects' eye movements and fixations were recorded and stored for subsequent analyses. Two types of tasks were used; namely, long and short tasks. The long task (LT) lasted approximately

30 min, whereas the improved short test (ST) required about 10 min, including calibration.

Participants performed a memory paradigm based on eye movements. Each trial in the task consisted of the following two phases: an initial familiarization phase and a subsequent test phase. Subjects were asked to complete the 9-point calibration procedure before taking the VPC task. During the familiarization phase, two identical two-dimensional black-and-white images were presented side by side on the monitor for 5 s. Next, the monitor went dark for a delay interval of either 2 s or 2 min. In the subsequent test phase, the images were again presented side by side for 5 s. One of the images was identical to the previously presented image, whereas the other was a new image. Presentation of the novel image on either the left or right side was randomly selected and equally distributed. After the test phase, the monitor went dark for 20 s and the next task was initiated. To ensure the subject maintained complete attention during the test trials with a 2-min delay interval, the experimenter alerted all the subjects 10 s before the presentation of the next image pair. For the long task, participants were administered two blocks of 10 trials (delay order: 2-s delay, 2-min delay) for a total of 20 trials. The short task contains three trials (Figure 2). The visual search task was used to determine the NP parameter. The eye data parameter called novelty preference (NP) was obtained by calculating the percentage of time spent staring at the novel image by extracting and analyzing the eye fixation and movement data for each participant. The cognitive and eye-tracking assessments were performed on the same day or within a 5-day interval. The whole assessment was completed within approximately 1.5 h, including the rest intervals (Xiao et al., 2013; Pereira et al., 2014).

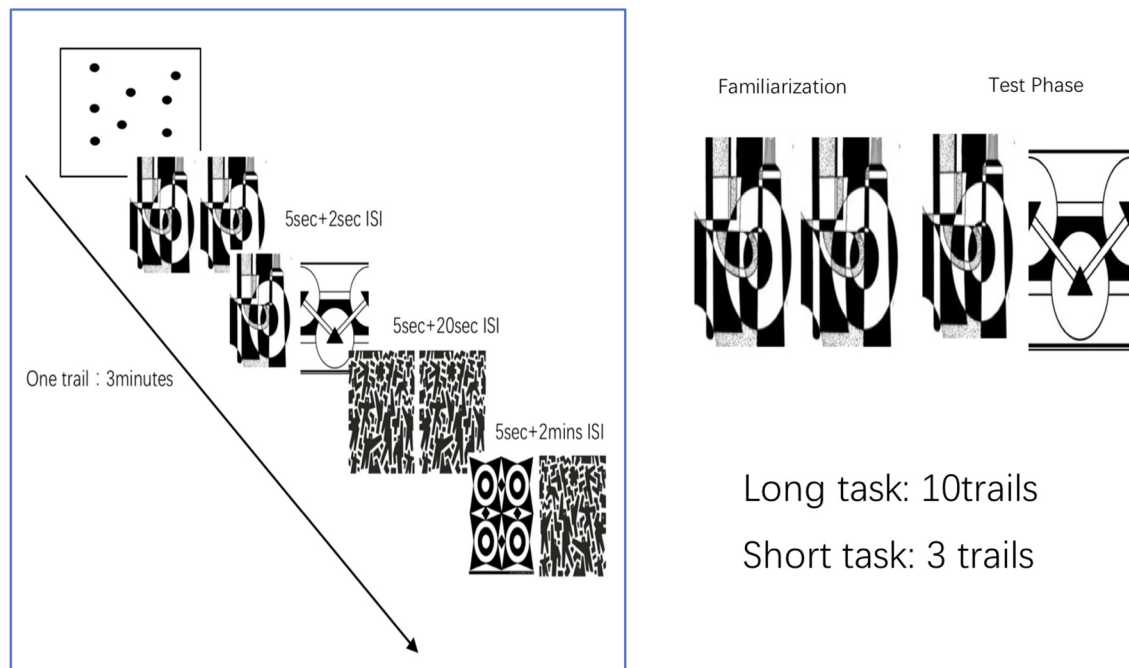

## Statistical Analysis

Statistical analysis was performed using SPSS Version 22. We used independent sample *t*-tests to perform between-group comparisons of the demographic data, cognitive tests scores. Non-parametric test was applied to compare the rate of decline of MoCA score. The eye-tracking parameters among groups were analyzed by one-way ANOVA followed by the Tukey–Kramer test and multiple comparison adjusted for age and years of formal education. Partial correlation was used to determine the correlation between the novel preference score and the cognitive scores, and cortical thickness. The diagnostic performances of the eye-tracking-based cognitive assessment were determined using a ROC analysis. Statistical significance was set at  $p < 0.05$  on a two-tailed test.

## RESULTS

### Demographic and Clinical Characteristics

The mean age of the control group was 71.1 years with a female-to-male ratio of 2.7:1; the mean age of the MCI group was 73.0 years ( $p < 0.001$ ) with a female-to-male ratio of 3.4:1 ( $p > 0.05$ ). The control group had a significantly higher mean c-MoCA scores (25.8) than the MCI group (20.9;  $p < 0.001$ ), and mean NTB scores (218.4) than the MCI group (184.8;  $p < 0.001$ ). All participants with MCI scores (11.8) had lower

**FIGURE 2 |** Visual paired comparison task (VPC). Subjects were asked to complete the 9-point calibration procedure before taking the VPC task. During the familiarization phase, participants viewed the two identical pictures presented on the monitor side by side for 5 s. Next, the monitor went dark for a delay interval of either 2 s or 2 min. The test parameters consisted of the presentation of one previously presented image and the novel image. After the test phase, the monitor went dark for 20 s and the next task was initiated. For the long task, participants were administered two blocks of 10 trials (delay order: 2-s delay, 2-min delay) for total 20 trials. The short task contains three trials.

years of education than the control group (12.8;  $p < 0.001$ ). Moreover, the MCI group performed significantly worse than the normal elderly group in cognitive function tests, especially in verbal fluency ( $p < 0.05$ ), attention ( $p < 0.01$ ), abstraction ( $p < 0.001$ ), and verbal memory domains ( $p < 0.001$ ) in the NTB and C-MoCA tests (Table 1).

## Eye-Tracking Performance

At baseline, the MCI group [0.62 (0.08)] performed significantly worse than the control group [0.66 (0.09)] in the time spent looking at the novel image in the long task ( $p < 0.05$  for MCI vs. controls). There was no significant between-group difference in the novelty preference score in the short task [0.57 (0.05) vs. 0.56 (0.07),  $p > 0.05$  for MCI vs. controls]. Two weeks later 44 MCI patients and 107 healthy controls completed a retest of the VPC task; in the retest task, compared with cognitively normal elderly individuals, the MCI group had significantly shorter novelty exploration durations in the short task [0.54 (0.05) vs. 0.61 (0.09),  $p < 0.05$  for MCI vs. controls; Table 2]. Receiver operating characteristic (ROC) curve analysis revealed an area under the ROC curve (AUC) for novelty preference scores in the long task to be 0.62 (asymptotic significance = 0.03; 95% CI = 0.52–0.73). A cutoff value of 0.605 (a phonemic advantage) indicated 70% accuracy, 72% specificity, 53% sensitivity, 40% positive predictive values (PPV), and 82% negative predictive values (NPV) for the diagnosis of MCI.

Results of independent sample  $t$ -test indicated that, based on the three test pairs of long task twice, short task twice, or one long task and short task each, there were no significant between-group differences in the NP score in the repeated long tasks [normal group: 0.65 (0.02) vs. 0.66 (0.02),  $t = 0.3$ ,  $df = 51$ ,  $p = 0.75$ ; MCI group: 0.62 (0.02) vs. 0.63 (0.03),  $t = 0.2$ ,  $df = 20$ ,  $p = 0.81$ ] and the repeated short tasks [normal group: 0.58 (0.02) vs. 0.63 (0.02),  $t = 1.9$ ,  $df = 44$ ,  $p = 0.05$ ; MCI group: 0.55 (0.01) vs. 0.53 (0.01),  $t = 0.68$ ,  $df = 18$ ,  $p = 0.51$ ; Table 3].

## Correlations Between Eye-Tracking Parameters, Cortical Thickness, and Cognitive Functions

From the results of partial correlation analysis (with age and years of education as the control factors), novelty preference score correlated positively with performance in the verbal fluency test in the vegetable categories ( $R = 0.37$ ,  $p = 0.04$ ), short-term memory ( $R = 0.41$ ,  $p = 0.02$ ), and delay recall scores ( $R = 0.14$ ,  $p = 0.00$ ; Figure 3). There are no significant differences in the following cortical thickness between the two groups. The MRI results demonstrated a positive correlation between the novelty preference score and cortical thickness in various cerebral regions on the right hemisphere [temporal thickness, superior frontal lobe, rostral anterior cingulate cortex (rACC), and precuneus thickness;  $R = 0.24$ ,  $p = 0.02$ ;  $R = 0.22$ ,  $p = 0.04$ ;

$R = 0.24$ ,  $p = 0.04$ ; and  $R = 0.22$ ,  $p = 0.04$ ; respectively]. The statistically significant correlations are summarized in **Figure 4**.

## Longitudinal Case–Control Analysis

One-hundred and fourteen participants completed the 12-month follow-up, 31 of whom completed only the MoCA test, and the rest have completed both the MoCA and the long version of the VPC task. Moreover, nine participants progressed from normal to MCI during the study period, 57 of the subjects are stable normal, and 17 participants are stable MCI (**Table 4**). There was no difference in novelty preference scores between progressors and non-progressors including stable MCI and normal. Among all the participants who completed the 12-month follow-up, 62 participants show a decline in cognition scores—46 normal elderly individuals and 16 patients with MCI. The degree of decline of MoCA score (%) was calculated as follows:  $\text{MoCA total score baseline} - \text{MoCA total score endpoint} / \text{MoCA total score baseline} \times 100$ . Results of the non-parametric test showed that there were no significant differences between the MCI and control groups for the degree of decline of cognition [normal group vs. MCI group, 0.04 (0.00–0.07) vs. 0.05 (0.01–0.09),  $z = -1.1$ ,  $p = 0.26$ ; **Figure 5A**]. Based on the ROC analysis above, we find that the novelty preference scores of 0.605 in the long task had high specificity to discriminate MCI from normal. According to that, 62 participants who took the long task at baseline were categorized into the following two groups: above cutoff point group ( $n = 23$ ) and below cutoff point group ( $n = 39$ ). Cognitive score in the below cutoff point group decreased more than that in

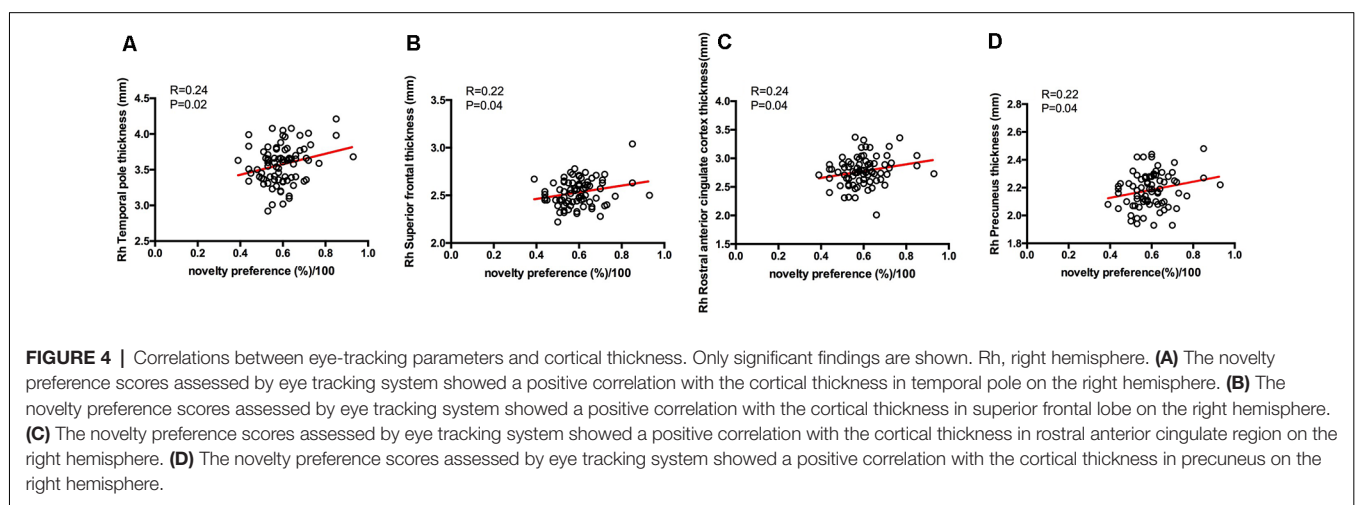

the above cutoff point group [above cutoff point group vs. below cutoff point group: 0.04 (0.00–0.04) vs. 0.04 (0.04–0.09),  $z = -2.5$ ,  $p = 0.01$ ; **Figure 5B**].

On partial correlation analysis (with age and years of education as the control factor), novelty preference score correlated negatively with the degree of decline of MoCA score ( $R = -0.33$ ,  $p = 0.01$ ; **Figure 5C**).

## DISCUSSION

In this study, we assessed the NP score in the eye-tracking task as a simple, novel, and non-invasive diagnostic biomarker of MCI. We found that this NP score accurately distinguished patients with MCI from cognitively normal subjects. In our subsequent retest study, we found that eye movement parameters were stable indicators of cognition and were not affected by the paired testing types and testing times. The improved version could reduce data loss and ensure retention of the sensitivity and specificity of the test. Furthermore, participants with poor novelty preference score showed more decline in cognition in 1-year follow-up. Our study suggests that the VPC task in combination with near-infrared eye-tracking might be helpful to explore the underlying dysfunctions in brain regions.

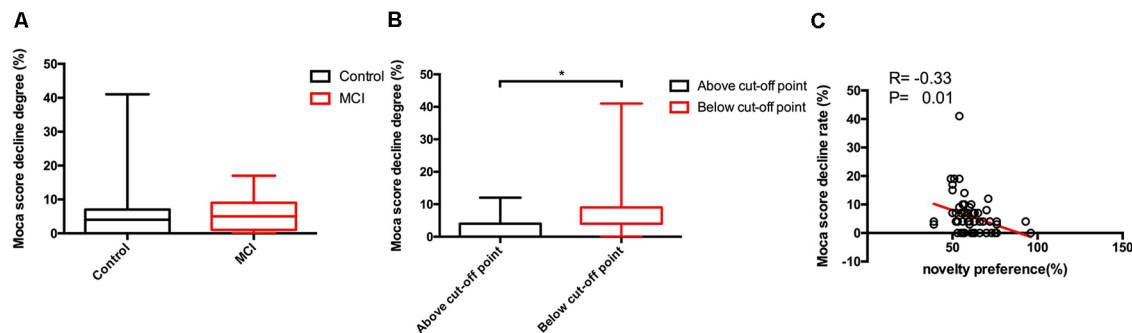

Therefore, although further longitudinal clinical studies are needed, our findings suggest that novelty preference scores in the VPC task could be an easily accessible physiological marker for diagnosis of MCI and might help to identify “seemingly healthy” subjects who are underdiagnosed for MCI.

**TABLE 4 |** Eye movement indices according to the Group (non-Progressor groups: MCI stable and control stable group, Progressor group) using the Kruskal–Wallis test followed by Steel–Dwass multiple comparison tests.

Eye-tracking variables	Non-progressor Control group		Non-progressor MCI group		Progressor group		<i>p</i> -value
	<i>n</i>	Mean (SD)	<i>n</i>	Mean (SD)	<i>n</i>	Mean (SD)	
Novelty preference, in percentages (SD)	57	0.60 (0.08)	17	0.58 (0.08)	9	0.60 (0.10)	0.885

Only significant findings are shown. Control, normal elderly; MCI, mild cognitive impairment; MoCA, Montreal Cognitive Assessment. Data are expressed as mean  $\pm$  SD. **(A)** No significant differences of the decline degree of Moca scores in 1 year follow-up were found between control and MCI group. **(B)** Significant differences of the decline degree of Moca scores in 1 year follow-up were apparent between above cut-off point and below cut-off point group. **(C)** The novelty preference scores assessed by eye tracking system showed a negative correlation with the decline degree of Moca scores in 1 year follow-up. \* $p < 0.05$ .

## Eye Movement Parameters in the MCI Group

Patients with MCI show equally distributed observation times between the new and familiar pictures; however, normal individuals tend to focus disproportionately more on the novel pictures (Berlyne, 1960; Loftus and Mackworth, 1978; Fernández et al., 2018). The original long task allows participants to understand the operational process; however, the short task cannot. Therefore, our major finding from the eye-tracking task was the novelty preference score of the long task, which was low in the MCI group, similar to that reported by Crutcher et al. (2009). It should be noted that diagnosing MCI is more difficult than diagnosing dementia owing to the lack of objective indicators and boundaries between MCI and normal elderly are difficult to ascertain. Our method achieved a specificity of 72% for distinguishing subjects with MCI from normal controls. The results indicated that the VPC task could distinguish patients with cognitive impairment from normal elderly individuals based on the eye-tracking data and that the novelty preference score could probably be used as an objective indicator. Our test can also be suitably expanded to communities for its convenience. However, there remains a need for further improvement of eye movement parameters for the PPV exhibited by our method is a little lower than the values reported for some test for AD subjects (Lagun et al., 2011). In the retest task, the subjects, especially the cognitive-normal elderly individuals, could not concentrate on the test, as observed in the findings from our subjects. Given the increased potential for loss of data because of the poor attention spans and physical condition of elderly individuals, the discriminatory effect was not found in the retest task. Interestingly, patients with MCI who were subjected to a 2-week delay had low novelty preference scores in the short task.

Based on the results of our repeated tasks, eye movement parameters were identified as stable indicators of cognition that remain unaffected by learning effects. Therefore, use of

the long task followed by the short task and performing comparisons between the results of the two tasks could sufficiently increase task sensitivity and decrease the physical and psychological burden on subjects. Development of an improved version might further facilitate validity and decrease the failure rate.

Based on the 1-year follow-up results, participants who progressed to MCI during the study period did not show significantly low novelty preference scores. Compared with cognitive-normal elderly individuals, patients with MCI also did not show a larger magnitude of decrease in cognition. Based on the ROC analysis above, we find that the novelty preference scores of 0.605 in the long task has a high specificity for discriminating MCI from normal. According to it, the cognition score of participants, regardless of MCI or normal aging group whose novelty preference score was below the cutoff point, decreased more remarkably in 1 year. It is possible that some healthy control patients were actually undiagnosed cases of MCI. They might have cognition impairment that is not detected by the available scales. This shows that the diagnosis of MCI urgently needs to be combined with objective indicators in the future.

## Correlations Between Cognitive Function, Neuroanatomical, and Eye Movement Parameters

The novelty preference score positively correlated with verbal fluency and verbal memory in both the short-term memory and delay recall tasks. At the neuroanatomical level, the aforementioned cognitive functions are controlled by the temporal and parietal regions of the brain. In our study, 80 of our subjects underwent MRI scanning at baseline, which showed no evidence of acute territorial infarction, mass effect, hemorrhage, infection, or midline shift. We found that the novelty preference score tends to correlate positively with the cortical thickness of specific functional regions of the right brain, including the temporal pole region, superior frontal

lobe, rACC, and precuneus. Previously, patients with MCI were reported to have poor performance for episodic memory and executive function, which correlated with the level of atrophy in the right superior temporal pole structures (Ruiz López et al., 2008). Compared to the left hemisphere, the correlations between verb and letter fluency were more robust in the right hemisphere. The temporal lobe is considered the center of verbal recognition memory; furthermore, semantic verbal fluency task is more sensitive to assess temporal region impairments (Henry and Crawford, 2004; Clark et al., 2014; Wong et al., 2018). Previous findings indicate that the VPC task is specifically more sensitive to assess medial temporal lobe (MTL) dysfunction in patients with MCI (Clark et al., 2014). More importantly, a study on patients with schizophrenia indicated decreased cortical thickness in the superior frontal region, which is related to decreased cognitive function and role control (Ong et al., 2005). The rACC plays a key role in the regulation of both emotional and motivational information, as well as in the regulation of emotional response (Tully et al., 2014). A previous study indicated that individuals with late-onset depression and cognitive impairment have decreased cortical thickness of the rACC (Bush et al., 2000). The precuneus not only is involved in self-consciousness but also plays an essential role in the integration of visual-spatial information and retrieval of episodic memory (Lim et al., 2012). The function of the precuneus might be influenced by cortical thinning, early amyloid deposition, and hypometabolic alterations in this region that are induced by the pathologic processes in MCI (Bailly et al., 2015a,b; Haussmann et al., 2017). Taken together, our results show that these regions tend to be closely related to cognitive function and emotional regulation, and reduced cortical thickness may impede their function. Findings of MRI and VPC task provide some evidences of impaired performance in the VPC task preceding detectable structural changes in the memory and emotional control system; however, the correlations between VPC score and MRI findings are weak; additional evidences are needed to support and validate our findings.

### Possible Clinical Practice of VPC Task in Profiling and Predicting Preclinical Dementia

Two to five years before the onset of AD, patients experience slight neurological deficits in cognitive abilities, indicative of MCI. A previous study (Coutinho et al., 2015) reported that damage in the MTL memory system can predict the risk of dementia and that there were related deficits in visual short-term memory (VSTM) between the AD and MCI stage. Given that we observed possible correlation among novelty preference score with temporal-parietal cognitive functions and typical regional thickness, the potential utility of the novelty preference score as an early marker of MCI cannot be ruled out. However, future longitudinal studies are required to confirm these correlations and the ability to identify underdiagnosed cases of MCI.

Despite not being widely available, the measure derived from the device-based VPC task is valuable clinically. As a

physiological marker, its performance is not influenced by subjects' educational and intelligence levels. Our improved eye-tracking tasks were well-tolerated because of their shorter testing times compared to those of the original type. For example, our visual search task required only 5–10 min to complete, including calibration. However, this device has shortcomings in that participants with eyelid apraxia or ophthalmological disorders may have difficulty completing the task.

### Limitations and Future Research Directions

The present study has several limitations. Since there was lack of information on the premorbid intelligence of the participants, the assessed cognitive function may not completely reflect the true cognitive decline. Moreover, it is undeniable that the correlation between NP scores and cognitive tests scores and MRI findings is weak, and more evidences between them are needed in future. MCI patients are quite heterogeneous; however, we did not subdivide different MCI subtypes, like amnesic plus additional cognitive domains. Older-old people ( $\geq 75$  years old) have an even high risk of dementia, and the mean age of our subjects was 71 years, which was relatively young. We will pay more attention to investigate the characteristics of various types of MCI and expand age range in further research.

In our study, we identified a simple, novel, non-invasive diagnostic biomarker of MCI and established an optimal model to distinguish patients with MCI from cognitively normal elderly individuals in China using a relative large scale. Furthermore, we observed that eye movement parameters may predict the rate of cognition decline. It is worthy to conduct further follow-up assessments of our current subjects to test the robustness of the correlations with disease progression. Since we have already started the follow-up visits and have accumulated the results for 1-year follow up, we hope to further establish the relationship between cognitive functions and eye-tracking parameters and adopt the VPC task as a possible adjunctive measurement to identify underdiagnosed cases of MCI with further follow-up visits.

Graphical, voxel, and region-based analysis has become a popular approach to studying neurodegenerative disorders such as Alzheimer's disease (AD) and its prodromal stage [mild cognitive impairment (MCI)]. These methods have been used previously for classification or discrimination of AD in subjects in a prodromal stage called stable MCI (MCIs), which does not convert to AD but remains stable over a period of time, and converting MCI (MCIC), which converts to AD, but the results reported across similar studies are often inconsistent. Furthermore, the classification accuracy for MCIs vs. MCIC is limited. In this study, we propose combining different neuroimaging modalities (sMRI, FDG-PET, AV45-PET, DTI, and rs-fMRI) with the apolipoprotein-E genotype to form a multimodal system for the discrimination of AD, and to increase the classification accuracy. Initially, we used two well-known analyses to extract features from each neuroimage for the discrimination of AD: whole-brain parcellation analysis (or region-based analysis), and voxel-wise analysis (or voxel-based morphometry). We also investigated graphical analysis (nodal and group) for all six binary classification groups (AD vs. HC, MCIs vs. MCIC, AD vs. MCIC, AD vs. MCIs, HC vs. MCIC, and HC vs. MCIs). Data for a total of 129 subjects (33 AD, 30 MCIs, 31 MCIC, and 35 HCs) for each imaging modality were obtained from the Alzheimer's Disease Neuroimaging Initiative (ADNI) homepage. These data also include two APOE genotype data points for the subjects. Moreover, we used the 2-mm AICHA atlas with the NiftyReg registration toolbox to extract 384 brain regions from each PET (FDG and AV45) and sMRI image. For the rs-fMRI images, we used the DPARSF toolbox in MATLAB for the automatic extraction of data and the results for REHO, ALFF, and fALFF. We also used the pyClusterROI script for the automatic parcellation of each rs-fMRI image into 200 brain regions. For the DTI images, we used the FSL (Version 6.0) toolbox for the extraction of fractional anisotropy (FA) images to calculate a tract-based spatial statistic. Moreover, we used the PANDA toolbox to obtain 50 white-matter-region-parcellated FA images

on the basis of the 2-mm JHU-ICBM-labeled template atlas. To integrate the different modalities and different complementary information into one form, and to optimize the classifier, we used the multiple kernel learning (MKL) framework. The obtained results indicated that our multimodal approach yields a significant improvement in accuracy over any single modality alone. The areas under the curve obtained by the proposed method were 97.78, 96.94, 95.56, 96.25, 96.67, and 96.59% for AD vs. HC, MCIs vs. MCIC, AD vs. MCIC, AD vs. MCIs, HC vs. MCIC, and HC vs. MCIs binary classification, respectively. Our proposed multimodal method improved the classification result for MCIs vs. MCIC groups compared with the unimodal classification results. Our study found that the (left/right) precentral region was present in all six binary classification groups (this region can be considered the most significant region). Furthermore, using nodal network topology, we found that FDG, AV45-PET, and rs-fMRI were the most important neuroimages, and showed many affected regions relative to other modalities. We also compared our results with recently published results.

**Keywords:** Alzheimer's disease, multimodal fusion, sMRI, FDG-PET, AV45-PET, DTI, rs-fMRI, APOE genotype

## INTRODUCTION

Alzheimer's disease (AD) is a neurodegenerative disorder that is characterized by chronic cortical atrophy (such as posterior cingulate atrophy and medial temporal atrophy), and by a progressive decline in cognitive function (Bishop et al., 2010; Albert, 2011). AD is typically diagnosed in people older than 65 years (Qiu and Kivipelto, 2009). As the life span of the population increases, the prevalence of AD and its costs to society are also increasing. Therefore, the detection of AD or its precursor forms, i.e., mild cognitive impairment (MCI) (Petersen, 2004) is an important aim in biomedical research for providing new therapeutics that help to slow the progression of AD. MCI is a transitional phase (which signifies an intermediate stage of functional and cognitive decline in normal aging and dementia patients) that is characterized by memory disturbance in the absence of dementia (Petersen, 2004; Angelucci et al., 2010), followed by widespread cognitive deficits in multiple domains until a disability threshold is reached. MCI is said to be prodromal AD (Petersen, 2004); subjects go on to develop an AD [this type of patient falls into an MCI-converting (MCIC) group]. Symptoms emerge, on average, within 2–3 years (Lopez et al., 2012). A prospective population-based study in the elderly showed that the conversion rate of MCIC patients to AD or to different forms of dementia is about 10–15% per year (Mitchell and Shiri-Feshki, 2009; Lopez et al., 2012; Wei et al., 2016). Despite our substantial knowledge of MCI converters, little is understood about the 47–67% (Ganguli et al., 2004; Lopez et al., 2012; Clem et al., 2017) of subjects diagnosed with MCI who neither return to normal cognition nor convert to dementia. In a study performed in a large community sample, 10 years identified as a MCI, 21% of those suspected to be at a greater risk for converting to dementia (Dubois and Albert, 2004; Jicha et al., 2006) managed to remain with a diagnosis of MCI (Ganguli et al., 2004; Clem et al., 2017). These studies suggest that certain subjects may not convert to AD, but rather remain diagnostically stable over a period of time (this type of patient falls into an

MCI-stable, or MCIs group). Recent results from neuroimaging studies support the hypothesis that AD includes a disconnection syndrome (implying network-wide functional changes due to local structural changes) generated by a breakdown of the organized structure and functional connectivity (FC) of multiple brain regions, even in the early phase of MCI or before conversion to AD (Dubois and Albert, 2004; Bishop et al., 2010; Daianu et al., 2013; Clem et al., 2017; de Vos et al., 2018).

Previous studies have shown the potential of invasive and non-invasive biomarkers to predict conversion from MCI to AD dementia. For invasive markers, the APOE- $\epsilon 4$  genotype (for the carriers of the APOE- $\epsilon 4$  allele, brain alterations associated with AD may begin as early as infancy) (Liu et al., 2013; Dean et al., 2014), and amyloid-beta ( $A\beta$ ) accumulation and neurofibrillary lesions are considered to be most important biomarkers for AD (Murphy and LeVine, 2010). Apolipoprotein-E (APOE) genotype polymorphism is considered to be the most common polymorphism in neurodegenerative diseases and has been consistently linked to normal cognitive decline in AD and MCI patients. APOE- $\epsilon 4$  is the strongest genetic risk factor, and it increases the risk for AD twofold to threefold. Furthermore, it lowers the age of AD onset (Michaelson, 2014). Recent developments in non-invasive neuroimaging techniques, including functional and structural imaging, have given rise to a variety of commonly used neuroimaging biomarkers for AD. Among the multiple neuroimaging modalities, structural magnetic resonance imaging (sMRI) has attracted significant interest due to its ready availability for mildly symptomatic patients and its high spatial resolution (Cuingnet et al., 2011; Salvatore et al., 2015; Wei et al., 2016; Long et al., 2017; Gupta et al., 2019b,c; Sun et al., 2019). sMRI can also reveal abnormalities in a wide range of brain areas, including gray matter (GM) atrophy in the medial temporal lobe and hippocampal/entorhinal cortex, which are identified as valuable AD-specific biomarkers for the discrimination or classification of AD patients (Cuingnet et al., 2011). In diffusion tensor imaging (DTI, or diffusion MRI), water diffusion

in the brain is interpreted as an MR signal loss. Because neurodegenerative processes are accompanied by a loss of obstacles that restrict the motion of water molecules (Acosta-Cabronero and Nestor, 2014), DTI can reveal promising markers of microstructural white matter (WM) damage in AD and MCI patients. A connectivity-based analysis that applied graph theory to DTI data demonstrated disrupted topological properties of structural brain networks in AD, supporting the disconnection theory. Specifically, regional diffusion metrics for the limbic WM in the fornix, posterior cingulum, and parahippocampal gyrus have shown better performance than volumetric measurements of the GM in predicting MCI conversion (Sun et al., 2019). In clinical studies, fluorodeoxyglucose-positron emission tomography (FDG-PET), florbetapir-PET AV45 (amyloid protein imaging), and resting-state fMRI (rs-fMRI) are the most commonly used functional neuroimaging methods for AD diagnosis (Hojjati et al., 2018, 2017; Gupta et al., 2019a; Pan et al., 2019a,b). FDG-PET measures cerebral glucose metabolism via 18F-FDG in the brain, and helps to detect characteristic regional hypometabolism in AD patients, which reflects the neuronal dysfunctions in the brains of AD patients (Mosconi et al., 2008). In contrast, florbetapir-PET AV45 measures the accumulation of amyloid protein in AD brain homogenates and has faster *in vivo* kinetics. The use of florbetapir in amyloid imaging was recently validated in an autopsy study, and its safety profile allows its clinical application for brain imaging (Camus et al., 2012). Moreover, rs-fMRI imaging has been developed as a tool for mapping the intrinsic activity of the brain and for depicting the synchronization of interregional FC (Bi et al., 2018; de Vos et al., 2018). A recent rs-fMRI study showed that the FC pattern may be altered in some specific functional networks (default mode network) of AD and MCI patients. The authors found decreased FC between the hippocampus and several regions throughout the neocortex, i.e., reduced FC within the default mode networks and increased FC within the frontal networks (de Vos et al., 2018).

From the above studies, we observe that there is no clear evidence supporting the supremacy of any biomarker above another (CSF vs. APOE- $\epsilon 4$  vs. imaging) for the diagnostic estimation of AD. The choice of biomarkers mainly depends on price and availability. Nevertheless, some authors argue for the perfection of imaging above fluid biomarkers, given that imaging modalities can distinguish the different phases of the disease both anatomically and temporally (Khouri and Ghossoub, 2019; Márquez and Yassa, 2019). The above-mentioned studies used only a single modality to detect biomarkers for the detection of the conversion of MCI to AD. The proposed algorithm performance is approximately 80–90%, which is low compared with that of recently published multimodal studies (Zhang et al., 2011; Liu et al., 2014; Ritter et al., 2015; Xu et al., 2016; Gupta et al., 2019a). To date, it is true that no single imaging modality for biomarkers meets all of the diagnostic requirements set by previous studies (Hyman et al., 2012; Jack et al., 2018, 2016) (because each biomarker has their own advantage over others) and no single (whether genotype or fluid or imaging) biomarker can by itself correctly discriminate a heterogeneous disorder

of AD with high accuracy, but several methods may provide complementary information, which leads to a call to develop a panel of neuroimaging biomarkers, or a combination of imaging and APOE or imaging with CSF data that merges information about the disease manner to improve diagnostic accuracy (Márquez and Yassa, 2019). Combining information (multimodal) from different types of neuroimaging (structural and functional) with genotype (APOE) or biochemical (CSF) information, as do sMRI, AV45-PET, FDG-PET, DTI, and rs-fMRI, can help to improve diagnostic performance for AD or MCI compared with single-modality methods (Zhang et al., 2011; Young et al., 2013; Schouten et al., 2016; Wei et al., 2016; Gupta et al., 2019a). Furthermore, it has been noted lately that a combination of biomarkers yields a powerful diagnostic technique for classifying the AD group with cognitively healthy subjects, with specificity and sensitivity scores reaching above 90% (Bloudek et al., 2011; Rathore et al., 2017; Khouri and Ghossoub, 2019).

Multiple studies have reported a combination of different neuroimaging modalities for investigating AD or MCI. Dai et al. (2012) used regional GM volumetric measures and functional measures (amplitude of low-frequency fluctuations, regional homogeneity, and regional FC strength) as features. They trained distinct maximum uncertainty LDA classifiers on functional and structural properties and merged the output of the classifiers by weighted voting. Zhang et al. (2011) used a multimodal method for the discrimination of healthy controls (HC) to AD patients. They used a kernel-based support vector machine (SVM) classifier for the classification, and they combined volumetric regional features with regional FDG-PET and CSF biomarkers. Young et al. (2013) proposed a method where they combined sMRI, FDG-PET, and APOE genotype data for the discrimination of AD with HC. These authors used Gaussian processes as a multimodal kernel method, and they applied an SVM classifier for the classification of MCIs vs. MCIC groups. However, their diagnostic accuracy was low. Another study proposed a system where multiple kernel learning (MKL) with the Fourier transform of the Gaussian kernels was applied to AD classification using both sMRI and rs-fMRI (Liu et al., 2014) neuroimages. Moradi et al. (2015) used GM density maps, age, and cognitive tests as features, and employed classification algorithms such as low-density separation and random forest for AD conversion discrimination. Another study proposed a novel method for the classification of AD using a multi-feature technique (regional thickness, regional correlative-calculated from thickness measures, and the APOE genotype) using an SVM classifier (Zheng et al., 2015). Schouten et al. (2016) combined regional volumetric measures, diffusion measures, and correlation measures between all brain regions calculated from functional MRI. They employed a logistic elastic net for classification. In addition, Liu et al. (2017) used independent component analysis and the COX model for the discrimination of MCIs to MCIC. In their study, they used sMRI and FDG-PET scans in combination with APOE data and some cognitive measures. Hojjati et al. (2018) combined the features extracted from sMRI (cortical thickness) and rs-fMRI (graph measures) for the detection

of AD, employing SVM for the classification. It is worth noting that most of the above-presented multimodal methods used brain atrophy from a few manually extracted regions as a feature of sMRI and PET images for the detection of AD among different groups. However, using only a small number of brain regions as a feature in any imaging modality may not accurately reflect the spatiotemporal pattern of structural and physiological abnormalities as a whole (Fan et al., 2008). Furthermore, simply by increasing the number of modalities, combining modalities did not increase predictive power.

Therefore, the primary goal of this study was to combine five different imaging modalities (sMRI, AV45, FDG-PET, DTI, and rs-fMRI) with the APOE genotype to establish a multimodal system for the detection of AD. Moreover, in this study, we used three methods (that were completely different from each other) for the discrimination of AD from other groups. Moreover, we also aimed to discover which single modality of neuroimaging achieves high performance or plays a significant role in classifying all six binary classification groups (AD vs. HC, MCIs vs. MCIC, AD vs. MCIC, AD vs. MCIs, HC vs. MCIC, and HC vs. MCIs) based on these methods, and wanted to know which combined methods would perform well in the classification stage (whole-brain or voxel-wise analysis). Furthermore, we also aimed to discover the regions where these six binary groups massively differed from each other using voxel of interest (VOI) and graph methods. Whole-brain parcellation and voxel-wise methods were used to study regional and voxel differences in all six binary classification groups. We used NiftyReg (Young et al., 2013; Gupta et al., 2019a), the pyClusterROI script (Craddock et al., 2012), PANDA (Cui et al., 2013), DPRASF (Chao-Gan and Yu-Feng, 2010), and the CAT12 toolbox with the integration of SPM12 (Ashburner and Friston, 2001) for the extraction of features from the structural and functional neuroimaging data. Furthermore, graph-based analysis (John et al., 2017; Peraza et al., 2019) was performed to study the organization of (nodal and group) network connectivity using anatomical features (including GM volume, cortical thickness, and WM pathways between GM regions), and using the regional time series of the 200 brain regions included in the Craddock atlas. For this graph-based analysis, we used the BRAPH toolbox (Mijalkov et al., 2017). Later, we applied an MKL algorithm based on the EasyMKL (Aioli and Donini, 2015; Donini et al., 2019) classifier for classification and for data fusion. This classifier works by simultaneously learning the predictor parameters and the kernel combination weights. Moreover, we applied a leave-one-out cross-validation technique that helps to find the optimal hyperparameter for this MKL classifier. In this study, we also applied the radial basis function (RBF)-SVM classifier to compare its results with the results obtained from the EasyMKL. Our results showed that grouping different measurements (or complementary information) from the six different modalities exhibited much better performance for all six binary classification groups (using any combined-ROI, or combined-VOI, or a combination of all) than using both classifiers with the best individual modality.

## MATERIALS AND METHODS

### Participants

The participants included in this study were enrolled via the ADNI, which was launched in 2003 as a multicenter public-private partnership, guided by Principal Investigator Michael W. Weiner, MD. The participants were enrolled from 63 locations across the United States and Canada. The primary goal of ADNI was to test whether sMRI, PET, new biological markers, and clinical and neuropsychological evaluation could be combined to measure the development of MCI and early AD. The criteria used for the inclusion of subjects were those defined in the ADNI procedure.<sup>1</sup> The enrolled subjects were between 56 and 92 (inclusive) years old, had a study partner able to offer an independent assessment of functioning, and spoke either Spanish or English. All subjects were willing and able to undergo all test trials, including neuroimaging, and agreed to a longitudinal follow-up. Specific psychoactive medications were excluded. For this study, we downloaded data from all subjects for whom all five imaging modalities (sMRI, rs-fMRI, FDG-PET, AV45-PET, and DTI) with their APOE genotype were available on the ADNI homepage. A total of 129 subjects were classified as either healthy controls (HC,  $n = 35$ ), MCIC ( $n = 31$ ), MCIs ( $n = 30$ ), or AD ( $n = 33$ ), with matched sex and age ratios. The groups were classified according to the criteria set by the ADNI consortium (Petersen et al., 2010). In the HC group, participants had global clinical dementia rating (CDR) scores of 0, mini-mental state examination (MMSE) scores between 27 and 30, functional activities questionnaire (FAQ) scores between 0 and 4, and geriatric depression scale (GDS) scores between 0 and 4. In the MCIs group, the MMSE score was between 25 and 30, the FAQ score between 0 and 16, and the GDS score was between 0 and 13. In the MCIC group, the MMSE score was between 19 and 30, the FAQ score between 0 and 18, and the GDS score was between 0 and 10.

In the AD group, patients had a global CDR score of 1, an MMSE score between 14 and 24, an FAQ score between 3 and 28, and a GDS score between 0 and 7 (Morris, 1993). We did not consider MCI subjects who had been tracked for less than 18 months and did not convert within this period. **Table 1** shows participant demographic information, including the mean age and the sex ratios per group. To assess statistically significant changes in the demographics and clinical features between these groups, a Student's *t*-test was used with the significance level set to 0.05. We found no significant differences ( $p$ -value > 0.05) between the groups for age or sex ratio. To attain unbiased estimates of performance, the classification groups were then randomly split into two clusters in a ratio of 70:30 for the training and testing sets. The model was trained on the training set, and the performance measures of diagnostic specificity and sensitivity were carried out on a separate testing set. The splitting procedure preserved the age and sex distribution.

**TABLE 1 |** Demographic and neuropsychological characteristics of the participants.

Group	AD (n = 33)	MCIC (n = 31)	MCIs (n = 30)	HC (n = 35)
Sex (M/F)	21/12	16/15	17/13	14/21
Age	75.65 ± 8.61	72.27 ± 7.40	72.90 ± 7.86	77.83 ± 6.17
Body weight (kg)	75.81 ± 13.60	80.71 ± 17.43	82.14 ± 15.03	75.76 ± 18.62
FAQ score	19.34 ± 6.53	6.16 ± 7.38	1.86 ± 2.99	0.13 ± 0.48
NPI-Q score	4.46 ± 4.01	2.64 ± 3.32	1.66 ± 1.61	0.33 ± 0.78
GDS score	2.37 ± 2.59	2.03 ± 2.02	1.26 ± 0.96	1.13 ± 1.79
MMSE score	19.59 ± 4.56	26.32 ± 3.85	28.03 ± 1.25	29.13 ± 1.20

Values are numbers or means ± standard deviations. FAQ: functional activities questionnaire; NPI-Q: neuropsychiatric inventory questionnaire; GDS: geriatric depression scale; MMSE: mini-mental state examination.

## sMRI Acquisition

We acquired 1.5-T T1-weighted MR images from the ADNI homepage. The MRI images were obtained from data centers using Philips, GE, or Siemens Medical system scanners. Because the acquisition protocol was different for each scanner, an image normalization step was carried out by ADNI. The image corrections included calibration, image geometry distortion due to gradient non-linearity (grad-warp), and reduction in the intensity non-uniformity due to waves, or residual intensity non-uniformity of the 1.5-T scans utilized on each image by ADNI. Further details about the sMRI images are available on the ADNI website.<sup>2</sup> All scans had a resolution of  $176 \times 256 \times 256$  with 1 mm spacing between each scan. In our study, we again pre-processed the obtained sMRI images using the FMRIB Software Library (FSL, v.6.0) (Smith, 2002) toolbox. For the anatomical sMRI images, this included the extraction of non-brain tissue from each image using the BET function. We then passed the skull-stripped images to the ANTs (Tustison et al., 2010) toolbox for N4 bias field correction to correct for inhomogeneous artifacts in each image. For co-registration to the standard Montreal Neurological Institute (MNI) 152 template (Grabner et al., 2006), we also used the FSL toolbox (Jenkinson et al., 2012).

## FDG-PET Image Acquisition

ADNI provides four different types of FDG-PET samples, which are labeled as: (1) Co-registered Dynamic; (2) Co-registered, Averaged; (3) Co-reg, Avg, Standardized image and Voxel size; and (4) Co-reg, Avg, Std Img and Vox Siz, Uniform Resolution. The type (3) baseline FDG-PET images were downloaded from the ADNI homepage.

The downloaded baseline FDG-PET samples were in DICOM format. In the first step, we converted these DICOM format images to the Nifty format using the dcm2nii (Li et al., 2016) toolbox. Later, these images were spatially normalized to the MNI 152 template using the SPM12 toolbox (integrated within MATLAB 2019b) with a standard  $91 \times 109 \times 91$  tensor dimension image grid, having a voxel size of  $2 \times 2 \times 2 \text{ mm}^3$ . This image grid was oriented so that the subjects' anterior-posterior (AC-PC) axis was parallel to the AC-PC line. The above normalization step was carried out on two levels: a global affine transformation, followed

by a non-rigid spatial transformation. The general affine transformation requires a 12-parameter design, whereas the non-rigid spatial transformation uses a sequence of the lowest frequency elements of the three-dimensional cosine transform. Furthermore, the intensity normalization step was performed by splitting each voxel depth-wise with the average score of the global GM, which was obtained with the help of the AAL template image. More details concerning the FDG-PET imaging can be found on the ADNI homepage.<sup>3</sup> Moreover, after the completion of these pre-processing steps, we co-registered the FDG-PET images to their corresponding sMRI T1-weighted images using the SPM12 toolbox.

## AV45-PET Image Acquisition

Alzheimer's Disease Neuroimaging Initiative provides four different types of AV45-PET samples, which are: (1) AV45 Co-registered Dynamic; (2) AV45 Co-registered, Averaged; (3) AV45 Co-reg, Avg, Standardized image and Voxel size; and (4) AV45 Co-reg, Avg, Std Img and Vox Siz, Uniform Resolution. The type (3) baseline AV45-PET images were downloaded from the ADNI homepage. For each scan, the 5-min frames (four for florbetapir, acquired 50–70 min post-injection) were co-registered to the frame (rigid-body translation/rotation, six degrees of freedom) using the NeuroStat "mcoreg" routine (followed by the ADNI organization) (Jagust et al., 2015). The downloaded baseline AV45-PET samples were in DICOM and ECAT formats. In the first step, we converted this DICOM and ECAT format images to the Nifty format using the dcm2nii (Li et al., 2016) toolbox. Later, these images were spatially normalized to the MNI 152 template using the SPM12 toolbox (integrated within MATLAB 2019b) with a standard  $91 \times 109 \times 91$  tensor dimension image grid, having a voxel size of  $2 \times 2 \times 2 \text{ mm}^3$  using the same process we introduced in section "FDG-PET Image Acquisition" for the FDG-PET image. More details about AV45-PET imaging can be found on the ADNI website (see text footnote 3). Furthermore, after the completion of the above stated pre-processing steps, we co-registered the AV45-PET images to their corresponding sMRI T1-weighted images using the SPM12 toolbox.

## Resting-State Functional MR Image Acquisition

A 3.0-T Philips Medical sMRI scanner was used to acquire the fMRI images. All rs-fMRI images were obtained from the ADNI homepage. The sample for each subject consisted of 6720 DICOM images. The patients were required to relax, not to think, and to lie in the scanner during the scanning procedure. The sequence parameters were as follows: pulse sequence = GR, TR = 3000 ms, TE = 30 ms, flip angle =  $80^\circ$ , data matrix =  $64 \times 64$ , pixel spacing X, Y = 3.31 mm and 3.31 mm, slice thickness = 3.33 mm, axial slices = 48, no slice gap, time points = 140. Because the signal-to-noise ratio (SNR) of the rs-fMRI images was limited, the collected data were pre-processed to reduce the impact of noise on the

<sup>2</sup><http://adni.loni.usc.edu/methods/mri-tool/mri-analysis/>

<sup>3</sup><http://adni.loni.usc.edu/methods/pet-analysis-method/pet-analysis/>

fMRI images. For the pre-processing of the rs-fMRI images, we used the Data Processing Assistant for Resting-state fMRI (DPARSF) (Chao-Gan and Yu-Feng, 2010) software, which can be downloaded from [http://d.rnet.co/DPABI/DPABI\\_V2.3\\_170105.zip](http://d.rnet.co/DPABI/DPABI_V2.3_170105.zip). For each subject, the entire pre-processing was divided into nine steps as follows: converting the DICOM format into the NIFTY format, removing the first ten time points, timing the slicing, head motion correction to adjust the time series of the images so that the brain was located in the same orientation in every image, normalization, smoothing by full width at half maximum (FWHM), removing the linear trend to eliminate the residual noise that systematically increases or decreases over time (Smith et al., 1999), temporal filtering to retain 0.01–0.08 Hz fluctuations, and removing covariates to eliminate physiological artifacts (Fransson, 2005), non-neuronal blood oxygen level-dependent (BOLD) fluctuations, and head motion.

## Diffusion Tensor Imaging Image Acquisition

Diffusion tensor imaging images were also downloaded from the ADNI homepage. The DTI protocol used spin-echo diffusion-weighted echo-planar imaging with a TR/TE of 12000/1046 ms, a voxel size of  $0.9375 \times 0.9375 \times 2.35 \text{ mm}^3$ , a matrix size of  $256 \times 256$ , 45 slices, 30 gradient directions, and a  $b$ -value of  $1000 \text{ s/mm}^2$ . More details about DTI imaging can be found on the ADNI webpage.<sup>4</sup> This ADNI protocol was chosen after conducting a detailed comparison of several different DTI protocols to optimize the SNR in a fixed scan time (Jahanshad et al., 2013; Chen et al., 2018). The pre-processing of DTI data was performed using the diffusion toolbox of FSL (Version 6.0, FMRIB, Oxford, United Kingdom). FSL pre-processing included (i) corrections for eddy currents and head motion, (ii) skull stripping, and (iii) fitting the data to the diffusion tensor model to compute maps of fractional anisotropy (FA) and mean diffusivity (MD). A single diffusion tensor was fitted at each voxel of the eddy- and EPI-corrected DWI images using the FSL toolbox. Scalar anisotropy maps were obtained from the consequential diffusion tensor eigenvalues  $\lambda_1$ ,  $\lambda_2$ , and  $\lambda_3$ . FA, a measure of the degree of diffusion anisotropy, was defined in the standard way as

$$FA = \sqrt{\frac{3}{2}} \frac{\sqrt{(\lambda_1 - \langle \lambda \rangle)^2 + (\lambda_2 - \langle \lambda \rangle)^2 + (\lambda_3 - \langle \lambda \rangle)^2}}{\sqrt{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}}, \in [0, 1] \quad (1)$$

$$\langle \lambda \rangle = \frac{\lambda_1 + \lambda_2 + \lambda_3}{3} \quad (2)$$

where  $\langle \lambda \rangle$  is equal to the MD or average proportion of diffusion in all directions. The resulting images were smoothed with a Gaussian kernel of 5 mm FWHM to improve the SNR and ensure a Gaussian distribution of the maps.

<sup>4</sup><http://adni.loni.usc.edu/data-samples/data-types/>

## APOE Genotype

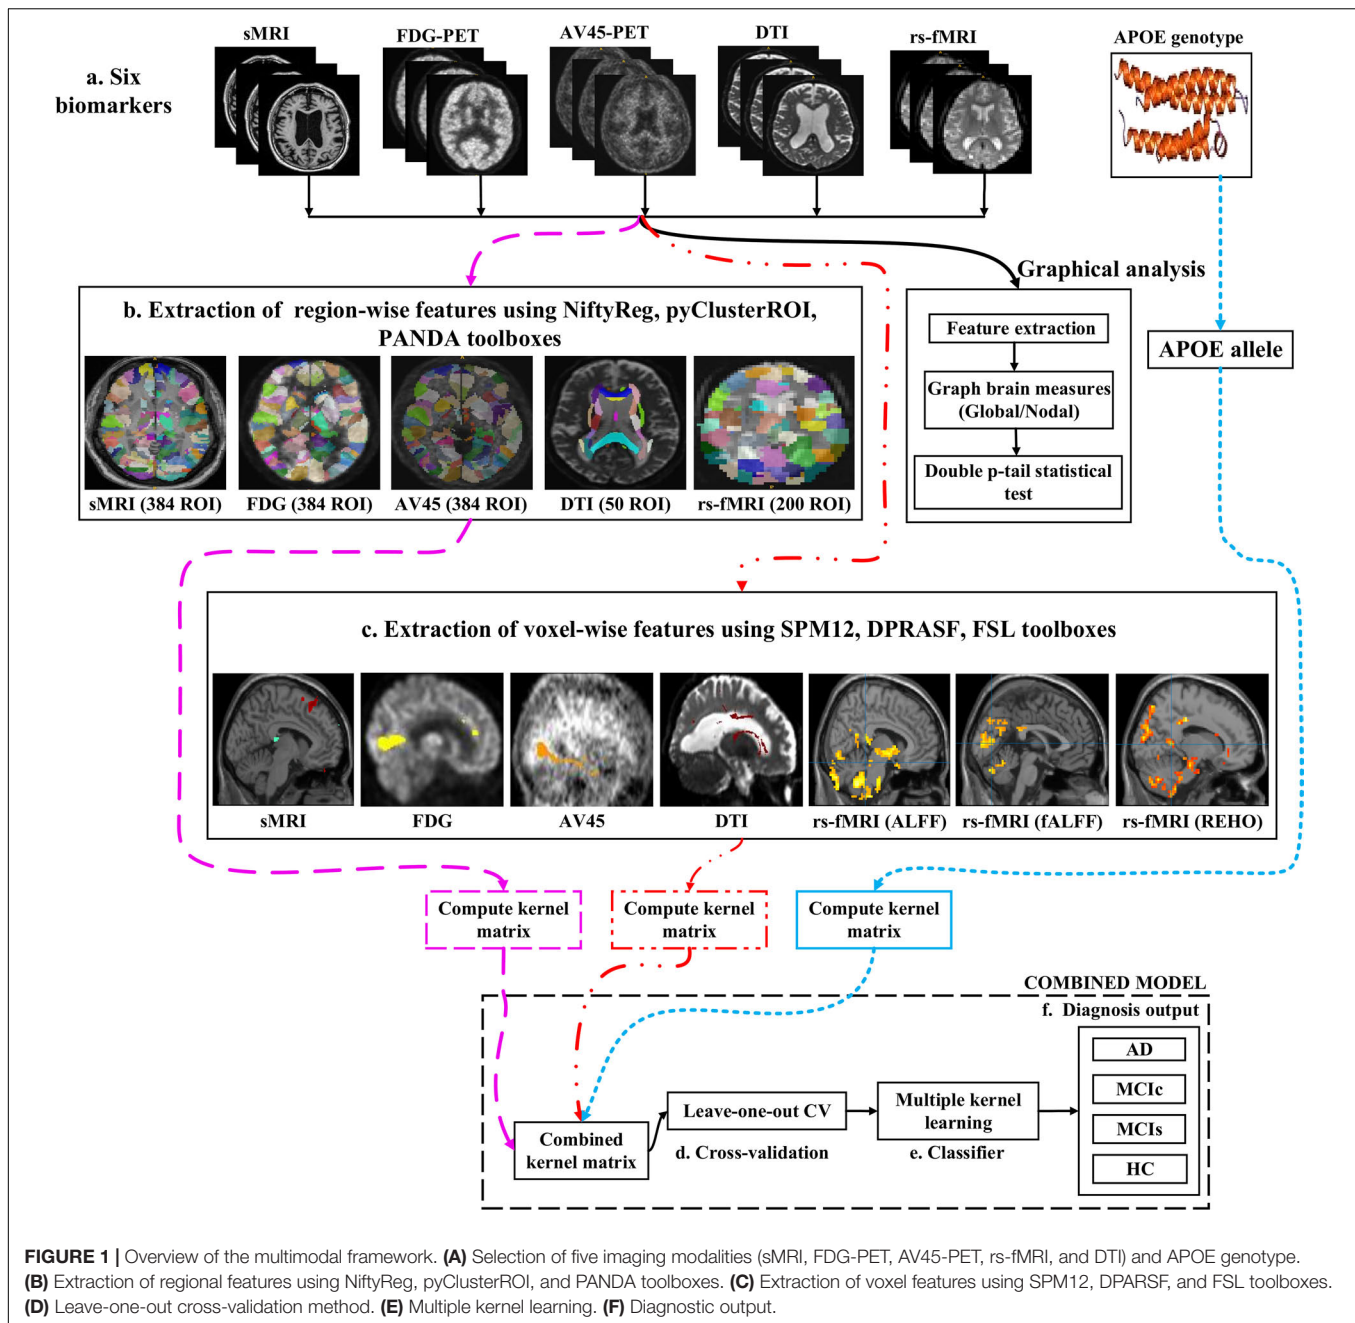

The APOE genotype for each subject was also obtained from the ADNI homepage. The APOE genotype is known to affect the risk of developing sporadic AD in carriers. The APOE genotype of each subject was noted as a pair of numbers representing which two alleles were present in the blood. This genetic feature was a single categorical variable for each participant and could have had one of five possible values: ( $\epsilon 2$ ,  $\epsilon 3$ ), ( $\epsilon 2$ ,  $\epsilon 4$ ), ( $\epsilon 3$ ,  $\epsilon 3$ ), ( $\epsilon 3$ ,  $\epsilon 4$ ), and ( $\epsilon 4$ ,  $\epsilon 4$ ). The most common allele is APOE  $\epsilon 3$ , but carriers of the APOE- $\epsilon 4$  variant have an increased risk of developing AD, whereas the APOE  $\epsilon 2$  variant confers some protection on carriers (Michaelson, 2014). Of the three genetic polymorphisms, APOE shows the highest correlation with MCI status and stability (Brainerd et al., 2013). Several recent studies have linked the APOE- $\epsilon 4$  status to a relatively late risk of preclinical progression to AD. Until recently,  $\epsilon 4$  variants (including  $\epsilon 4/\epsilon 4$  and  $\epsilon 4/\epsilon 3$  combinations) were inconsistently linked to the MCI status, likely reflecting both clinical and methodological differences in status classification. In this study, the genotype data were obtained from a 10 ml blood sample taken at the time of the scan and sent immediately to the University of Pennsylvania AD Biomarker Fluid Bank Laboratory for analysis.

## Three Feature Extraction Processes

Figure 1 shows a block diagram of the proposed framework. In this study, we performed three types of analysis for the extraction of features from each imaging modality:

- (1) Whole-brain parcellation (or atlas-based segmentation) is a quantitative method that provides a non-invasive way to measure brain regions via neuroimaging. It works by assigning tissue labels to the unlabeled images using sMRI scans as well as the corresponding manual segmentation. For sMRI, FDG, and AV45-PET scans, we used the 2-mm Atlas of Intrinsic Connectivity of Homotopic Areas (AICHA) template image (Joliot et al., 2015) for the extraction of 384 regions of interest (ROIs) from each image, whereas for the rs-fMRI and DTI scans, we used the 2-mm Craddock atlas template (Craddock et al., 2012) for the extraction of 200 ROIs from each rs-fMRI image and the 2-mm Johns Hopkins University (JHU) WM labels atlas for the extraction of 50 ROIs from each DTI image (Hua et al., 2008).
- (2) Voxel-wise analysis or morphometry (VBM) is a computational approach to neuroanatomy that measures differences in local concentrations of brain tissue through a voxel-wise comparison of multiple brain images. It uses statistics to recognize differences in brain structure between groups of patients, which in turn can be used to infer the presence of atrophy or normal-tissue expansion in patients with disease. For sMRI, FDG, and AV45-PET scans, we used the SPM12 toolbox to apply VBM, whereas, for the rs-fMRI scans, we used the DPARSF toolbox integrated with SPM12 to apply VBM. For the DTI scans, we used the tract-based spatial statistics (TBSS) function from FSL (v.6.0).

(3) Graph theory methods are powerful methods for quantifying the organization of a network by means of brain anatomical features, including cortical thickness, GM volume, and WM tracks between GM regions. When applying graph theory to different neuroimaging modalities, the outcome is a network with vertices or nodes that are represented by brain voxels or regions defined by a predetermined parcellation structure, while the edges are denoted by inter-individual data relations between the regions estimated, for example, as the intensity of correlation between the regional measurements. Note that the edges of a structural network are not always denoted by

correlations between regional capacities, but by the density or number of WM tract-linking regions. In an analysis of sMRI, FDG, and AV45-PET networks, the nodes are generally defined using an anatomical segmentation or parcellation of the brain into different regions. In this study, we used the 2-mm AICHA atlas template image (which was already segmented into 384 distinct regions) for the extraction of 384 ROIs from each sMRI, FDG, and AV45-PET image. In the case of functional networks, for the rs-fMRI and DTI images, we used the 2-mm Craddock atlas template image for the extraction of 200 ROIs, and the 2-mm JHU-WM (ICBM-DTI-81) label atlas for the

extraction of 50 ROIs from each DTI image. After the nodes of the network were defined, the edges indicating the relationship between different regions was computed. For this, we used the BRAPH toolbox (Mijalkov et al., 2017) integrated into MATLAB 2019a. In BRAPH, the edges are calculated in a GUI graphical analysis as the statistical correlation between the values of pairs of brain regions for an individual or for a group of subjects, depending on the neuroimaging technique.

### Feature Extraction Using Atlas-Based Segmentation

After completing a series of image pre-processing steps for each imaging modality as shown in **Figure 1**, we extracted the features from each modality. The dashed pink line in **Figure 1** shows the feature extraction for a whole-brain analysis. For sMRI, FDG, and AV45-PET images, we used the 2-mm AICHA atlas template image for the extraction of 384 ROIs from each image (Gupta et al., 2019a). We then processed these images using the open-source NiftyReg toolbox (Modat et al., 2010), which is a registration toolkit that performs fast diffeomorphic non-rigid registration on images. After the registration process, we obtained the subject-labeled image based on a template with 384 segmented regions. For each of the 384 ROIs in the labeled MR and PET images, we computed the GM volume and the relative cerebral metabolic rate of glucose from the baseline MRI, FDG, and AV45-PET data, respectively and later used it as a feature. Therefore, for each sMRI and PET image, we obtained 384 features. For the rs-fMRI images, we ran a pyClusterROI Python script, which was downloaded from [https://ccraddock.github.io/cluster\\_roi/](https://ccraddock.github.io/cluster_roi/), for the extraction of 200 ROIs from each rs-fMRI image. This method employs a spatially constrained normalized-cut spectral clustering algorithm to generate individual-level and group-level parcellations. A spatial constraint was imposed to ensure that the resulting ROIs were spatially coherent, i.e., that the voxels in the resulting ROIs were connected. Moreover, for DTI images, we ran a pipeline to analyze the brain diffusion images (PANDA toolbox), which can be downloaded from <https://www.nitrc.org/projects/panda/>, integrated with MATLAB R2019a in the Ubuntu 18.04 operating system for the processing of diffusion MRI images. The PANDA pipeline uses the FMRIB Software Library (FSL), Pipeline System for Octave and MATLAB (PSOM), Diffusion Toolkit, and MRICron packages for the extraction of diffusion metrics (e.g., FA and MD) that are ready for statistical analysis at the voxel level or atlas level. For the parcellation of DTI images, it uses the 2-mm JHU-WM (ICBM-DTI-81) label atlas, which is already segmented into 50 distinct ROIs. After completion of this process, we gained the subject-labeled image based on a template with 50 distinct segmented regions.

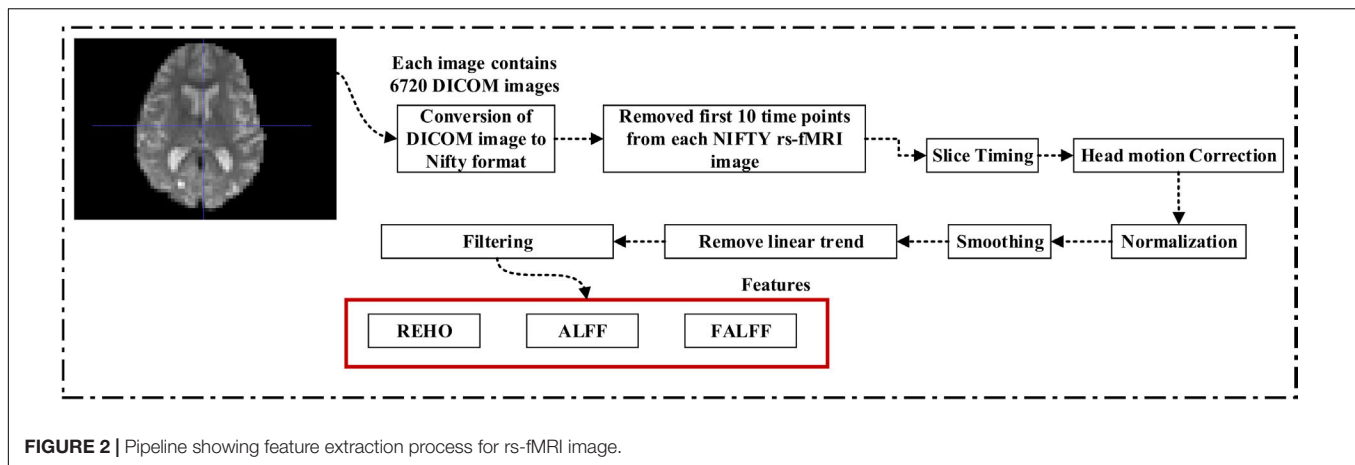

### Feature Extraction Using Voxel-Wise Morphometry

The dashed and dotted red line in **Figure 1** shows the pipeline for the voxel-wise analysis (or the extraction of features) from sMRI, FDG, AV45-PET, rs-fMRI, and DTI images. For the voxel-wise analysis of sMRI, FDG, and AV45 images, we used the statistical mapping method (SPM12) toolbox integrated with the computational anatomy toolbox (CAT version 12),

which can be obtained from <https://www.fil.ion.ucl.ac.uk/spm/software/spm12/> and <http://www.neuro.uni-jena.de/cat/>. First, the MRI data were anatomically standardized using the 12-parameter affine transformation offered by the SPM template to compensate for differences in brain size. We chose the East Asian brain image template and left all other factors at their default setting. The sMRI images were then parcellated into GM, WM, and CSF images using the unified tissue segmentation method after the image strength non-uniformity correction was complete. The obtained linearly transformed and parcellated images were then non-linearly distorted using diffeomorphic anatomical registration via exponentiated lie algebra (DARTEL) methods and modulated to create an improved template for a DARTEL-based MNI152 template image, followed by smoothing using an 8 mm FWHM kernel. The final step consisted of voxel-wise statistical assessments. To construct a statistical parametric map, we calculated contrast values based on general linear model-estimated regression parameters. This technique executes a two-sample *t*-test to determine if there are major regional density differences between two sets of GM images. We obtained these regional information values representing the major density differences between two sets of GM images after executing a false discovery rate (FDR) and family wise error rate (FWER) correction. Based on this data, cluster values were obtained to create ROI binary masks, which were subsequently used to acquire GM volumes from GM brain images for use as a morphometric feature. Moreover, before submitting FDG and AV45 images to VBM analysis, the first step was to register the FDG and AV45 images with their corresponding sMRI images. We used the SPM12 toolbox for this registration. After the registration, we followed the same method as was used for the sMRI VBM analysis. SPM12 was used to produce statistical maps of between-group alterations in the regional-to-whole-brain dimensions of the cerebral metabolic rate for glucose (CMRgl) consumption in likely AD, MCIs, MCIc, and HC groups.

For rs-fMRI images, to decrease the influence of the SNR, the selected data should be pre-processed. In this study, we used the DPARSF toolbox,<sup>5</sup> which was integrated with MATLAB R2019a, to calculate the whole-brain ALFF, fractional (fALFF), and REHO feature maps, as shown in **Figure 2**. Spatial smoothing was performed with a  $4 \times 4 \times 4$  mm FWHM Gaussian kernel before the ALFF, fALFF, and REHO calculation. To minimize the low-frequency drift, linear trending was removed from the process. To explore the ALFF, fALFF, and REHO differences between the AD patient group and the other groups, a random-effects two-sample *t*-test was implemented on the individual ALFF, fALFF, and REHO maps in a voxel-wise way by taking the patients' age as a confounding covariate. The ALFF was calculated by filtering the time courses of each individual voxel of the subjects with a fast Fourier transformation of the frequency area, and the power range or spectrum was then gained. Because the power of a specified frequency is relative to the square of the amplitude of this frequency, the square root was computed at each frequency domain of the power range, and then the averaged square root was found across 0.01–0.08 Hz at each individual voxel. Later,

<sup>5</sup>[http://d.rnet.co/DPABI/DPABI\\_V2.3\\_170105.zip](http://d.rnet.co/DPABI/DPABI_V2.3_170105.zip)

this averaged square root was taken as the ALFF index. The FALFF was calculated as the ratio of the amplitude within the low-frequency spectrum (0.01–0.08 Hz) to the total amplitude over the full frequency spectrum (0–0.25 Hz). It is generally calculated as a fraction of the sum of amplitudes across the entire frequency range detectable in a given signal. REHO is a voxel-based measure of brain activity that evaluates the similarity or synchronization between the time series of a given voxel and its nearest neighbors (Zang et al., 2004). It was calculated using Kendall's coefficient of concordance with the time series of every 27 neighboring voxels. Then, a Kendall's coefficient of concordance value (ranging from 0 to 1) was assigned to each voxel center. Voxels of higher strength in the REHO maps show greater similarity with the neighboring voxel's time series. For the DTI images, FA maps were then created using the DTIfit approach and were entered into the TBSS environment to investigate changes in diffusivity measures along the WM tract. First, all FA data were non-linearly aligned to a common space (FMRIB58\_FA), then the normalized FA images were averaged to create the mean FA image and a threshold set ( $FA > 0.2$ ) (to exclude voxels that were primarily GM or CSF) to create a mean FA skeleton. Next, each participant's FA data were projected onto the mean FA skeleton, followed by voxel-wise statistical analysis. Voxel-wise statistical analysis of FA in the WM skeleton was performed using Randomize, FSL's non-parametric permutation interference tool. Multiple comparisons were corrected for by using threshold-free cluster enhancement ( $p < 0.05$ ). WM regions were identified with the JHU-WM (ICBM-DTI-81) label atlas included in FSL.

### Graph Generation and Construction of sMRI, FDG-PET, AV45-PET, fMRI, and DTI Brain Networks

To assess the sMRI, FDG-PET, and AV45-PET network topology in AD, MCIs, MCIC, and HC subjects, the T1 images of these subjects were pre-processed using the NiftyReg toolbox with the integration of the 2-mm AICHA atlas template image. In total, 384 regions were extracted from each modality and included as a node in the network study. The edges between these brain regions were computed as a Pearson correlation, and the negative correlations were set to zero. The network connectivity analyses were carried out on the binary undirected

graphs while controlling the number of networks across a range of densities from 5–25% with a step size of 0.5%. To assess the functional network topology of rs-fMRI images, we used the DPARSF toolbox integrated into MATLAB 2019a. Moreover, we followed the same method for the extraction of features that we followed for the rs-fMRI images in (see section “Feature Extraction Using Voxel-Wise Morphometry”). A regional time series of the 200 brain regions included in the Craddock template atlas was extracted for each patient. To compute the relationship between these regions, we used the Pearson coefficient and performed network analysis on the binary undirected graphs. To assess the DTI network topology in AD, MCIs, MCIC, and HC subjects, the DWI images of these subjects were pre-processed using the PANDA toolbox, which was integrated into MATLAB 2019b. The PANDA toolbox uses a 2-mm JHU-WM (ICBM-DTI-81) label atlas template image for the extraction of 50 WM regions from each DTI image. These extracted regions were later included as a node in the network analysis. The same procedure was followed with the same parameters as that described above for constructing a network for sMRI brain images. Moreover, several graph metrics were calculated to quantify the nodal or global topological organization of the structural and functional networks, including local efficiency, characteristic path length, transitivity, and modularity. Local efficiency is a measure of the average efficiency of data transfer within local subgraphs or regions, and it is defined as the converse of the shortest average path length between the regions of a given node and all other nodes. The local efficiency of node  $i$  is defined as:  $LE_i = 1/d_i(d_i - 1) \sum_{j \in G_i} 1/l_{i,j}$ , where  $d_i$  represents the number of nodes in the subgraph ( $G_i$ ) and  $l_{i,j}$  is the length of the shortest path between nodes  $i$  and  $j$ . The distance between two vertices in a graph is the length of the shortest path between them if one exists. Otherwise, the distance is infinite, and the average of the shortest path between one node and all remaining other nodes is termed the characteristic path length. The characteristic path length  $l_G$  is computed as:  $l_G = 1/n(n - 1) \sum_{i \neq j} d(v_i, v_j)$ , where  $n$  is the number of vertices ( $v$ ) in a graph network, and  $d(v_i, v_j)$  denotes the shortest distance between vertices  $v_i$  and  $v_j$ . Transitivity (or the clustering coefficient) is defined as the ratio of paths that cross two edges to the number of triangles.

Moreover, if a node is connected to a second node, which in turn is linked to a third node, the transitivity reproduces the probability that the initial node is linked to the third node. It can be computed by:  $T = \frac{1}{N} \sum_k \frac{\sum_{i,j} a_{ij} a_{ik} a_{jk}}{d_k(d_k-1)}$ , where  $a_{ij}$  is the  $(i, j)$  entry of the binary connection matrix.  $a_{ij} = a_{ji} = 1$  if there is a link between nodes  $i$  and  $j$ , and  $a_{ij} = a_{ji} = 0$  otherwise. There are no self-loops in the network, thus  $a_{ij} = 0$ . Modularity is the fraction of the network edges that fall within the given groups, minus the expected fraction if edges were distributed at random. It also calculates to what extent a network can be divided into communities. It can be calculated by,  $Q = \sum_{i \in M} [q_{ii} - (\sum_{j \in M} q_{ij})^2]$ ,

where the network is fully partitioned into  $M$  non-overlapping modules (or clusters), and  $q_{ij}$  represents the proportion of all links connecting nodes in module  $i$  with those in module  $j$ .

## Classification Techniques

In supervised learning, classification resembles the task of determining to which category a new sample belongs, based on a training set of data containing instances for which associations have previously been identified. In neuroimaging, different information sources may contain different imaging modalities (e.g., sMRI, FDG, AV45, DTI, and rs-fMRI), different ways of extracting features from the same modality (e.g., ROI-based or voxel-based for every image), or a different feature subset. In the present study, we applied three different methods to extract features from the same neuroimaging modality as follows: whole-brain parcellation, voxel-wise analysis, and graphical representation. We were mainly interested in the first two approaches, where we used feature subsets as a kernel for each of the two methods. Later, we will combine (or concatenate) the approaches. We were particularly interested in examining models based on subsets of features extracted according to voxels or an anatomical criterion to attain predictions that enabled us to estimate the anatomical localization.

## Multiple Kernel Learning

Kernel methods such as SVM (Cortes and Vapnik, 1995; Samper-González et al., 2018), which are based on similarity measures between data points, have been used with great success for dimensionality reduction and classification. Kernelization projects the native data space onto a higher-dimensional feature space. Non-linear relations between variables in the original space become linear in the transformed space. Let  $\{x^{(i)}, y^{(i)}\}_{i=1}^N$  be the training sample, where  $x^{(i)} = (x_1^{(i)}, x_2^{(i)}, \dots, x_M^{(i)})^T \in \mathbb{R}^M$  is a data sample,  $M$  is the number of features from all modalities, and  $y^{(i)} \in \{1, -1\}$  is the corresponding class label. The aim is to simultaneously acquire an optimal feature description and a max-margin classifier in kernel space because of its systematic and elegant way of forming complicated patterns. Therefore, to project the data, we will use the kernel trick. As we know, for any kernel ( $K$ ) on an input space ( $X$ ), there exists a Hilbert space ( $f$ ), called the feature space, and the projection  $\phi$  is given by the mapping  $\phi: X \rightarrow f$ , such that for any two-object  $(x, y)$  in  $X$ ,  $K(x, y) = \langle \phi(x), \phi(y) \rangle$ , where  $\langle \cdot, \cdot \rangle$  is the Euclidean or inner dot product of the data point. Examples of kernel functions

include the linear, RBF, and others. Recent papers have shown that using multiple kernels rather than using a single kernel can improve the interpretability of a decision function, and in some instances, it improves the final performance. In MKL, the data are represented as a combination of base kernels. Each base kernel represents a different modality or feature of the entity. MKL seeks to find the optimal combination of base kernels so that the analysis tasks that follow are benefited the most. Classification tasks are represented especially well through MKL, as the optimal combination is the one that gives the maximum classification accuracy. The dual form of MKL optimization, as it is solved by conventional solvers like LIBSVM, is given as

$$\begin{aligned} \max_{\alpha} L(\alpha) &= \sum_{i=1}^n \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j \beta_m k^m(x_i^m, x_j^m) \\ \text{Subject to } \sum_{i=1}^n \alpha_i y_i &= 0; \quad 0 \leq \alpha_i \leq C; \quad i = 1, \dots, n \end{aligned} \quad (3)$$

where  $\alpha_i, \alpha_j$  are Lagrange multipliers, which are the variables obtained on converting the primal support vectors to the dual problem, and  $k^m(x_i^m, x_j^m)$  is the  $m$ -th kernel function, which is applied to each pair of the samples, and  $C$  is the regularization parameter that controls the distance between the hyperplane and the support vectors. From the set of  $n$  training samples, the features of the  $i$ -th sample from the  $m$ -th modality are in the vector  $x_i^m$ , and its corresponding class label,  $y_i$ , is either  $+1$  or  $-1$ . The weight on the  $m$ -th modality kernel, represented as  $\beta_m$ , is optimized using a grid search, or as a separate optimization problem with fixed  $\alpha$ . For each new test sample,  $s$ , the kernel functions are computed against the training samples. An MKL overview is depicted in **Figure 3**. Recent research has shown that including the base datasets in more than one kernel, each differing in their selection of kernel parameters, improves performance. All kernels are then normalized to the unit trace through the formula  $K_m(x, y) = k_m(x, y) / \sqrt{k_m(x, x) k_m(y, y)}$ . Here, we set the weights accordingly to conform with sMRI, FDG, AV45, DTI, rs-fMRI, and APOE genotype features. The combined kernels can be described as follows,

$$\begin{aligned} K(x, y) &= w_{smri} k_{smri}(x, y) + w_{fdg} k_{fdg}(x, y) + w_{av45} k_{av45}(x, y) \\ &+ w_{dti} k_{dti}(x, y) + w_{rs-fmri} k_{rs-fmri}(x, y) \\ &+ w_{apoe} k_{apoe}(x, y) \\ \text{With, } w_{smri} + w_{fdg} + w_{av45} + w_{dti} \\ &+ w_{rs-fmri} + w_{apoe} = 1 \end{aligned} \quad (4)$$

Then, we use the EasyMKL (Aioli and Donini, 2015; Donini et al., 2019) solver to search for the combination of basic kernels that maximizes the classifier performances by optimizing a simple quadratic problem addressed by SVM by computing an optimal weighting. Besides its proven empirical success, a clear advantage of EasyMKL compared with other MKL approaches is its high scalability with respect to the number of kernels to be combined. It finds the coefficients  $\eta$  that maximize the edges in the training dataset, where the margin is calculated as the distance between the convex hull of the positive and negative samples. In particular, the general problem that EasyMKL aims to optimize

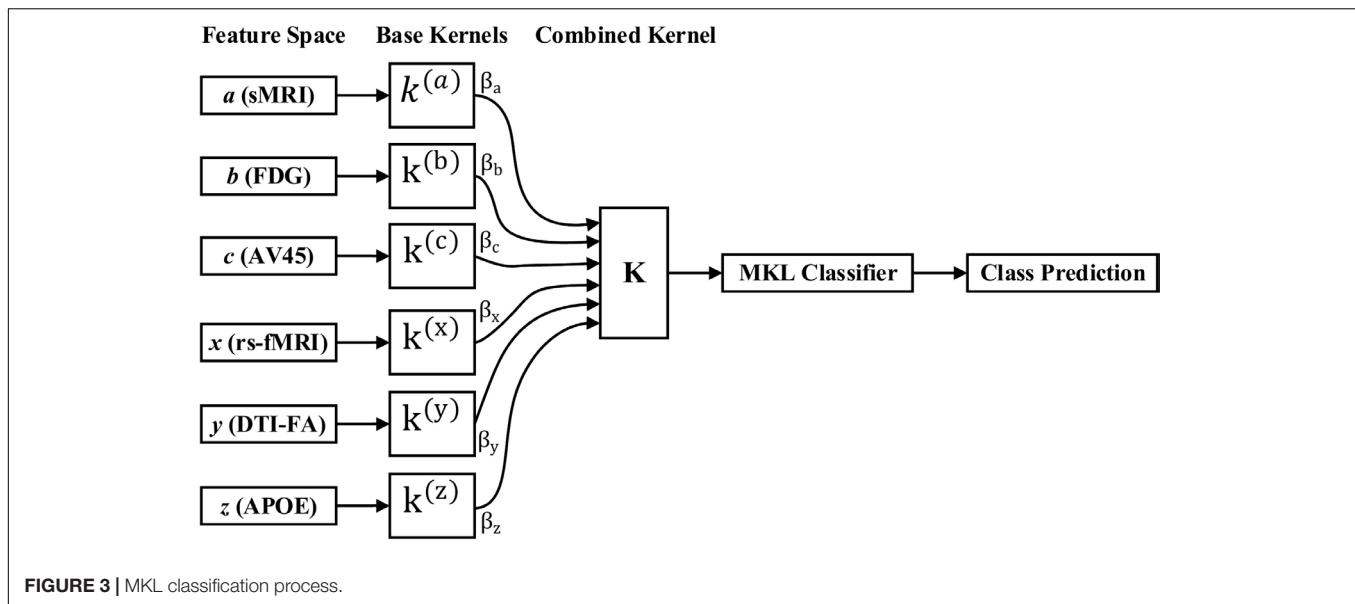

FIGURE 3 | MKL classification process.

is the following,

$$(\eta^*, \gamma^*) = \arg \max_{\eta: \|\eta\|_2=1} \min_{\gamma \in \Gamma} \lambda^\Gamma Y \left( \sum_{r=0}^R \eta_r K_r \right) Y_\gamma + \lambda \|\gamma\|_2^2 \quad (5)$$

where  $\gamma$  is a diagonal matrix with training samples on the diagonal, and  $\lambda$  is a regularization hyperparameter, whereas domain  $\Gamma$  signifies two probability distributions over the set of negative and positive samples in the training set, that is  $\Gamma = \left\{ \gamma \in R_+^l \mid \sum_{y_i=+1} \gamma_i = 1, \sum_{y_i=-1} \gamma_i = 1 \right\}$  (Aioli and Donini, 2015; Donini et al., 2019). Note that any element  $\gamma \in \Gamma$  resembles a pair of samples in the convex hull of the positive and negative training samples. At the solution, the first expression of an objective function denotes the obtained (squared) edge, which is the (squared) distance between a point in a convex hull of positive samples and a point in a convex hull of negative samples, in the considered feature space. It enforces sparsity across modalities while allowing more than one discriminative kernel to be chosen from the same modality. In other words, there is sparsity across modalities and non-sparsity within modalities, thereby making it a convex optimization problem. Moreover, in addition to the EasyMKL classifier, we also applied a RBF kernel (or Gaussian kernel) with SVM classifier for the comparison of our obtained results. An RBF kernel is a function with a score that depends on the distance from the origin (or from some points). It is represented by  $K(x_1, x_2) = e^{-(\|x_1 - x_2\|^2 / 2\sigma^2)}$ , where  $\|x_1 - x_2\|^2$  is the squared Euclidean distance between two data points  $x_1$  and  $x_2$ . An RBF kernel has two parameters: gamma ( $\gamma$ ) and  $C$ , and its performance depends on them. When the  $C$  value is small, the classifier is fine with misclassified input points (high bias, low variance), but when the  $C$  value is high, the classifier is severely penalized for misclassified data, and hence it leans over backward to avoid any misclassified input points (low bias, high variance). Moreover, when the  $\gamma$  value is low, the curve of the

decision margin is quite low, and therefore the decision area is very large, but when the  $\gamma$  value is high, the curve of the decision margin is high, which creates decision-boundary bars around the input points. In our case, we applied the GridSearch method from a scikit-learn (v0.20) (Pedregosa et al., 2011) library to find the optimal hyperparameter ( $C$  and  $\gamma$ ) value for the RBF-SVM classifier. The GridSearch was performed over the ranges of  $C = 1$  to 9 and  $\gamma = 1 \times 10^{-4}$  to 7.

### Cross Validation

Cross validation (CV) is one of the most widely utilized data resampling methods for estimating the generalization knowledge of a predictive design and for preventing under- or overfitting. CV is largely applied in settings where the aim is prediction and it is necessary to evaluate the accuracy of a predictive model. For a classification problem, a model is generally fitted with a known sample, called the training sample, and a set of unknown samples against which the model is examined, known as the test sample. The aim is to have a sample for testing the proposed model in the training period, and then present insight into how the particular model adapts to an independent sample. A round of CV involves the partitioning of samples into complementary subsets, then conducting analysis on an individual subset. After this, the study is verified on other subsets (called testing samples). To reduce variability, multiple rounds of CV are performed using several different partitions, and later an average of the outcomes is taken. CV is a powerful procedure in the evaluation of model performance. In this study, we utilized leave-one-out CV (LOOCV) from the scikit-learn (v0.20) (Pedregosa et al., 2011) library. LOOCV is a CV process in which the bulk of the fold is "1," with "k" being fixed to the number of attributes in the dataset. This means that the number of folds equals the number of instances in the sample. Thus, the learning algorithm is employed once for each instance, utilizing all other instances as a training sample, and utilizing the selected instance as a

single-item test sample. This type of CV is useful when the training samples are of limited size and the number of attributes to be verified is not high.

## Implementation

Our classification framework and validation experiments were implemented in Python 3.5 using an interface to the scikit-learn v0.20 (Pedregosa et al., 2011) library to measure performance, and using MKLpy (v0.5)<sup>6</sup> for the MKL framework. The main source code will be made available on the GitHub website.<sup>7</sup> The dataset list will be available in the **Supplementary Material**. Nonetheless, please note that you must prepare the original image features independently.

## RESULTS

In this section, we present the performance results of each classification (AD vs. HC, MCIs vs. MCIC, AD vs. MCI, AD vs. MCIC, HC vs. MCIs, and HC vs. MCIC) for all five neuroimaging and APOE genotype modalities using whole-brain parcellation, the voxel-wise method, and the graphical method. We implemented the multimodal fusion approaches for the integration of the sMRI, FDG, AV45, rs-fMRI, DTI, and APOE genotype data. We used the combined representation to distinguish patients with AD from healthy subjects. The combined approach is considered successful if the classification task is performed with greater accuracy and higher AUC score, higher precision, and better sensitivity and specificity against unimodal classification. Along with the unimodal approaches, we evaluated the classification of a concatenated data vector comprising data from the five neuroimaging modalities and two APOE genotype modalities, and used it as a baseline. Moreover, after the completion of extracting features from each modality using whole-brain parcellation and voxel-wise analysis, we passed these extracted features through a polynomial kernel function to map the original non-linear low-dimensional features onto a higher-dimensional space in which they became separable. After that, a data fusion technique was used to combine the multiple kernel features into a single form before passing them through the EasyMKL classifier for the binary classification of the six groups. For an unbiased performance assessment, the classification groups were randomly split into two sets at a 70:30 ratio as training and testing sets, respectively. In a training set, finding the right values for the lambda ( $\lambda$ ) parameter is quite difficult, and their values influence the classification result. Therefore, to find the optimal hyperparameter values for a lambda from 0 to 1 of an EasyMKL algorithm, we used the leave-one-out cross-validation technique on the training set. For each method, the optimized values obtained for the hyperparameter were then used to train the EasyMKL classifier using the training group. The performance of the resulting classifier was then estimated on the remaining 30% of the data in the testing dataset, which was not used during the training step. Here, cross

validation was used to assess how the result of the classification analyses could generalize to an independent group. One round of cross validation includes partitioning the data sample into disjoint subsets of instances, performing the analysis on one subsection (the training group), and validating the study on the other subset (the testing or validation set). To reduce variability, numerous rounds of cross validation are done using different subsets, and the validation outcomes are averaged over the rounds. In the present study, we used an LOOCV, which involves separating a single instance (either control or patient) from the complete example for testing while the remaining instances are used for training purposes. This splitting is iterated so that each instance in the whole sample is used once for validation. After all iterations, the final accuracy is quantified as the mean of the accuracies gained across each fold. In this way, we attained unbiased estimations of the performance for each classification problem. Moreover, after the completion of whole-brain and voxel-wise analysis, we used the BRAPH toolbox to perform the brain graphical analysis for each classification group with the same five neuroimaging features (sMRI, FDG, AV45, rs-fMRI, and DTI), which we extracted in the whole-brain analysis. For each analysis, we measured the accuracy (ACC, calculated as the average of the proportion of correctly classified subjects from each class individually), the sensitivity (SEN, described as true positive – the number of subjects correctly classified), and the specificity (SPEC, described as true negative – the number of healthy controls correctly categorized), precision (PRE, referring to how well the measurements agree with each other across multiple tests), F1-score (explained as a weighted average of recall and precision, where an F1-score attains its best value at one and its worst at zero), and AUC-ROC [a receiver operating characteristic curve (ROC curve) is a graphical plot that illustrates the diagnostic aptitude of a binary classifier scheme as its differential threshold is varied]. An AUC-ROC curve is constructed by plotting the true positive rate (TPR) against the false positive rate (FPR). The TPR is the proportion of observations that were correctly predicted to be positive out of all positive observations [ $TP/(TP + FN)$ ]. Likewise, the FPR is the proportion of observations that are incorrectly predicted to be positive out of all negative observations [ $FP/(TN + FP)$ ]. The ROC curve shows the trade-off between sensitivity (or TPR) and specificity ( $1 - FPR$ ). Classifiers that give curves closer to the top-left corner show better performance. As a baseline, a random classifier is expected to give points lying along the diagonal ( $FPR = TPR$ ). The closer the curve comes to the 45-degree diagonal of the ROC space, the less accurate the testing data are. For each classification group, we also measured Cohen's kappa values, which measures the inter-rater reliability between two individuals (Cohen, 1960). Kappa measures the percentage of information scores in the main diagonal of a table and then adjusts these scores for the quantity of agreement that could be assumed due to chance alone. The formula for calculating Cohen's kappa for two raters is given by  $K = p_0 - p_c / 1 - p_c$ , where  $p_0$  is the relative observed agreement among raters and  $p_c$  is the hypothetical probability of chance agreement. Kappa is always less than or equal to 1. A value of 1 suggests perfect agreement, and scores less than 1 suggest less than the best

<sup>6</sup><https://github.com/IvanoLauriola/MKLpy>

<sup>7</sup><https://github.com/Alzheimer1/Classification-of-Alzheimer-s-disease>

agreement. In rare circumstances, Kappa can achieve a negative score. This signifies that the two groups agreed less than would be predicted by chance alone.

## Classification Performance Across Single and Combined Modalities Using Whole-Brain Parcelation Analysis

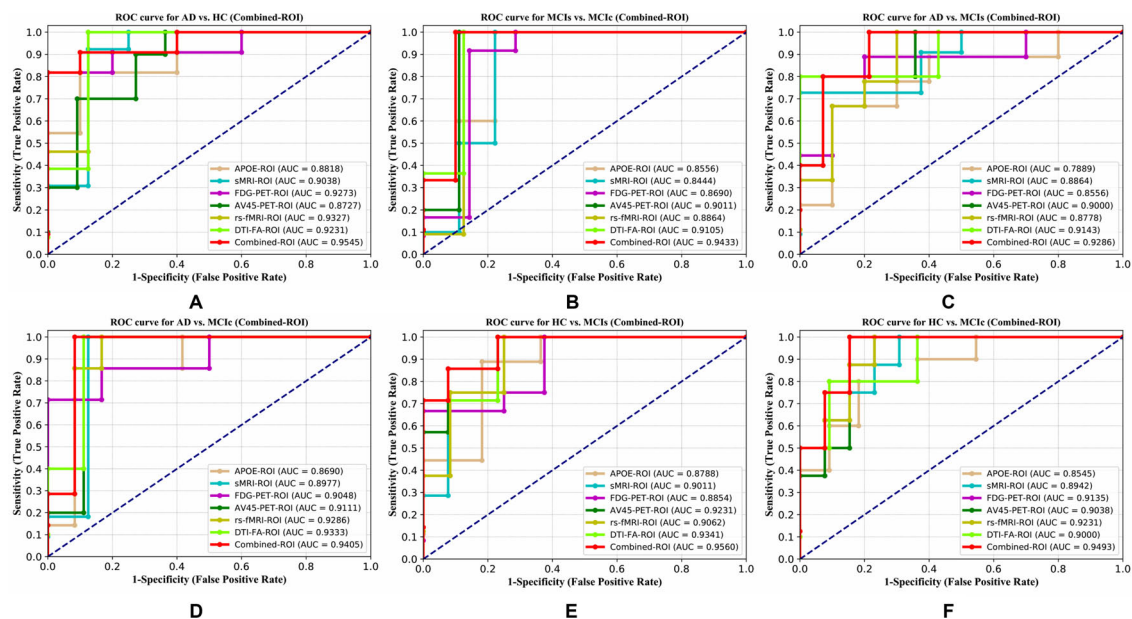

For the whole-brain analysis, we used the 2-mm AICHA atlas template image for sMRI, FDG, and AV45-PET images with the NiftyReg toolbox for the extraction of 384 ROIs from each neuroimaging modality (as shown in **Figure 1B**). For each rs-fMRI and DTI image, we used the 2-mm Craddock atlas template and the 2-mm JHU-WM (ICBM-DTI-81) label atlas for the extraction of 200 and 50 ROIs, from each rs-fMRI and DTI image, respectively, using the pyClusterROI Python script and the PANDA toolbox (as shown in **Figure 1B**). In total, we obtained 1404 features for a single image, 384 features from each sMRI, FDG, and AV45-PET image, 200 from each rs-fMRI image, 50 features from each DTI image, and two features from the APOE genotype data. Afterward, we passed these obtained features through a normalization technique to minimize the redundancy within the dataset. Furthermore, we passed these low-dimensional, normalized features from the polynomial kernel matrix to map them onto a high-dimensional feature space. Then we fused all these high-dimensional features in one form before passing them through the EasyMKL algorithm for classification. The obtained AUC-ROC graph and Cohen's kappa scores are plotted in **Figures 4, 5**.

For the single modalities, whole-brain MKL analysis for AD vs. HC (**Table 2**), using only the APOE genotype, achieved 85.71% accuracy. Similar accuracy was obtained using sMRI (90.48%), FDG-PET (91.5%), AV45-PET (89.39%), and rs-fMRI (92.42%). Using DTI-FA, the accuracy was increased to 93.17% compared with both genotype and functional imaging. When the combined-ROI features were passed through the classifier, the accuracy increased to 96.05%. Additionally, the obtained Cohen's kappa value was 0.9066, which is closer to 1 than the kappa values of the individual modalities. **Figure 5** shows the Cohen's kappa plot for the combined-ROI.

Here, for AD vs. HC classification, the combined-ROI features performed very well compared with the single modalities. Similarly, for the single modalities, whole-brain MKL analysis for MCIs vs. MCIC (**Table 2**) using only the APOE genotype achieved 85.24% accuracy. Similar accuracy was obtained using FDG-PET (86.88%), AV45-PET (89.47%), and rs-fMRI (88.52%). Using sMRI-extracted ROI features, the achieved accuracy was lower (84.71%) in comparison with other single modalities. Using DTI-FA, the accuracy increased to 91.80% in comparison with both genotype and functional images. Moreover, when the combined-ROI features were passed through the classifier, the accuracy increased to 94.74% and the obtained Cohen's kappa value was 0.8950 (**Figure 5**), which is closer to 1 than that for the individual modalities. Here, for the MCIs vs. MCIC classification, the combined-ROI features performed very well compared with the single modalities. Likewise, for the AD vs. MCIC classification problem, the best performance was attained using a combination of six modalities of features, which achieved

an accuracy of 94.89% with a Cohen's kappa of 0.8502. In this case, the rs-fMRI and DTI-FA unimodal features performed better for classifying the (AD vs. MCIC) group than the other unimodal features, and their obtained accuracies were 92.06 and 93.65%. For the AD vs. MCIs group, our proposed technique achieved 93.59% accuracy, which was 1.66% higher than the best accuracy obtained by the DTI-FA (unimodal) feature for classifying this group. The Cohen's kappa score obtained for the AD vs. MCIs group was 0.8562 (**Figure 5**) which is close to the maximum agreement value of 1. For the HC vs. MCIC classification problem, our proposed method combining all six modalities of a biomarker to distinguish between HC and MCIC achieved good results compared with the single modality biomarkers. For this classification problem, our proposed method achieved 94.24% accuracy with a Cohen's kappa of 0.8814 (**Figure 5**). In this case, from **Table 2**, we can see that all three (FDG-PET, AV45-PET, and rs-fMRI) functional imaging features performed well compared with the other unimodal features, and their obtained Cohen's kappa scores were 0.7610, 0.7981, and 0.8129, which are all close to 1. Likewise, for the HC vs. MCIs group, our proposed technique achieved 95.55% accuracy, which is 1.62% higher than the best accuracy obtained by the DTI-FA (unimodal) feature for classifying this group. The obtained Cohen's kappa score for the HC vs. MCIs group was 0.8697 (**Figure 5**), which is close to the maximum agreement value of 1. Therefore, from **Table 2** and **Figures 4, 5**, we can state that for all classification combinations, our proposed method attained a high level of performance compared with the individual modality of biomarkers, varying from 1 to 3%, and our proposed scheme also attained a higher level of agreement between all six classification combinations than the individual modality-based methods.

The number of extracted ROIs was slightly higher for the sMRI, FDG-PET, and AV45-PET images than for the other modalities, although the real number of features used as input for each single and combined model varied across the models. Except for the HC vs. MCIC group, in the (AD vs. HC, MCIs vs. MCIC, AD vs. MCIC, AD vs. MCIs, and HC vs. MCIs) classification sets, it is interesting to observe that even though the number of extracted ROI features for sMRI, FDG-PET, AV45-PET, and rs-fMRI were higher than the number of DTI-FA ROI features, the obtained accuracy was lower than for the DTI-FA ROI features for the stated classification groups. Out of the 1404 ROIs, 384 ROIs selected from sMRI, 384 ROIs selected from FDG-PET, 384 ROIs selected from AV45-PET, 200 ROIs from rs-fMRI, 50 ROIs from DTI-FA, and the remaining two ROIs from APOE genotype corresponded to 27.3% (each of sMRI, FDG-PET, and AV45-PET), 14.5% (rs-fMRI), 3.5% (DTI-FA), and 0.1% (APOE) of the total number of features. In **Figure 4**, we show the ROC curves (plots of the TPR vs. the FPR for dissimilar possible cut-points) for each study presented in **Table 2**. The obtained AUC is presented in each plot. **Figure 4** shows that our proposed method achieved higher AUC values for all classification sets than did the individual modalities. For the AD vs. HC and HC vs. MCIs classification groups, our proposed method achieved an AUC greater than 95%, while for the MCIs vs. MCIC, AD vs. MCIs, AD vs. MCIC, and HC vs. MCIC groups, the proposed method achieved an AUC less than 95%, (MCIs vs. MCIC, AD vs. MCIs, AD vs. MCIC, and HC vs. MCIC) < 95% < (AD

**FIGURE 4 |** ROC curve for (A) AD vs. HC, (B) MCIs vs. MCICs, (C) AD vs. MCIs, (D) AD vs. MCICs, (E) HC vs. MCIs, and (F) HC vs. MCICs using whole-brain parcellation analysis. The red solid line shows the result of a combined-ROI curve with single modality features.

**FIGURE 5 |** Cohen's kappa plot for AD vs. HC, MCIs vs. MCICs, AD vs. MCIs, AD vs. MCICs, HC vs. MCICs, and HC vs. MCIs are grouped using whole-brain parcellation analysis. The above graph clearly shows the benefit of the combined-ROI modality over any single modality.

vs. HC and HC vs. MCIs). The obtained result using the RBF-SVM classifier can be found in **Supplementary Table S31**. From **Supplementary Table S31**, we can say that the combined-ROI features performed very well as compared with the individual modality outcomes for all six binary classification groups. **Table 2** and **Supplementary Table S31** clearly show the advantage of using combined features over individual ones (see **Supplementary Table S31**).

## Classification Performance Across Single and Combined Modalities Using Voxel-Wise Analysis

For the voxel-wise analysis of the sMRI, FDG-PET, and AV45-PET images, we used the SPM12 toolbox with the integration of the CAT12 toolbox in MATLAB R2019a. For the DTI images, we used the DTIfit and TBSS functions from the FSL toolbox.

**TABLE 2 |** Classification results for AD vs. HC, MCIs vs. MCIC, AD vs. MCIs, AD vs. MCIC, HC vs. MCIC, and HC vs. MCIs groups using ROI features (EasyMKL).

For the voxel-wise analysis of rs-fMRI images, we used the DPARSF toolbox in MATLAB R2019a. Afterward, we passed these obtained features with two features from the APOE genotype data through a normalization technique to minimize

the redundancy within the dataset. Furthermore, we passed these low-dimensional, normalized features from the polynomial kernel matrix to map them onto a high-dimensional feature space. Then we fused all these high-dimensional features in one

form before passing them through the EasyMKL algorithm for classification. The obtained result are shown in **Table 3** and **Figure 6** shows the Cohen's kappa plot for all six classification groups using voxel-wise analysis.

### AD vs. HC

We calculated the statistical values that represented the significance levels of the groups in the activation map as presented in **Supplementary Tables S1–S5** after comparing the outcomes of the statistical two-sample *t*-tests for the AD vs. HC group. These tables specify the main affected area observed in the AD vs. HC set and the obtained voxel cluster with detailed information, including its peak areas in the form of the MNI space, cluster-level *p*-score, and the peak intensity in the *T*-score of each group. We used an uncorrected threshold value of  $p_{uncorrected} \leq 0.001$  at the voxel level, an FDR value of  $p_{FDR} = 0.05$ , and an FWER value of  $p_{FWER} = 0.05$  at the cluster level to achieve a bias alteration for multiple comparisons. An ROI binary mask was created from the selected clusters of each modality, and later the GM and WM volumes were removed from the two sets of images (AD vs. HC) (see **Supplementary Tables S1–S5**). **Figure 7A** shows the most significant regions where these groups differ from each other using an AV45-PET neuroimage, and the obtained voxel cluster is shown in **Supplementary Table S3**. Likewise, **Figure 8A** shows the most significant regions where these groups differ from each other using a DTI-FA neuroimage, and the obtained voxel cluster is shown in **Supplementary Table S5** (see **Supplementary Tables S3, S5**).

### MCIs vs. MCIC

**Supplementary Tables S6–S10** show the main affected areas in the MCIs vs. MCIC group, the obtained voxel clusters with detailed information about its peak coordinates in the MNI space, the cluster-level *p*-score, and the peak intensity in the *T*-score of each group. For the MCIs vs. MCIC group, we used an uncorrected threshold value of  $p_{uncorrected} \leq 0.001$  at the voxel level, an FDR value of  $p_{FDR} = 0.05$ , and an FWER value of  $p_{FWER} = 0.05$  at the cluster level to accomplish a bias alteration for multiple comparisons. An ROI binary mask was created from the selected clusters of each modality and later GM and WM volumes were removed from the two sets of images (MCIs vs. MCIC) (see **Supplementary Tables S6–S10**). **Figure 7B** shows the most significant region where these groups differ from each other using an AV45-PET neuroimage, and the obtained voxel cluster is shown in **Supplementary Table S8**. Likewise, **Figure 8B** shows the most significant region where these groups differ from each other using a DTI-FA neuroimage, and the obtained voxel cluster is shown in **Supplementary Table S10** (see **Supplementary Tables S8, S10**). Moreover, we followed the same procedure for the calculation of voxel clusters for the AD vs. MCIC, AD vs. MCIs, HC vs. MCIC, and HC vs. MCIs groups as we followed for the AD vs. HC and MCIs vs. MCIC groups. The obtained voxel clusters with detailed information about its peak coordinates in the MNI space, the cluster-level *p*-score, and the peak intensity in the *T*-score of each group are shown in **Supplementary Tables S11–S30** (see **Supplementary Tables S11–S30**). Likewise, **Supplementary Figures S1a,b** show the most significant region

for the AD vs. MCIC and HC vs. MCIC groups using the DTI-FA modality of the biomarker.

The obtained voxel cluster for these two groups is shown in **Supplementary Tables S15, S25** (see **Supplementary Figures S1a,b** and **Supplementary Tables S15, S25**). After completing the extraction of the series of features from each individual modality, we passed these obtained features through the polynomial kernel matrix to map these low-dimensional features onto a high-dimensional feature space. We then fused all these high-dimensional features in one form before passing them through the EasyMKL algorithm for classification. **Table 3** shows the classification results for the AD vs. HC group using voxel-wise features. It shows that the combined features performed very well for this group compared with the single-modality results. The combined features achieved a 95.55% AUC for classifying the AD vs. HC group, as shown in **Figure 9**, with a Cohen's kappa value of 0.9014, which is close to 1, as shown in **Table 3** and **Figure 6**. This indicates that these two groups have a good level of agreement between them. **Table 3** shows the classification results for the MCIs vs. MCIC group using voxel-wise features. This table also shows that the combined features performed very well for classifying the MCIs vs. MCIC group compared with the single-modality performances. The combined features achieved an AUC of 94.90% when classifying the MCIs vs. MCIC group, as shown in **Figure 9**. The Cohen's kappa value was 0.8825, which is close to 1, as shown in **Table 3** and **Figure 6**. This indicates a good level of agreement between the two groups. Furthermore, for the AD vs. MCIC and AD vs. MCIs classification groups, our proposed system attained a high level of performance and agreement (0.9145 and 0.8869) compared with the individual modalities biomarkers. For the AD vs. MCIC group, AV45-PET and DTI-FA attained high classification accuracy compared with other unimodal biomarkers, but their gained accuracy was 3% less than the accuracy gained by the combined-VOI process, which was 96.20% with a 0.9145 (**Figure 6**) Cohen's kappa score. Likewise, for the AD vs. MCIs group, the proposed method achieved 95.16% accuracy with a 0.8869 (**Figure 6**) Cohen's kappa score. For the HC vs. MCIC classification group, the AV45-PET individual modality biomarkers performed very well compared with the other single modality biomarkers. The obtained accuracy and Cohen's kappa score using AV45-PET biomarkers were 94.02% and 0.8481 (**Figure 6**). Moreover, we then passed the combined-VOI features through the EasyMKL classifier for the classification of the HC vs. MCIC group, and after the classifier was applied, the accuracy increased by 1.5%. This suggests that the combined-VOI features were beneficial for classifying this group. Likewise, for the HC vs. MCIs classification group, the rs-fMRI features of ALFF and fALFF achieved a good level of performance and agreement (0.8386 and 0.8248) compared with the other individual modality biomarkers. In this case, the individual features of the APOE genotype also performed well compared with the FDG-PET imaging modality biomarker, but the individual modality biomarker's performance was not very good compared with the combined-VOI result (**Table 3**). The combined-VOI features achieved a 94.43% accuracy and an AUC of 94.67% with a 0.8864 Cohen's kappa score for classifying the HC vs. MCIs group. **Figure 9** shows the

**TABLE 3 |** Classification results for AD vs. HC, MCIs vs. MCIC, AD vs. MCIs, AD vs. MCIC, HC vs. MCIC, and HC vs. MCIs groups using voxel-wise (VOI) features (EasyMKL).

**FIGURE 6 |** Cohen's kappa plot for AD vs. HC, MCIs vs. MCIC, AD vs. MCIC, AD vs. MCIs, HC vs. MCIC, and HC vs. MCIC are grouped using voxel-wise analysis. The above graph clearly shows the benefit of the combined-VOI modality over any single modality.

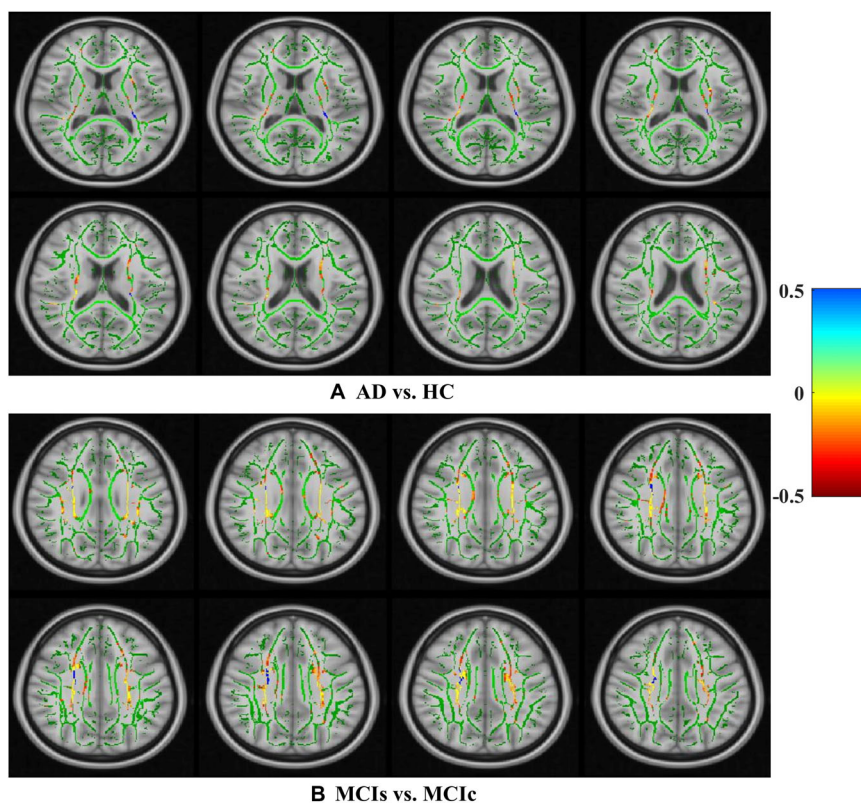

**FIGURE 7 |** Affected region for (A) AD vs. HC, and (B) MCIs vs. MCIC is shown using AV45-PET image.

ROC curve for all six classification groups; the red solid line in every classification task indicates the combined-VOI features for that particular group. Consequently, from **Table 3** and **Figures 6, 9**, we can state that for all classification combinations, our proposed method attained a high level of performance compared with the individual modality biomarkers, varying from 1 to 3%, and our proposed scheme also attained a high level of agreement between each of the six classification combinations compared with the individual modality-based methods. The obtained result using the RBF-SVM classifier can be found in **Supplementary Table S32**. From **Supplementary Table S32**, we can say that the combined-VOI features performed very

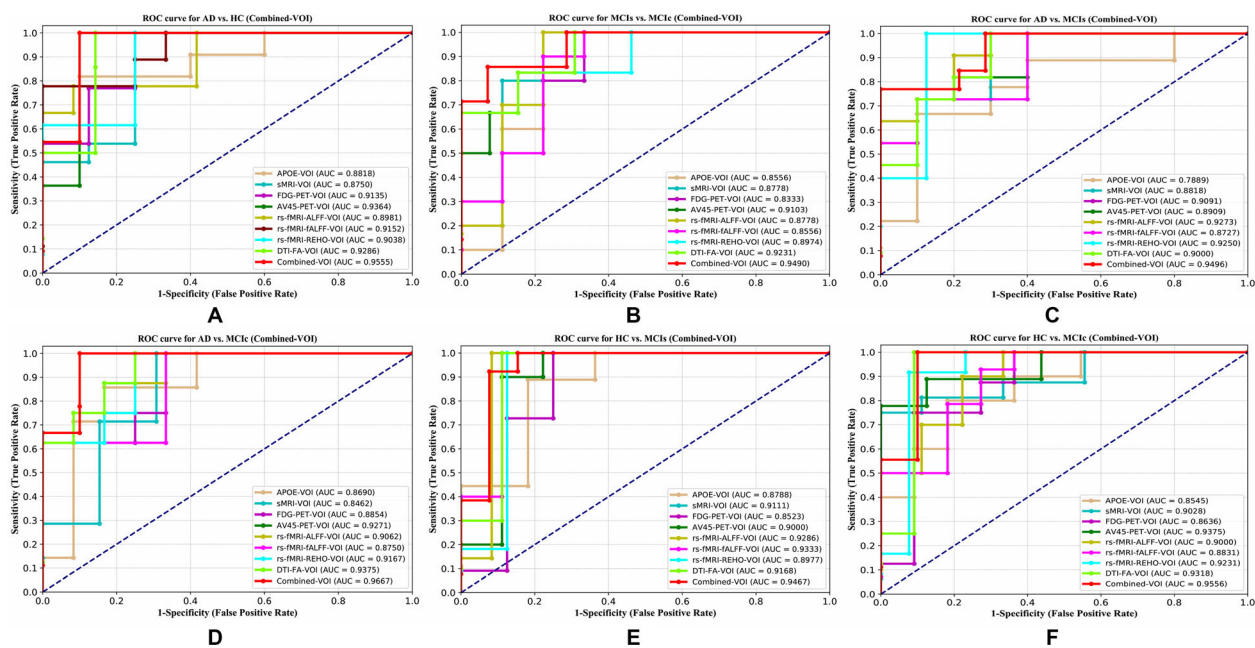

well as compared with the individual modality outcomes for all six binary classification groups. **Table 3** and **Supplementary Table S32** clearly show the advantage of using combined features over individual ones (see **Supplementary Table S32**).

While searching for the most significant region where AD vs. HC subjects differed from each other, we found that the (left/right) temporal-mid, (left/right) frontal-sup, (left/right) occipital-mid, (left/right) occipital-inf, (left/right) temporal-sup, (left/right) fusiform, (left/right) hippocampus, (left/right) temporal-inf, (left/right) precentral, and the (left/right) sagittal stratum were the regions where these subjects differed from each other most (**Supplementary Tables S1–S5**). Likewise,

**FIGURE 8 |** Selected WM voxels for the (A) AD vs. HC, and (B) MCIs vs. MCIC classification using DTI image.

**FIGURE 9 |** ROC curves for (A) AD vs. HC, (B) MCIs vs. MCIC, (C) AD vs. MCIs, (D) AD vs. MCIC, (E) HC vs. MCIs, and (F) HC vs. MCIC using voxel-wise (VOI) analysis. The red solid line shows the result of the combined-VOI curve, including all single-modality features.

for the MCIs vs. MCIC group, we found that the (left/right) precentral, (left/right) precuneus, (left/right) frontal-mid, (left/right) cingulum-mid, (left/right) temporal-inf, (left/right) temporal-sup, (left/right) frontal-dup-medial, (left/right) cerebellum-9, (left/right) thalamus, and (left/right) fusiform were the regions where these subjects differed from each other most significantly (**Supplementary Tables S6–S10**). For the AD vs. MCIC group, we found that the (left/right) frontal-inf-tri, (left/right) frontal-inf-oper, (left/right) frontal-inf-orb, (right) hippocampus, (left/right) precentral, (left/right) thalamus, (left) pallidum, (left/right) lingual, and (left/right) inferior longitudinal fasciculus were the regions where these group subjects differed from each other most (**Supplementary Tables S11–S15**). As for the AD vs. MCIs group, we found that the (left/right) precentral, (left/right) frontal-mid, (left/right) hippocampus, (left/right) temporal-inf, (left/right) frontal-inf-orb, (left/right) occipital-mid, (right) posterior corona radiate, and (left/right) precuneus were the most significant regions where these group subjects differed from each other (**Supplementary Tables S16–S20**). For the HC vs. MCIC and HC vs. MCIs groups, we found that the (left/right) precentral, (left/right) cerebellum-6, (left/right) precuneus, (left/right) frontal-mid, (left/right) corticospinal tract, (left/right) lingual, (right) amygdala, and the (left/right) occipital-sup were the most significant regions where these two groups differed from each other (**Supplementary Tables S21–S30**). It is interesting to note that the (left/right) precentral region was found in every classification problem when computing voxel clusters (see **Supplementary Tables S1–S30**).

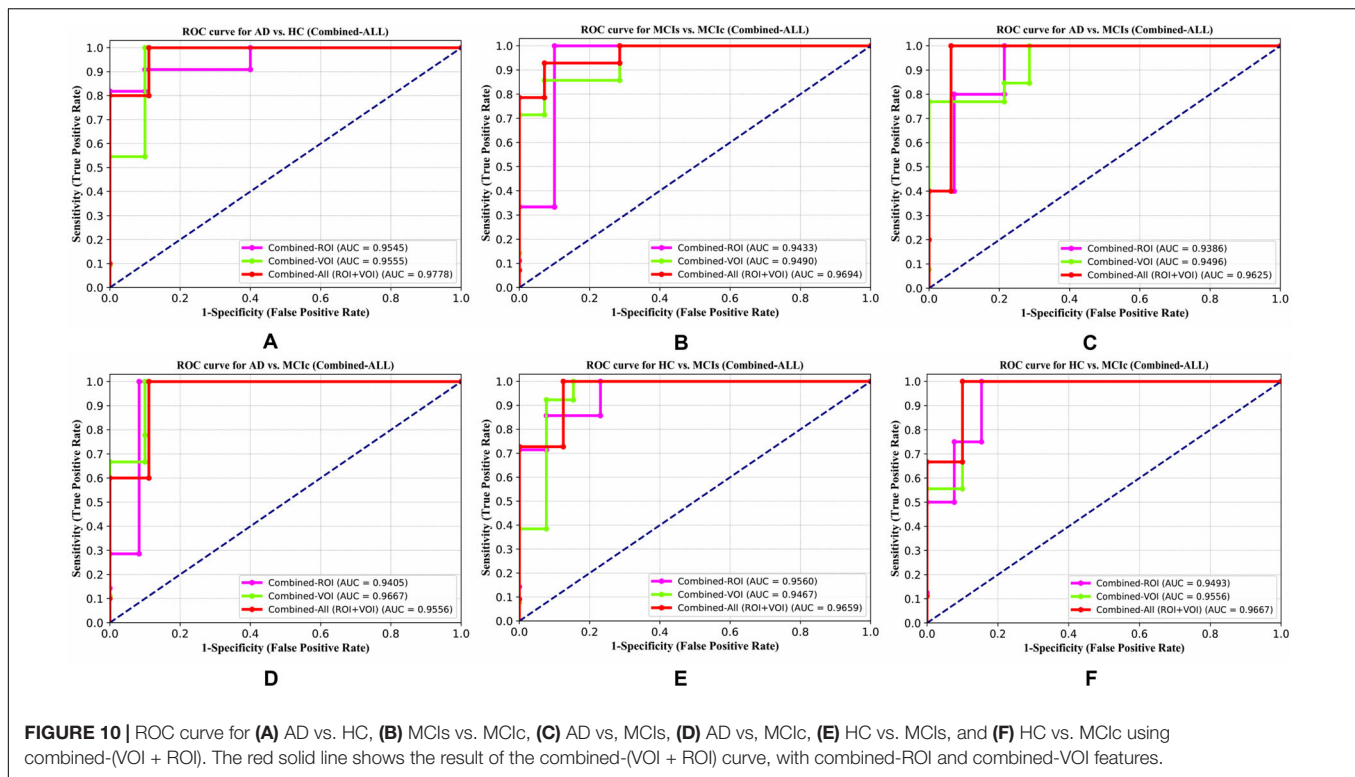

**Table 4** shows the combined (VOI + ROI) classification results for all six classification groups after concatenating the extracted features from the whole-brain and voxel-wise methods

with the APOE genotype. Before passing these features to the EasyMKL classifier, we applied a polynomial kernel matrix to map these low-dimensional features onto a high-dimensional feature space, so that every feature revealed its importance to the classifier. These high-dimensional features were fused into one form. We then passed these features to the MKL algorithm for classification.

For the AD vs. HC classification group, the combined-(VOI + ROI) feature performed very well compared with the combined-VOI and combined-ROI features. The AUC and Cohen's kappa scores were increased by 2–2.5% (97.78%, 0.9456) compared with those of combined-ROI and combined-VOI (**Figure 10** and **Table 4**). Moreover, for the MCIs vs. MCIC classification group, **Table 4** and **Figure 10** show that the combined-(VOI + ROI) features achieved an AUC of 96.94% (2% increment), which was very high compared with the other two combined features. The obtained Cohen's kappa value (0.9247) was also high compared with that of the combined-VOI and combined-ROI. Furthermore, for the AD vs. MCIs, HC vs. MCIs, and HC vs. MCIC classification groups, our proposed system performed very well compared with the results obtained by the combined-VOI and the combined-ROI for these groups. From **Table 4**, we can see that for these three (AD vs. MCIs, HC vs. MCIs, and HC vs. MCIC) groups, there is a 2–3% increment in every measured performance. The obtained AUC scores for these three groups are 96.25, 96.59, and 96.67%. Likewise, in the case of the AD vs. MCIC group, the Combined-ROI method performed very well compared with the combined-(VOI + ROI) and combined-VOI methods. The measured performance difference was not exceedingly high between the combined-ROI and the combined

**TABLE 4 |** Classification result of AD vs. HC, MCIs vs. MCIC, AD vs. MCIs, AD vs. MCIC, HC vs. MCIC, and HC vs. MCIs groups using combined-(VOI + ROI) features, with both whole-brain and voxel-wise features (EasyMKL).

	<b>Combined (VOI + ROI)</b>		<b>96.59</b>	<b>96.97</b>	93.75	<b>100</b>	<b>100</b>	<b>96.78</b>	<b>0.9187</b>

(VOI + ROI) method (just 1%) for the AD vs. MCIC group. The obtained result using the RBF-SVM classifier can be found in **Supplementary Table S33**. From **Supplementary Table S33**, we can say that the combined-(VOI + ROI) features performed very well as compared with the combined-ROI and combined-VOI features for all six binary classification groups. **Table 4** and **Supplementary Table S33** clearly show the advantage of using combined-(VOI + ROI) features over those of combined-ROI and combined-VOI (see **Supplementary Table S33**).

## Graph Network Construction and Analysis for All Six Classification Groups

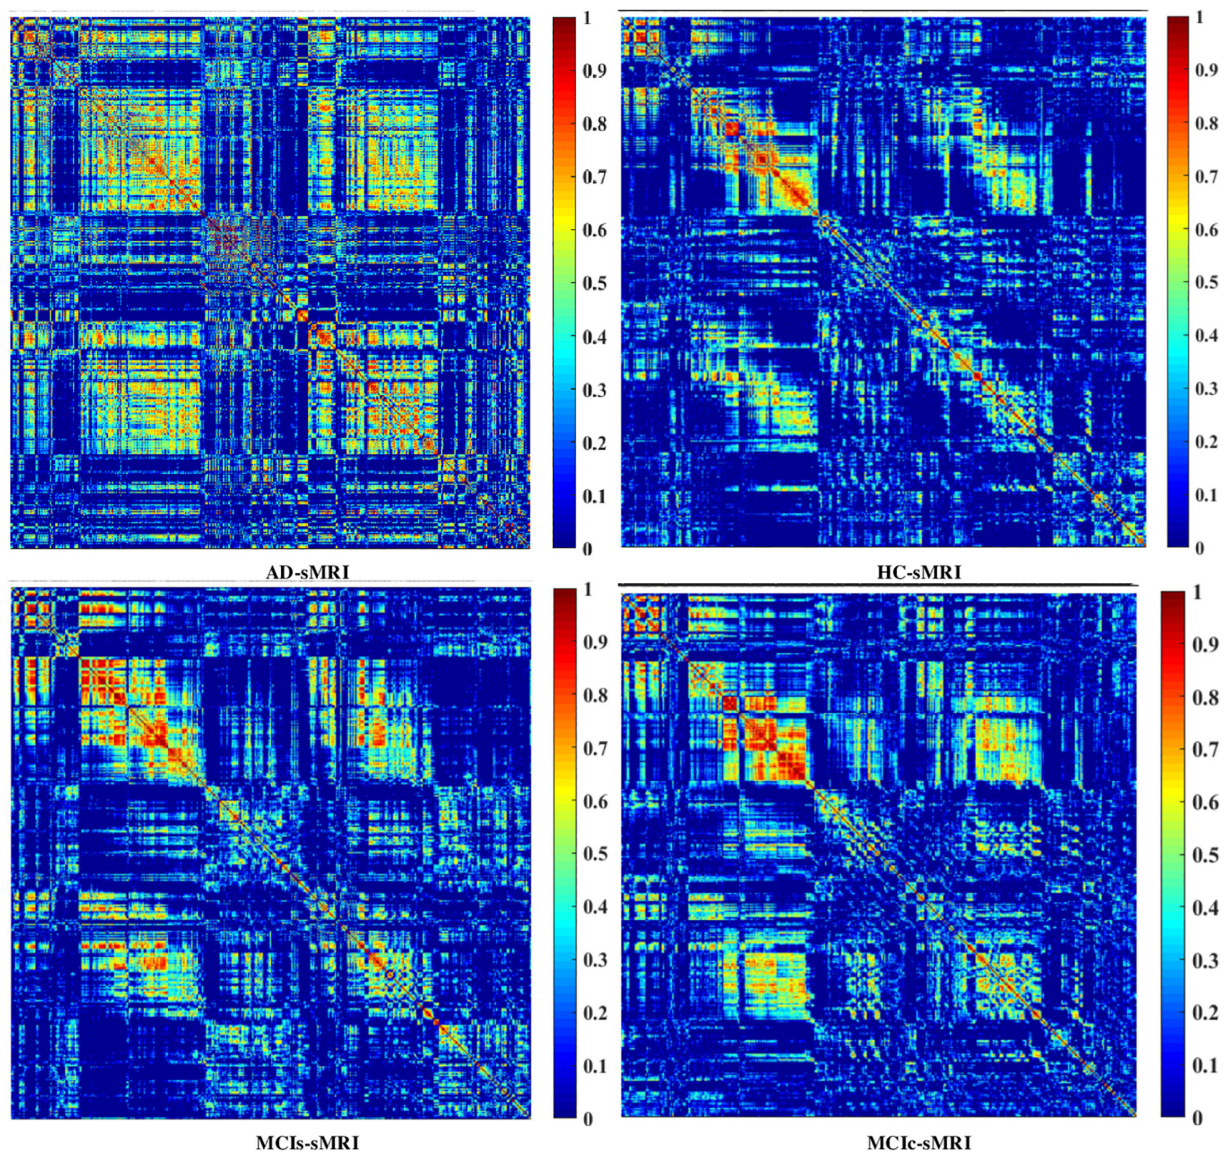

For graph analysis or construction of a graph network, we used the BRAPH toolbox integrated into MATLAB 2019a. Additionally, we performed structural and functional graph theory for all six binary classification groups (AD vs. HC, MCIc vs. MCIC, AD vs. MCIC, AD vs. MCIs, HC vs. MCIs, and HC vs. MCIC). Nodal measures were taken and comparisons were performed using the binary undirected graphs, and their measures were assessed over a set of network densities, which refers to the ratio between the number of connections in the network and the number of possible connections, ranging from 5–25% with a step size of 0.5%. Several graph metrics were calculated to quantify the nodal or global topological organization of the structural and functional networks, including local efficiency, characteristic path length, transitivity, and modularity. For all six binary classification groups, non-parametric permutation test samples with 1000 permutations each were conducted to assess the differences between the

groups, which were significant for a two-tailed test of the null hypothesis at  $p < 0.05$ . The structural correlation matrices graph of AD, HC, MCIs, and MCIC of the sMRI subjects is shown in **Figure 11**. All groups showed strong correlations between bilaterally homologous regions. The plots in **Figures 12, 13** and **Supplementary Figures S2–S5** show the lower and upper bounds (dark red spheres) of the 95% confidence intervals (CI) (dark gray shade) as a function of density. The blue, green, pink and purple spheres show the differences between sets and, when falling beyond the CI, indicate that the change was statistically significant at  $p < 0.05$ .

The small dark red dot in the middle with a value around zero specifies the mean value of the change in the global network measures between the randomized sets after the permutation tests.

We also compared the nodal degree for all six binary classification groups using all modalities. The FDR correction value was kept constant at 0.05 for all six binary classification groups. Regarding the global network topology shown for AD vs. HC in **Figure 12**, we found a longer characteristic path length using only FDG (which started at 0.15) than that with other neuroimaging modalities, and the path length was above the mean value of the difference. In the case of local efficiency, we found that the AV45 modality was the only one that started (at 0.05) above the mean value. Moreover, by comparing the modularity graph in the AD vs. HC group, we found that sMRI showed the greatest difference (modularity started at 0.14) of all modalities, and its network densities were almost constant until 25% (showing that the network topology is widely spread). The rs-fMRI modality performed very well for the transitivity

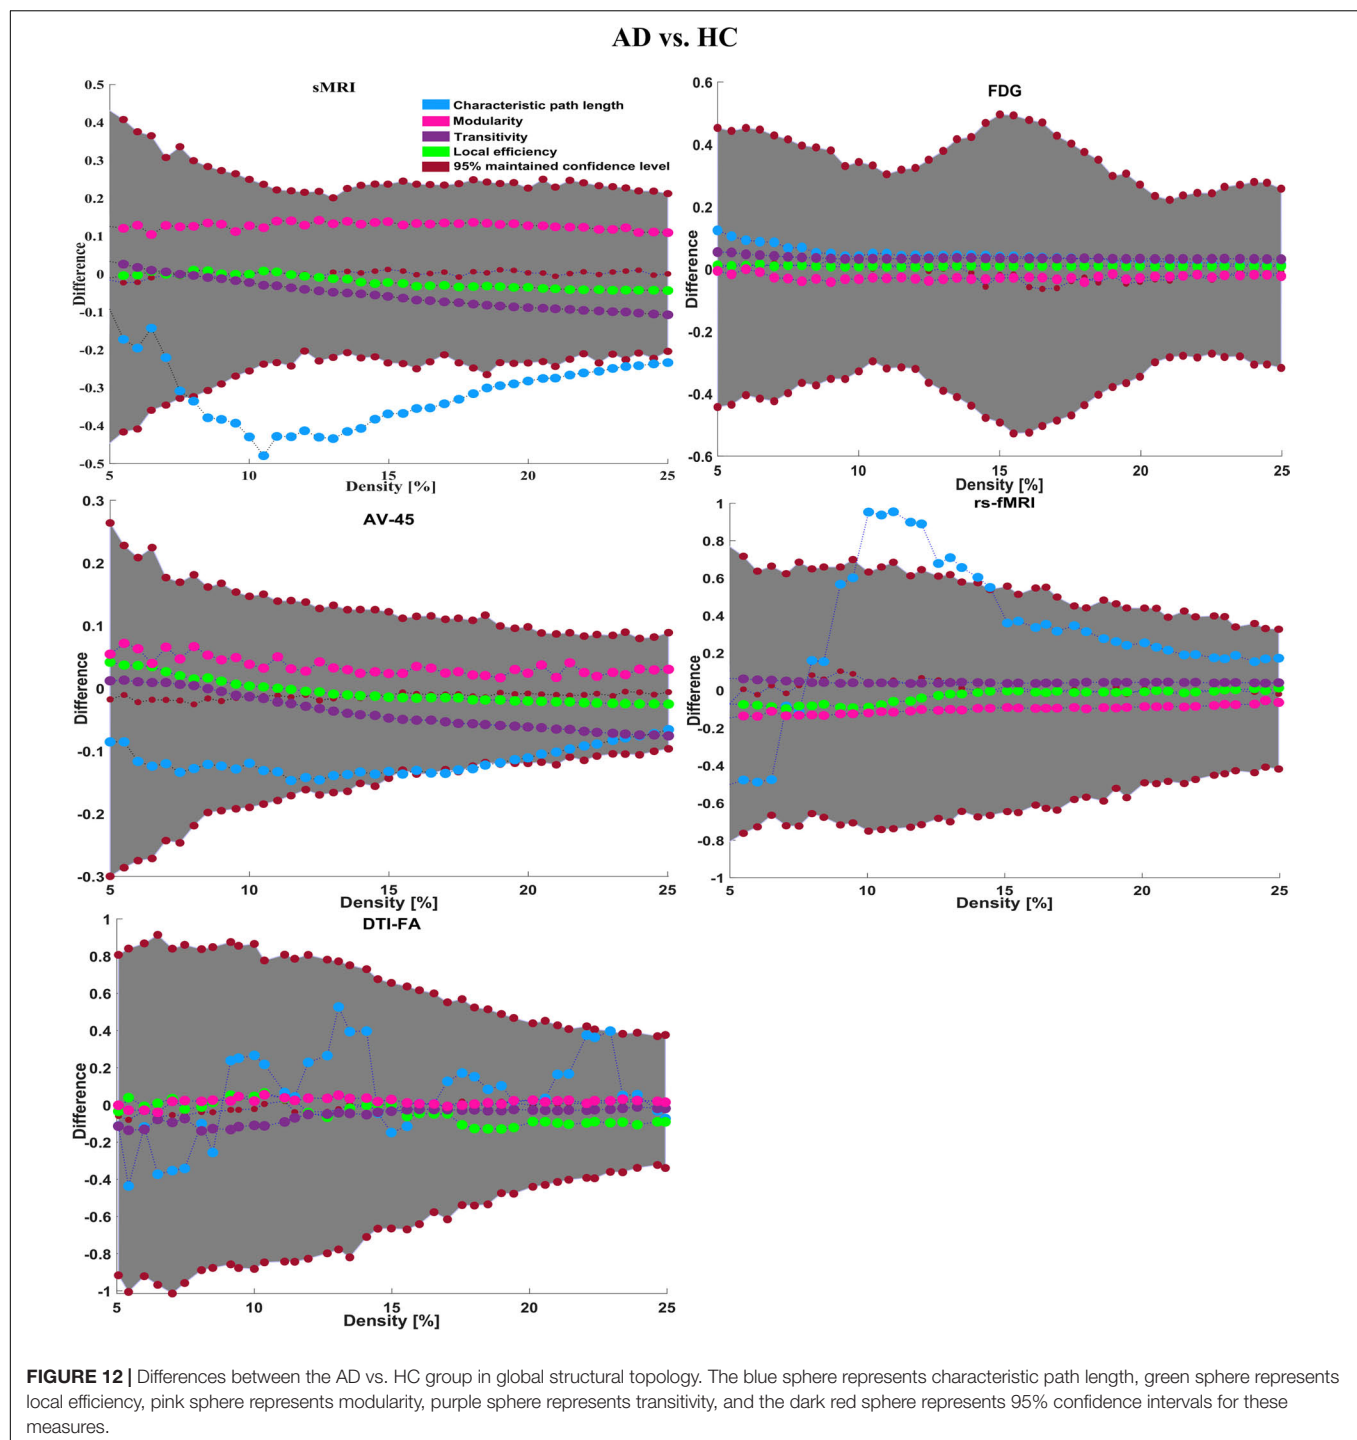

**FIGURE 11 |** Weighted correlation matrices graph (of 384 regions) for AD, HC, MCIs, and MCIC for sMRI biomarkers.

graph compared with the other modalities, starting from 0.06 and increasing to 25%, although it decreased in some network densities. Moreover, we also computed the regional or nodal network topology for the AD vs. HC group, which is shown in **Figures 14A,B**. **Figures 14A,B** show that the AV45 and FDG-PET modalities are the only one neuroimage that shows the numbers of significant region changes in a nodal network topology for the AD vs. HC group. The nodal degree showed significant increases in the right g-frontal-sup-1, left g-cuneus-2, left g-frontal-sup-3, left g-frontal-sup-1, left g-frontal-med-orb-1, and right s-precentral-3 regions. Likewise, for the MCIs vs. MCIC group, we found increases in the characteristic path length and local efficiency using FDG (in both cases, it started at 0.01, as shown in **Figure 13**). For the modularity, sMRI attained 5%

network density, but after that, it decreased to 25%. At the same time, the modularity in DTI neuroimages increased in network density from 10 to 25%. Likewise, for transitivity, compared with other modalities that started below the mean value, the AV45 modality was the only modality that started from 0 (difference), and its network increased in every single network density.

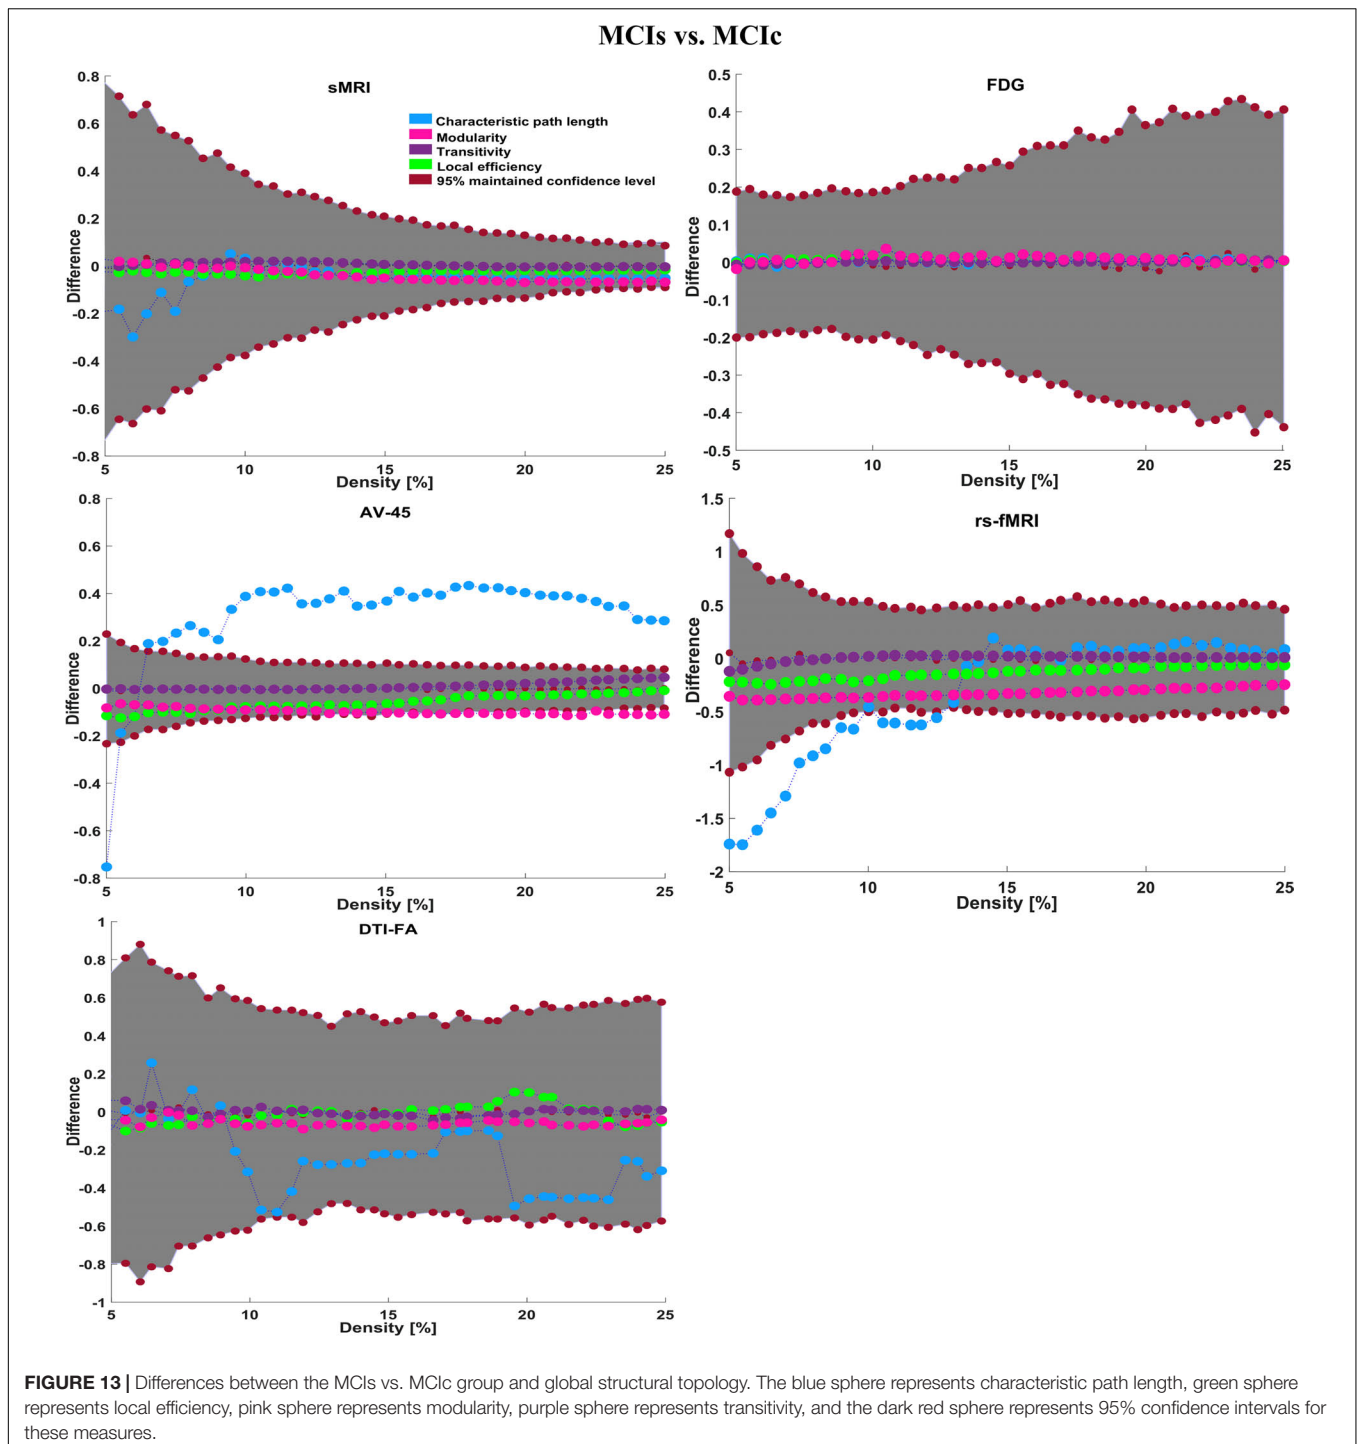

This transitivity plot shows the most widespread topological changes for the MCIs vs. MCIC group. **Figures 14C,D** show that the AV45-FDG is the most important modality to show the numbers of significant region changes in the nodal topology of the MCIs vs. MCIC group. Left s-postcentral-2, right g-parietal-inf-1, left g-frontal-inf-tri, right g-lingual-2, right g-parahippocampus-5, left n-thalamus-6, left s-parietooccipital-4, left-lingual-3, and left g-cingulum-post-2 are the most

significant regions shown by the nodal degree for the MCIs vs. MCIC classification group. For the AD vs. MCIC classification group, the global network topology is shown in **Supplementary Figure S2**. The rs-fMRI is the only modality that shows an increment in the characteristic path length measure. It starts at 0.38 (difference), and lies inside the CI and above the mean value, but at 15–17% network density, some of its networks lie outside of the CI upper bound, and again from

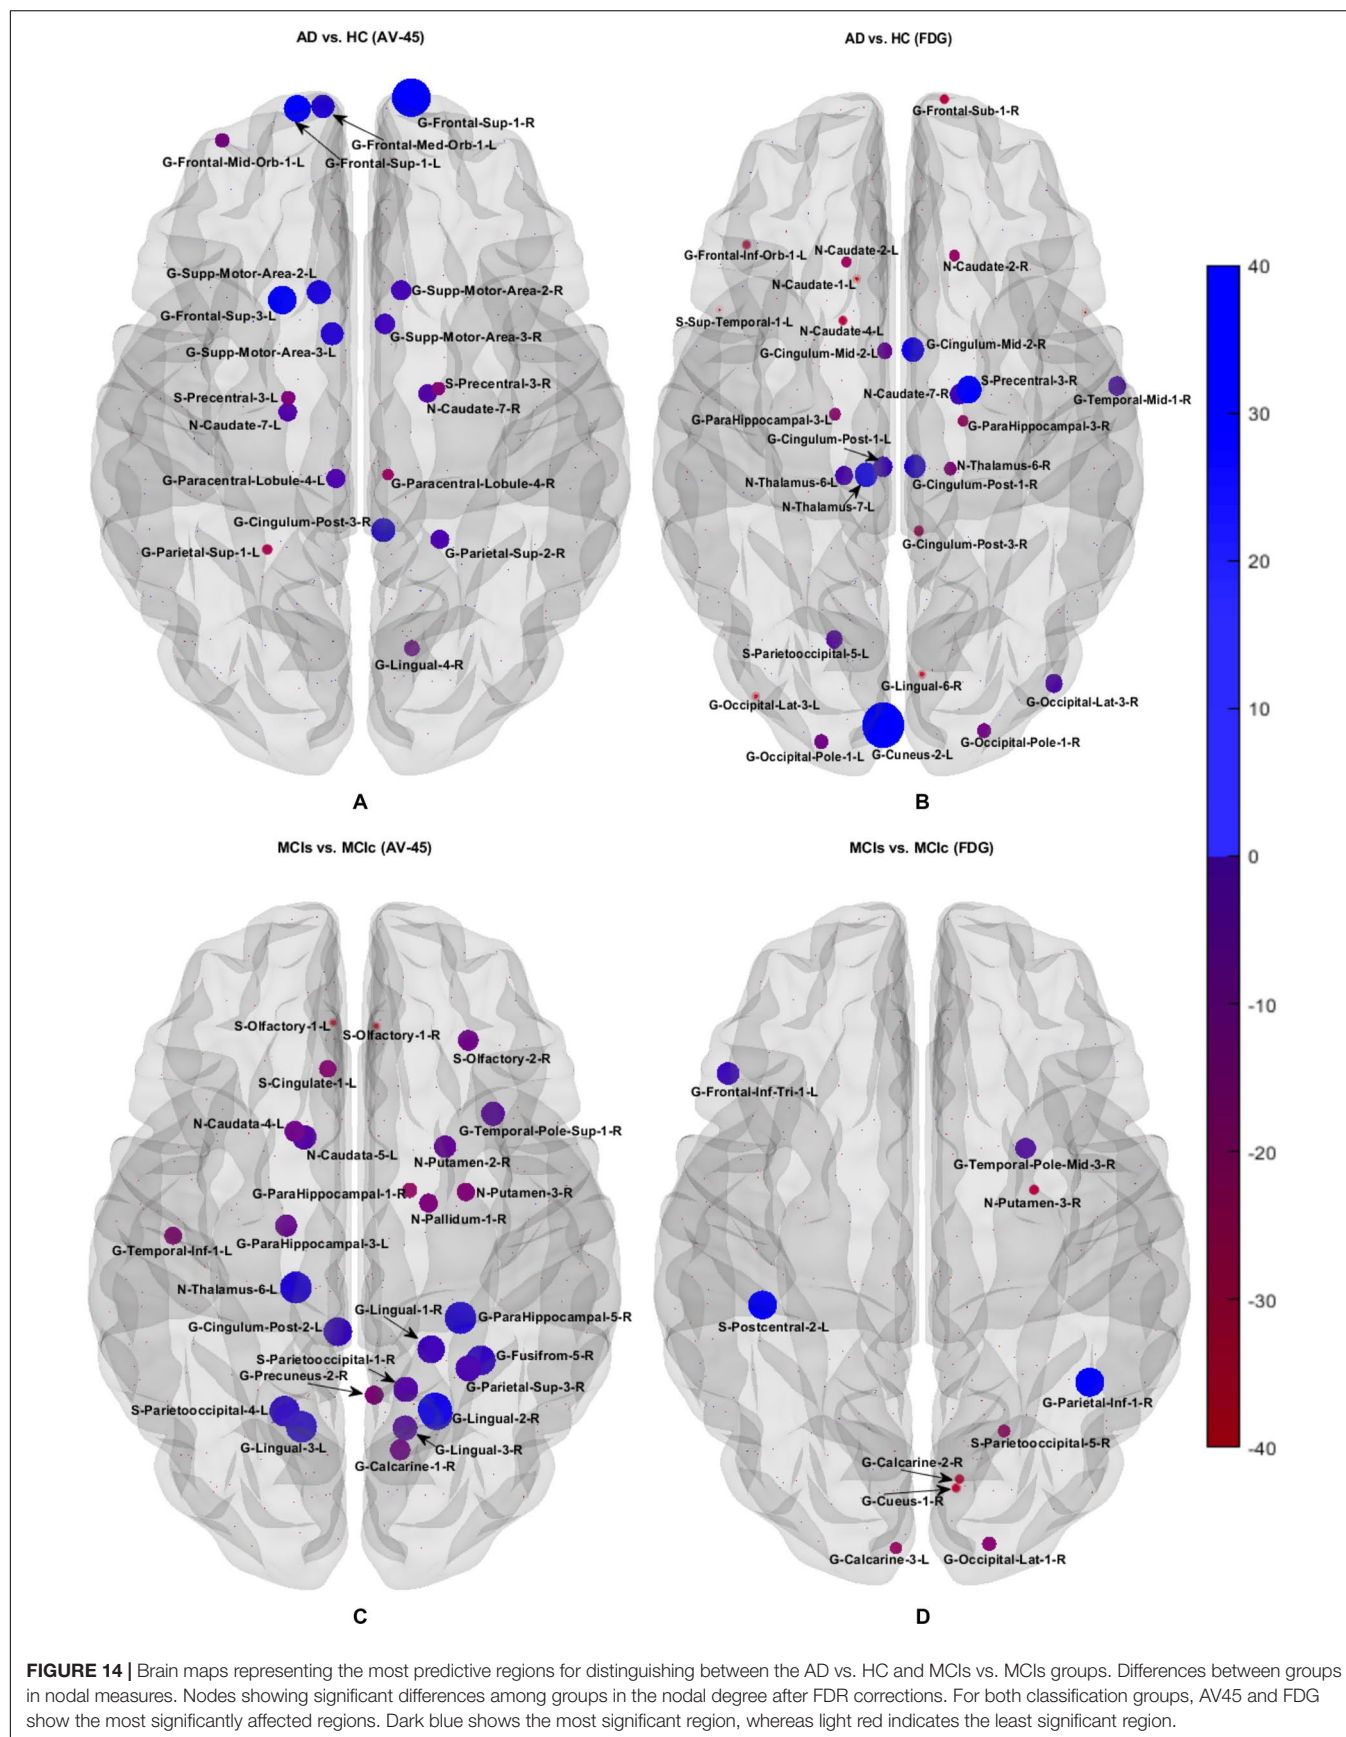

18% density, its network lies inside the CI until 25% density is reached. We can also see that at around 13% network density, some of its networks are close to the mean value (which is shown by small dark red dots). It shows the most widespread topological changes for the AD vs. MCIC group. The FDG-PET modality shows an increase only for the local efficiency measure. Modularity and transitivity increase across almost all network densities for the sMRI and AV45-PET modality compared with

the other individual modalities. **Supplementary Figures S6a,b** show that AV45 and rs-fMRI modalities are the only one that shows the numbers of significant region changes in a nodal network topology for the AD vs. MCIc group. The nodal degree shows significant increases in the left g-lingual, (left/right) g-lingual-3, (left/right) occipital pole, right cerebellum, left n-caudate-5, right n-caudate-2, left n-thalamus-2, and left frontal pole regions (see **Supplementary Figures S2, S6**). Likewise, for

the AD vs. MCIs group, the global network topology is shown in **Supplementary Figure S3**. The FDG-PET modality is the only one showing a characteristic path length that lies inside the CI and above the mean value. In comparing local efficiency measures in every modality, we found that the rs-fMRI modality was the only one neuroimage that lies above the mean value (which is plotted by small dark red), although every modality lies inside the CI. The modularity increased, and at the same time,

the transitivity decreased for the AD vs. MCIs group, as shown by the sMRI modality, but both plots lie inside the 95% CI. The right n-caudate-2, left g-insula-anterior-2, left g-frontal-mid-orb-1, left g-cuneus-2, right g-angular-3, right g-occipital-pole-1, right n-thalamus-6 were the most significant regions as shown by the nodal degree for the AD vs. MCIs classification group using FDG and sMRI images (**Supplementary Figures S3, S6c,d**). The global network topology is plotted in **Supplementary Figure S4** for the HC vs. MCIs classification group. From this plot we can see that the characteristic path length begins at 0.8 (difference) at a 5% density in the rs-fMRI modality (which is very high compared with other modalities). However, it suddenly begins to decrease at 8–13% density, and crosses lower bound (represented by a dark red sphere), and again later, it increases at 14% network density. The rs-fMRI modality is the only one neuroimage where the local efficiency, modularity, and transitivity lie above the mean values (small dark red sphere). Moreover, this plot lies in the middle of the 95% confidence interval. **Supplementary Figures S7a,b** show that the DTI-FA and rs-fMRI modalities are the only one neuroimage that show the numbers of significant region changes in the nodal network topology for the HC vs. MCIs group. The nodal degree shows significant increases in the right inferior-parietal-g, left superior occipital-g, right brainstem, right midbrain, left postcentral-g, left parahippocampal-g, left corticospinal tract, (left/right) posterior limb of the internal capsule, and the left uncinate fasciculus regions (see **Supplementary Figures S4, S7**). For the HC vs. MCIs classification group, the global network topology is shown in **Supplementary Figure S5**. In this case, characteristic path length using the sMRI modality is the only one that lies above the mean value. The local efficiency increases with both (sMRI and rs-fMRI) modalities, and their network lies above the mean value (which is represented by the small dark red sphere). The modularity plot shows that the rs-fMRI image is the only one in which there is an increment in the network density from 6 to 25%, whereas in the same image, the transitivity decreases from 6 to 25% density. However, both of these networks lie inside the CI. **Supplementary Figures S7c,d** show that the sMRI and FDG modalities are the only one neuroimage that shows the numbers of significant region changes in a nodal network topology for the HC vs. MCIs group. The nodal degree shows significant increases in the right g-cuneus-2, left g-occipital-sup-1, left g-Supp-motor-area-1, left n-Caudata-6, left n-thalamus-2, right n-thalamus-1, and the right temporal-pole-mid-3 regions (see **Supplementary Figures S5, S7**).

## DISCUSSION

The present study outcomes provided insights into multimodal behavior for classifying all six binary classification groups, and it also showed which regions or single modality are most significant for future analysis for the discrimination of AD at a clinical level. Here, our proposed idea was to combine multiple neuroimaging modalities (sMRI, AV45, FDG, rs-fMRI, and DTI) with a genetic biomarker (APOE) for the classification of AD patients and other groups using whole-brain, voxel-wise, and graphical analysis

methods. In this study, we utilized three different types of atlas (AICHA, pyClusterROI, and JHU-WM) to parcellate the sMRI/PET, rs-fMRI, and DTI neuroimages. Furthermore, to parcellate the sMRI and PET images, we employed the AICHA atlas, which is already segmented into 384 ROIs. Likewise, for rs-fMRI neuroimages, we applied pyClusterROI Python script with the Craddock atlas to parcellate the rs-fMRI images into 200 brain regions (because this is a well-known technique for parcellating fMRI images using a spatially constrained normalized-cut spectral clustering process). Moreover, we also knew that fMRI images are made up of a time series (ADNI rs-fMRI data is made up of 140 time series or time points), so to parcellate the brain using fMRI data, voxels with similar time points needed to be grouped to form a region. This is typically done using data-driven clustering methods, where each cluster constitutes one region. For this reason, we chose the pyClusterROI script for the rs-fMRI images. Moreover, for DTI images, we applied the JHU-WM (ICBM-DTI-81) label atlas, which was already segmented into 50 brain regions (these 50 WM tract labels were created by the hand segmentation of a standard-space average of the diffusion MRI tensor maps from 81 subjects). In this study, we selected different atlases for the different modalities of neuroimages because of their advantages, and also for the extraction of higher brain ROIs for that particular modality of neuroimage. After the completion of feature extraction from each method, we sent these low-dimensional extracted features through a polynomial kernel function to map them onto a high-dimensional feature. Afterward, we fused all six high-dimensional features into one form before further analysis. Later, we passed these unimodal and multimodal features through the EasyMKL classifier for classification and reported the average accuracy for each method. This procedure is widely used for comparing the performance of machine learning approaches. Although previous studies have already applied the multimodal method for the classification of AD (Zhang et al., 2011; Young et al., 2013; Liu et al., 2014; Ritter et al., 2015; Schouten et al., 2016; Hojjati et al., 2018; Gupta et al., 2019a) with other groups, this study was the first to combine five different types of neuroimage modalities with two APOE genotype scores for the classification of all six binary classification groups (AD vs. HC, MCIs vs. MCIs, AD vs. MCIs, AD vs. MCIs, HC vs. MCIs, and HC vs. MCIs). Our proposed method clearly showed an improvement using multimodal features in terms of performance over the unimodal features for classifying these six binary groups compared with the latest published results. Furthermore, in this study, we also adopted graph-theoretical strategies (in a global and nodal network topology) to study the plots of the six binary groups (characteristic path length, local efficiency, modularity, and transitivity), and to find the most significant regions where these groups differed from each other.

## Influence of the Different Types of Neuroimage Modality

We compared the Cohen's kappa score obtained for each modality using both ROI and VOI features. The score was calculated for each of the six classification groups. The Cohen's kappa outcomes, displayed in **Figure 5**, were computed using

ROI-based features. Likewise, the Cohen's kappa outcomes displayed in **Figure 6** were computed using VOI-based features. The results displayed in **Figures 5, 6** clearly show that the DTI-FA modality biomarker achieved a high level of agreement between groups while classifying the six binary classification groups compared with the other five biomarkers. Furthermore, we can say that VOI-based DTI-FA (lies above 0.8–0.87) feature performed slightly better than the ROI-based DTI-FA (lies above 0.75–0.84) feature.

## Influence of the Type of Features (ROI and VOI)

We compared the Cohen's kappa score obtained for the regional (ROI) features with the reference atlases (AICHA, Craddock, and JHU-WM) to the ones obtained for the voxel (VOI) features (SPM12, DPARSF, TBSS) for five different types of neuroimages using the EasyMKL classifier. The score was evaluated for the same six binary classification groups. The Cohen's kappa outcomes displayed in **Figure 5** are for an ROI-based analysis, and likewise, the Cohen's kappa outcomes displayed in **Figure 6** are for a VOI-based analysis. The results, displayed in **Figures 5, 6**, do not show notable differences in the Cohen's kappa scores obtained using regional or voxel features; both features performed very well and achieved a high level of agreement between each other for all six binary classification groups.

## Influence of the Classification Method

We compared the result obtained by the EasyMKL classifier with that of the RBF-SVM classifier. **Tables 2–4** and **Supplementary Tables S31–S33** show the obtained classification result for all six binary groups using the EasyMKL and RBF-SVM classifiers. Likewise, **Figure 15** shows the plot where we compared the

accuracy obtained for all six binary classification tasks using the EasyMKL and RBF-SVM classifiers. The result displayed in **Figure 15** shows that the EasyMKL classifier achieved high classification accuracy for all six binary groups compared with RBF-SVM. It also suggests that EasyMKL optimized a simple quadratic problem addressed by SVM in a more efficient way (see **Supplementary Tables S31–S33**).

## Most Significant Brain Regions Where Each Group Differs From the Others

**Table 5** shows the obtained most important brain regions for each binary classification group, using voxel-wise and graphical methods. For the AD vs. HC group, using VOI analysis, we found that (L) Thalamus, (L) Occipital Inferior, (R) Fusiform, (R) Temporal Inferior, (R) Temporal Mid, (R) Temporal Inferior, and (L) Sagittal stratum were the brain regions where the AD group differs from the HC group. Likewise, using graphical analysis, we found that (L) G-Cuneus-2, and (R) G-Frontal-Superior-1 were the brain regions where the AD group differs from the HC group. Furthermore, for the MCIs vs. MCIC group, using VOI analysis, we found that (L) Precuneus Vermis\_9, (L) Frontal Superior Medial, (L) Pallidum, (R) Lingual, (L) Frontal Mid, (R) External capsule were the brain regions where the MCIs group differs from the MCIC group. Likewise, after applying graphical analysis, we found that the (R) G-Parietal Inferior-1, and (R) G-Lingual-2 were the brain regions where the MCIs group differs from the MCIC group. For the AD vs. MCIs group, using the VOI method, our study found that the (L/R) Frontal Inferior Triangular, (R) Temporal Superior, (R) Frontal Inferior Orbital, (R) Thalamus, (R) Hippocampus, and (R) Anterior thalamic radiation were the brain regions where the AD group differs from the MCIs group. Moreover, after applying the graphical method, we found that the (R) N-Caudate-2 and (L) G-Cuneus-2 were the brain regions

**TABLE 5 |** Most significant brain regions found for all six binary classification groups using voxel-wise and graphical analysis.

Groups	Modality	Found to be the most significant brain region by applying VOI analysis	Modality	Found to be the most significant brain region by applying graphical analysis
AD vs. HC	sMRI	(L) Thalamus

HC vs. MCIs	rs-fMRI-ALFF	(L) Fusiform	rs-fMRI	(L) G-Lingual
	rs-fMRI-fALFF	(L) Occipital Middle		
	rs-fMRI-REHO	(L) Cingulum Posterior		
	DTI-FA	(R) Posterior corona radiata		
	sMRI	(R) Precentral	sMRI	(L) N-Caudate-6
	FDG-PET	(L) Precentral	FDG-PET	(L) G-Occipital Superior-1
HC vs. MCIC	AV45-PET	(L) Cerebellum_9		
	rs-fMRI-ALFF	(L) Precentral		
	rs-fMRI-fALFF	(L) Parietal Inferior		
	rs-fMRI-REHO	(L) Putamen		
	DTI-FA	(L) Superior longitudinal fasciculus		
	sMRI	(L) Lingual		
	FDG-PET	(L) Occipital Superior		
	AV45-PET	(R) Frontal Inferior Opercular		
	rs-fMRI-ALFF	(L) Frontal Inferior Orbital	rs-fMRI	(R) G-Parietal Inferior
	rs-fMRI-fALFF	(R) Frontal Superior Orbital	DTI-FA	(L) Corticospinal tract
	rs-fMRI-REHO	(L) Lingual		
	DTI-FA	(L) Superior corona radiata		

where the AD differs from the MCIs the most. Furthermore, for the AD vs. MCIC group, we found using VOI analysis that the (R) Frontal Middle orbital, (R) Occipital Middle, (R) Precentral, (L) Fusiform, (L) Occipital Middle, (L) Cingulum Posterior, and (R) Posterior corona radiata were the brain regions where the AD group differs from the MCIC group. Likewise, after applying graphical analysis, we found that the (L) N-Caudate-5 and (L) G-Lingual were the brain regions where the AD group differs from the MCIC group. For the HC vs. MCIs group, using the

VOI method, our study found that the (R/L) Precentral, (L) Cerebellum\_9, (L) Parietal Inferior, (L) Putamen, and (L) Superior longitudinal fasciculus were the brain regions where the HC group differs from the MCIs group. Moreover, after applying the graphical method, we found that the (L) N-Caudate-6 and (L) G-Occipital Superior-1 were the brain regions where the HC differs from the MCIs the most. Likewise, for the HC vs. MCIC group, using the VOI method, we found that the (L) Lingual, (L) Occipital Superior, (R) Frontal Inferior Opercular, (L) Frontal

Inferior Orbital, (R) Frontal Superior Orbital, (L) Lingual, and (L) Superior corona radiata were the brain regions where the HC group differs from the MCIC group the most. Moreover, using graph-based analysis, we found that the (R) G-Parietal Inferior and (L) Corticospinal tract were the brain regions where the HC group differs from the MCIC group the most. It is interesting to note that most of the affected brain regions lies in the left hemisphere rather than the right hemisphere.

## Exploring the Improvement in Performance Using Multimodal Features Compared With Unimodal Features

In this study, we applied two different types of methods for the classification of AD with another group. In the first method, we used the whole-brain parcellation approach to segment the brain images according to the atlas using some toolbox (see section “Three Feature Extraction Processes”) and later, after the completion of the data pre-processing step, we sent these features through the MKL algorithm to classify AD and the other groups. To verify the efficiency of this proposed method, we calculated the performance of each classification group using both unimodal and combined-ROI (or multimodal) features. **Table 2** shows the obtained classification results for all six binary classification groups using whole-brain analysis features. From **Table 2**, we can say that the combined features (combined-ROI) performed very well compared with the single-modality features in every classification problem. Their obtained Cohen’s kappa values were close to 1, which indicates that our proposed method achieved a good level of agreement between groups while classifying each set. **Table 2** further shows that the DTI-FA unimodal features attained high classification performance for every classification group except for the HC vs. MCIC group (where rs-fMRI features achieved better performance than DTI-FA features) in comparison with the performance of other individual modalities. This result demonstrates that the DTI-FA image can be used as a notable biomarker when investigating AD, and therefore should be included in clinical research.

Likewise, in the second step, we utilized the voxel-wise approach for the extraction of features from sMRI, FDG, AV45-PET, rs-fMRI, and DTI images using some toolbox (see section “Three Feature Extraction Processes”) and later, after the completion of data pre-processing step, we sent these features through the MKL classifier to classify AD with the other groups. To check the efficiency of this proposed method, we calculated the performance of each classification group using both unimodal and combined-VOI (or multimodal) features. **Table 3** shows the obtained classification results for all six binary classification groups using voxel-wise analysis features. From **Table 3**, we can say that our proposed approach (to combine all unimodal features into one before passing them through the MKL classifier) gained a high level of performance and agreement compared with the unimodal results for every classification group. **Table 3** further suggests that AV45-PET, rs-fMRI (ALFF, REHO), and DTI-FA individual features performed very well compared with sMRI, APOE, and FDG-PET individual modalities. It is interesting to note that the DTI-FA modality performed well for both whole-brain and voxel-wise analysis methods.

**Tables 2, 3** satisfied our hypothesis by showing that classification performance increased by 2–4% in every classification group after we passed concatenated features (combined-ROI and combined-VOI) through the MKL classifier. Moreover, the obtained result demonstrates that the multimodal method is more powerful than the unimodal system, and the obtained outcomes also indicate that every single biomarker has some important information, so it is better to combine the complementary information together for the classification of AD. Furthermore, we also examined the performance of every six classification groups by concatenating both ROI and VOI features into a single form. **Table 4** shows the obtained results for all six binary classification groups using combined (VOI + ROI) features. From **Table 4**, we can say that after applying combined (VOI + ROI) features, the classification performance increased slightly for every classification group except the AD vs. MCIC group (where combined-VOI dominated the combined-ROI and combined (VOI + ROI) methods in terms of performance). Their obtained Cohen’s kappa values were close to 1, which indicates that our proposed scheme achieved a good level of agreement between groups while classifying each set. **Supplementary Tables S1–S30** show the most significantly affected regions for all six binary classification groups measured by the sMRI, FDG-PET, AV45-PET, rs-fMRI, and DTI-FA modalities of neuroimage.

It is interesting to note that the (left/right) precentral region was found in every classification group when extracting the most significant voxel region. This finding suggests that, in the coming days, the precentral region can also be used as an important biomarker for the classification of AD and other groups.

## Global and Nodal Network Topology Result Analysis

We studied the global and nodal network topology for all six binary classification groups using graph theory. We calculated characteristic path length, local efficiency, modularity, and transitivity for every classification group, which can be seen in **Figures 12, 13** and **Supplementary Figures S2–S5**. In the global network topology analysis, our study found that in general, FDG, sMRI, and rs-fMRI were the modalities where characteristic path length increased efficiently compared with the other modalities. Likewise, for local efficiency, AV45, FDG-PET, rs-fMRI, and sMRI were the modalities where it increased compared with the remaining modalities. It is interesting to note that modularity increased in every classification group using sMRI neuroimages, except for the HC vs. MCIs group (where modularity increased efficiently by utilizing rs-fMRI images instead of sMRI images). Furthermore, in general, rs-fMRI, AV45-PET, and sMRI were the modalities where transitivity increased and decreased frequently. These changes symbolize that the regions of their networks communicated (more or less) efficiently within other brain regions. The increments in modularity (suggesting that their modules should have higher within-module connectivity and poor inter-module connectivity, or vice-versa) and increment or decrement of transitivity graph (suggesting that the regions of their network were connected very well to neighboring areas, or vice-versa). In the nodal network topology analysis, our study

found that every neuroimage was important to finding the most significant region where the six binary classification groups differ from each other; the found regions can be seen in **Figure 14** and **Supplementary Figures S6, S7**. The most significant regions were right g-frontal-sup-1, right s-precentral-3, left g-frontal-inf-tri, (left/right) n-thalamus-6, left s-parietooccipital-4, left g-cingulum-post-2, (left/right) occipital pole, left n-thalamus-2, left g-insula-anterior-2, (left/right) g-cuneus-2, left corticospinal tract, left n-Caudata-6, right temporal-pole-mid-3, left lingual-g, right fusiform, left g-precuneus-8, right n-Caudata-2, and (left/right) g-parahippocampal-4.

Recently, several studies have investigated neuroimaging techniques for the discrimination of AD, with the main focus on MCI subjects, who may or may not convert to AD, and separating patients with AD from healthy controls. However, it is difficult to make direct comparisons with these state-of-the-art methods because most of the studies used different validation methods and datasets, which both influence the classification performance. The first study by Cui et al. (2011) obtained an AUC of 79.6% for the classification of MCIs vs. MCIC groups. The authors used multimodal features (NM: neuropsychological and functional measures, CSF, and sMRI) for the classification. Young et al. (2013) used a Gaussian process method with SVM for the classification of MCIs vs. MCIC with three modalities (MRI, PET, and APOE). They reported an accuracy of 69.9% for classifying MCIs vs. MCIC groups. In another study, domain transfer learning was introduced using multimodal data (i.e., MRI, CSF, and FDG) with an accuracy of 79.4% for MCIs vs. MCIC with an AUC of 84.8% (Cheng et al., 2015). In another study by Xu et al. (2016), the authors used three different imaging modalities (sMRI, FDG, and AV45) for the discrimination of the conversion of MCIs subjects to MCIC patients. The authors used a weighted multi-modality sparse representation-based classification (wmSRC) classifier for classification. Their method achieved an ACC of 82.5% for classifying MCIs vs. MCIC with a sensitive biomarker selected using different numbers (from 1 to 90) of ranked features from each modality. Liu et al. (2017) proposed an algorithm that combines two imaging modalities of independent component study and the Cox model for discrimination of MCI progression. Their method achieved 80.8% of AUC with 73.5% of accuracy when classifying MCIs

vs. MCIC. Hojjati et al. (2017) used a subset of optimal features in an SVM classifier for the discrimination of the conversion of MCIs to MCIC subjects. Their proposed method with multivariate minimal redundancy maximal relevance feature selection achieved 94.9% AUC and 91.4% ACC. In another study, Pan et al. (2019b) used an ensemble classification with a feature ranking method for the classification of MCIs vs. MCIC. Their proposed method achieved 75.38% AUC and 80.70% ACC for classifying this group. Gupta et al. (2019a) used a multimodal feature (sMRI, FDG, CSF, and APOE) for the discrimination of the conversion from MCIs to MCIC. They used the NiftyReg toolbox for the extraction of 246 ROIs from each imaging modality and applied a kernel-based SVM for the classification of MCIs vs. MCIC. Their method achieved an AUC of 93.59% for classifying these groups. **Table 6** shows the comparison result for MCIs vs. MCIC classification. Our proposed multimodal method [combined-(ROI + VOI)] outperforms the latest published state-of-the-art methods in terms of AUC and ACC for MCIs vs. MCIC. The proposed method achieved 96.94% AUC and 95.08% ACC for classifying the MCIs vs. MCIC group.

## CONCLUSION

The novelty of the present study is that we combined five neuroimaging modalities (sMRI, FDG-PET, AV45-PET, rs-fMRI, and DTI) with the APOE genotype score for the discrimination between AD and other groups. Furthermore, we employed three different approaches [whole-brain (ROI), voxel-wise (VOI), and graph-based] on six binary classification groups to analyze each method performance independently. The combined-(ROI + VOI) feature performance outperformed the combined-ROI and combined-VOI features for all classification groups except the AD vs. MCIC group (where combined-VOI performed well). When the performance of each imaging modality in brain graph analysis was compared for all six binary classification sets, we found that FDG-PET, AV45-PET, and rs-fMRI were the only three modalities that revealed the most affected brain regions for all six classification groups. These highlighted central brain regions are an early indicator of developing dementia in healthy subjects.

## DATA AVAILABILITY STATEMENT

The datasets used in this study were acquired from the ADNI homepage, which is available freely for all researcher and scientist for experiments on Alzheimer's disease and can be easily downloaded from ADNI websites: <http://adni.loni.usc.edu/about/contact-us/>. Furthermore, all datasets presented in this study are included in the article/Supplementary Material.

## ETHICS STATEMENT

As per ADNI protocols, all procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee

**TABLE 6 |** Performance comparison for MCIs vs. MCIC classification group.

Method	Modality	Total sample size	AUC	ACC
Cui et al., 2011	NM + CSF + sMRI	143	79.6	67.13
Young et al., 2013	sMRI + FDG + APOE	143	79.5	69.9
Cheng et al., 2015	MRI + FDG + CSF	99	84.8	79.4
Xu et al., 2016	sMRI + AV45 + FDG	110	-	82.5
Liu et al., 2017	sMRI + FDG	234	80.8	73.5
Hojjati et al., 2017	rs-fMRI	80	94.9	91.4
Pan et al., 2019b	FDG	248	80.70	75.38
Gupta et al., 2019a	APOE + sMRI + FDG + CSF	82	93.59	94.86
Combined-(ROI + VOI)	sMRI + FDG + AV45 + rs-fMRI + DTI + APOE	61	<b>96.94</b>	<b>95.08</b>

and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. More details can be found at [adni.loni.usc.edu](http://adni.loni.usc.edu). (This article does not contain any studies with human participants performed by any of the authors).

## AUTHOR CONTRIBUTIONS

YG and J-IK designed the study and collected the original imaging data from the ADNI homepage. YG wrote the manuscript and did the coding section. J-IK and G-RK analyzed the imaging dataset. YG and BK analyzed the obtained results. All authors contributed and approved the final manuscript.

## FUNDING

This work was supported by the National Research Foundation of Korea Grant funded by the Korean Government (NRF-2019R1F1A1060166 and NRF-2019R1A4A1029769).

## ACKNOWLEDGMENTS

Data collection and sharing for this project was funded by the Alzheimer's Disease Neuroimaging Initiative (ADNI) (National Institutes of Health Grant U01AG024904) and DOD ADNI (Department of Defense award number W81XWH-12-2-0012). As such, the investigators within the ADNI contributed to the design and implementation of ADNI and/or provided data but did not participate in analysis or writing of this report. A complete listing of ADNI investigators can be found at: [http://adni.loni.usc.edu/wp-content/uploads/how\\_to\\_apply/ADNI\\_Acknowledgement\\_List.pdf](http://adni.loni.usc.edu/wp-content/uploads/how_to_apply/ADNI_Acknowledgement_List.pdf).

Alzheimer's disease (AD) is a progressive neurodegenerative disease characterized by senile plaques (SPs), which are caused by amyloid beta (A $\beta$ ) deposition and neurofibrillary tangles (NFTs) of abnormal hyperphosphorylated tau protein. The receptor for advanced glycation end products (RAGE) binds to advanced glycation end products deposited during vascular dysfunction. Alzheimer's disease may occur when RAGE binds to A $\beta$  and releases reactive oxygen species, further exacerbating A $\beta$  deposition and eventually leading to SPs and NFTs. As it is involved in early AD, RAGE may be considered as a more potent biomarker than A $\beta$ . Positron emission tomography provides valuable information regarding the underlying pathological processes of AD many years before the appearance of clinical symptoms. Thus, to further reveal the role of RAGE in AD pathology and for early diagnosis of AD, a tracer that targets RAGE is needed. In this review, we first describe the early diagnosis of AD and then summarize the interaction between RAGE and A $\beta$  and Tau that is required to induce AD pathology, and finally focus on RAGE-targeting probes, highlighting the potential of RAGE to be used as an effective target. The development of RAGE probes is expected to aid in AD diagnosis and treatment.

**Keywords:** AD, RAGE, PET, [<sup>18</sup>F]-FPS-ZM1, senile plaques, neurofibrillary tangles

## INTRODUCTION

Alzheimer's disease (AD) is the first major neurodegenerative disease with irreversible, occult, and rapid progression. With aging of the population, AD has become a major disease affecting public health (Nebel et al., 2018; Bo et al., 2019). The etiology and pathogenesis of AD are not fully understood, and currently, there is no specific treatment. More importantly, early diagnosis of AD is limited. The cost of treatment and care for AD is enormous, imposing a heavy burden on patients, families, and the society. Therefore, brain function imaging, developed on the basis of brain metabolism research targeting AD pathogenesis, plays an increasingly important role in the study of pathological processes in the AD brain.

The pathological features of AD are senile plaques (SPs), containing neurotoxic amyloid beta (A $\beta$ ) as the main component, and neurofibrillary tangles (NFTs), with abnormally activated tau as the main component in nerve cells. Neurofibrillary tangles and SPs are currently recognized as the earliest pathological changes in AD, with SPs reaching their maximum deposition in the early stage of AD, termed the "capping effect," which allows for amyloid plaque imaging *in vivo*. Tracking the slow progress of AD is difficult (Dubois et al., 2018). Therefore, an in-depth exploration of

AD pathogenesis with the development of new radioactive probes that detect pathological changes earlier to A $\beta$  deposition is currently a hotspot in AD research.

The receptor for advanced glycation end products (RAGE) belongs to the immunoglobulin superfamily of cell surface molecules and is situated in the major histocompatibility complex class III locus (Xue et al., 2011; Han et al., 2014). It binds to its ligand, advanced glycation end products (AGEs), through its V-type region, which is a key site that mediates intracellular signal transduction (Kim et al., 2013; Abedini et al., 2018). While mild hypoperfusion can increase the levels of neuronal A $\beta$  and NFTs, expressed as paired helix filaments, increasing evidence shows that RAGE levels are significantly elevated in patients with AD and AD models (Cai et al., 2016; Chellappa and Rani, 2020; Paudel et al., 2020). Receptor for advanced glycation end products-mediated A $\beta$ -injured tight junctions may also be associated with a variety of intracellular signal transduction pathways, Ca<sup>2+</sup>, or inflammatory damage (Nelson et al., 2016; Cai et al., 2017; Sole et al., 2019). Further, immunohistochemical evidence shows that the distribution of RAGE abnormalities is consistent with that of NFTs and SPs. In addition, glycosylated tau can induce significant oxidative stress and cause neuronal insufficiency or death (Srikanth et al., 2011; Cai et al., 2016). Receptor for advanced glycation end products may play an important role in the occurrence and development of AD, yet its underlying mechanism is still unclear. Thus, it is necessary to lay emphasis on the role of RAGE in AD pathology.

## Early Progression of AD

The etiology of AD is complex, and there are currently no specific drugs and methods to treat AD. Many drugs can only achieve remission (Wong et al., 2019). Positron emission tomography (PET), as a molecular imaging technique, can reflect pathological changes at the molecular level and can non-invasively detect the distribution of radionuclides in the body, which reflects physiological, biochemical, metabolic, and receptor changes, as well as gene expression and other abnormal changes (Hannestad, 2018; Mankoff and Katz, 2018). Thus, it is an important auxiliary tool for AD research. At present, there are several types of AD PET imaging agents (Bao et al., 2017) targeting glucose metabolism, receptors, or transmitters, A $\beta$ , Tau protein, neuroinflammation, and monoamine oxidase. However, these agents have certain limitations for the early diagnosis of AD.

In recent years, research on AD has mainly focused on the two major pathological features of AD: A $\beta$  and tau. However, although some individuals show A $\beta$  or Tau deposition as detected on medical images, they exhibit no dementia symptoms (Hardy and Selkoe, 2002). Moreover, studies have shown that A $\beta$  deposition is slow and protracted, likely lasting over 20 years, while the association of A $\beta$  accumulation with cognitive impairments is weak (Villemagne et al., 2013). Additionally, the current probes cannot distinguish among the six subtypes of Tau protein, and their off-target effects are more serious (Robertson et al., 2017). Therefore, finding new targets and developing the corresponding probes for AD are particularly important for AD research.

Current studies have shown that in early vascular dysfunction of AD, inflammatory mediators, such as tumor necrosis factor alpha (TNF- $\alpha$ ), in brain microvascular endothelial cells (BMECs), are released, thus increasing cerebral vascular permeability (Qiu et al., 2016), enabling AGEs and other neurotoxins to cross the blood-brain barrier (BBB) and cause AGE deposition. This leads to a significant upregulation of RAGE in BMECs (Liang et al., 2015), which leads to an inflammatory response by vascular endothelial and nerve cells, activates the release of reactive oxygen species (ROS), which promotes oxidative stress, and results in the secretion of nitric oxide synthase and further increases A $\beta$  deposition in the brain. A $\beta$  increases the activation of microglia, which, in turn, accelerates nerve vessel dysfunction. Neuronal dysfunction promotes the pathogenesis of NFTs, thus causing the formation of additional SPs and NFTs, disturbing the balance in the chemical components of the neuro-microenvironment. This further promotes neuronal dysfunction, injury, and loss (Wells et al., 2015; Cai et al., 2016) (see **Figure 1**). Based on the above, RAGE and AGEs could play an important role in the early pathological changes of AD.

## AGE-Related RAGE Processes and NFTs

Abnormally activated tau is the main component of NFTs, and NFT deposition in the hippocampus and entorhinal cortex is correlated with the severity of behavioral degeneration in the progression of dementia (Saint-Aubert et al., 2017). Advanced glycation end products are the final products of the non-enzymatic glycation of proteins, which is irreversible. The non-enzymatic saccharification processes accompanying neuronal metabolism have far-reaching effects despite the slow and insignificant cell damage they cause (Kamynina et al., 2018). In AD, AGEs have been shown to induce tau hyperphosphorylation in SK-N-SH cells, primary hippocampal neurons, and rat brains through the RAGE/GSK-3 pathway (Li X.H. et al., 2012; Son et al., 2012). As AGEs downregulate the brain-derived neurotrophic factor-tyrosine receptor kinase B pathway in rat brains and N2A cells (Li X.H. et al., 2012), they could activate glycogen synthase kinase 3 at Ser9, thus regulating its phosphorylation, which was found to be a trigger of tau hyperphosphorylation (Wu et al., 2019). Simultaneously, *in situ* techniques have shown that the major structures recognized by anti-AGE antibodies, hydroxymethyl lysine (CML) and glycosylated precursor hexitol-lysine, increase in the NFTs of patients with AD. In these patients, CML colocalizes with the tau protein. Immunostaining experiments have shown that almost all AGE-immunoreactive neurons contain the hyperphosphorylated tau protein, confirming the role of AGE aggregation in early NFT formation and neuronal degeneration (Qi et al., 2017) (see **Figure 2**). As an increase in AGEs causes an upregulation of RAGE, the connection between AGEs and NFTs indicates a strong link between RAGE and tau hyperphosphorylation.

The deposition of AGEs in the brain participates in the pathogenesis of AD through RAGE and cross-links with NFTs. This deposition activates microglia and nicotinamide adenine dinucleotide phosphate oxidase, leading to ROS release and the formation of peroxynitrite, a potent oxidant of proteins, lipids, and DNA (Nam et al., 2012), ultimately causing nerve

**FIGURE 1 |** Receptor of advanced glycation end products (RAGE) mediates the possible mechanism of Alzheimer's disease (AD). Interaction of RAGE with advanced glycation end products (AGEs) and  $\beta$ -amyloid ( $A\beta$ ) allows them to cross the blood-brain barrier and enter the brain.  $A\beta$  deposition in the brain promotes the expression of tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-1, and IL-6, and exacerbates the inflammatory response. Increased binding of  $A\beta$  to RAGE after entering the brain can also upregulate RAGE expression, resulting in increased release of reactive oxygen species (ROS) and upregulation of  $A\beta$  expression, which then promotes the generation of senile plaques (SPs). The upregulation of RAGE exacerbates phosphorylation of tau protein and promotes the generation of neurofibrillary tangles (NFTs). AGEs and RAGE phosphorylate glycogen synthase kinase 3 (GSK-3 $\beta$ ), which, in turn, exacerbates the phosphorylation of tau protein and promotes the generation of NFTs. Upregulation of  $A\beta$  and tau protein levels promote the occurrence and development of AD.

destruction. Therefore, treating AGEs may become a new way to treat AD.

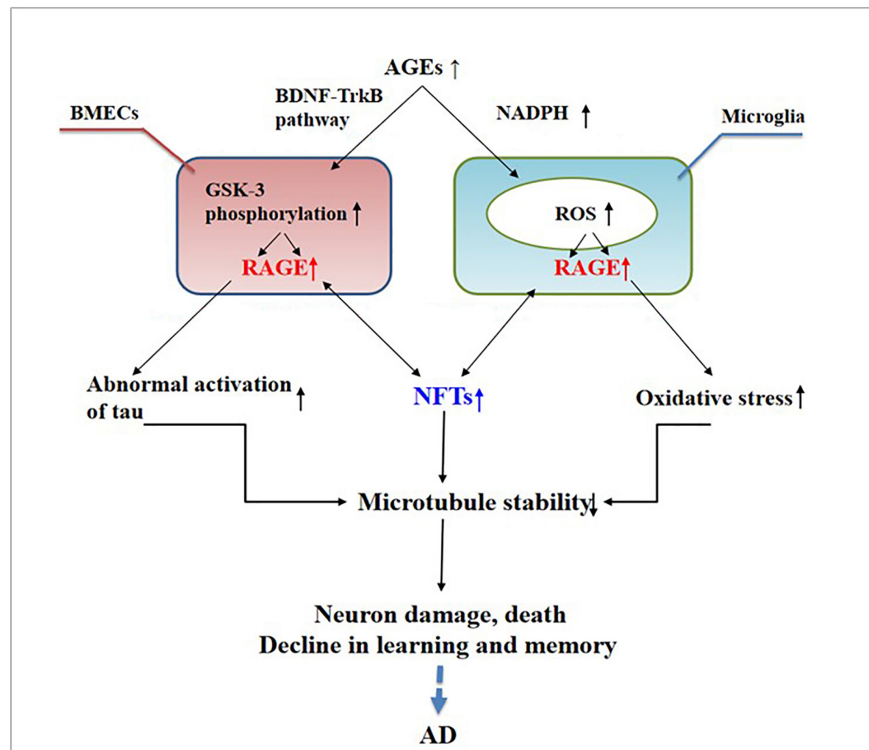

## Role of the Interaction Between RAGE and $A\beta$ in AD

A growing body of evidence suggests that RAGE is an important regulator of  $A\beta$  neurotoxicity.  $A\beta$ -damaged BMECs and the destruction of the BBB may be new characteristic pathological changes in AD (Lv et al., 2014). In AD, RAGE expression is significantly upregulated in areas where  $A\beta$  is deposited (Wang et al., 2009). Receptor for advanced glycation end products is a pattern recognition receptor, and  $A\beta$ , as one of its ligands, was shown to interact with it (Paudel et al., 2020); however, the specific mechanism underlying this interaction and its role in patients with AD need further clarification.

The interaction of RAGE with  $A\beta$  activates inflammatory signaling pathways, releases ROS to produce oxidative stress, and causes neuroinflammation, thus inducing the dysfunction of

mitochondria and neurons (Deane et al., 2008), as well as changes in various signaling mechanisms such as the mitogen-activated protein kinase pathway (Deane, 2012). Further, RAGE accelerates the uptake and transport of  $A\beta$ , which causes  $A\beta$  to cross the BBB and enter the central nervous system through endocytosis (Deane et al., 2003), causing cerebrovascular dysfunction, eventually leading to neurovascular inflammation and subsequent synaptic toxicity (Deane and Zlokovic, 2007), thereby affecting the normal activity of the central nervous system (Zhang et al., 2011; Galasko et al., 2014; Wang et al., 2014; Cai et al., 2016; Fang et al., 2018). The interaction between RAGE and  $A\beta$  is harmful to the body. Studies have found that, in transgenic mice with defective RAGE expression,  $A\beta$  in the brain is completely inhibited from crossing the BBB (Deane and Zlokovic, 2007).

High expression of RAGE is also harmful to the body. First, it activates the nuclear factor  $\kappa$ B, further increasing the expression of RAGE and forming a positive feedback effect on inflammation (Wan et al., 2015; Fang et al., 2018). Second, it increases the expression of nuclear factor-1 in activated T-cells and of

**FIGURE 2 |** Receptor of advanced glycation end products (RAGE) mediates the possible mechanism of neurofibrillary tangle (NFT) formation in the pathogenesis of dementia complicated with Alzheimer's disease.

amyloid precursor protein (APP)  $\beta$ -site cleavage enzyme 1 (also known as BACE1), an important enzyme that cleaves amyloid precursors (Yan et al., 1996; Fang et al., 2010; Guglielmotto et al., 2012; Galasko et al., 2014). Increased BACE1 activity increases A $\beta$  production (Maesako et al., 2019). In addition, A $\beta$  can activate RAGE, increasing the expression of pro-inflammatory cytokines like TNF- $\alpha$ , interleukin 6 (IL-6), and macrophage colony-stimulating factor (Dukic-Stefanovic et al., 2003). In turn, RAGE activation exacerbates the production and aggregation of A $\beta$  and the formation of NFTs and destroys synaptic transmission and neurons (Cai et al., 2016) (see **Figure 3**), which promote the occurrence and development of AD.

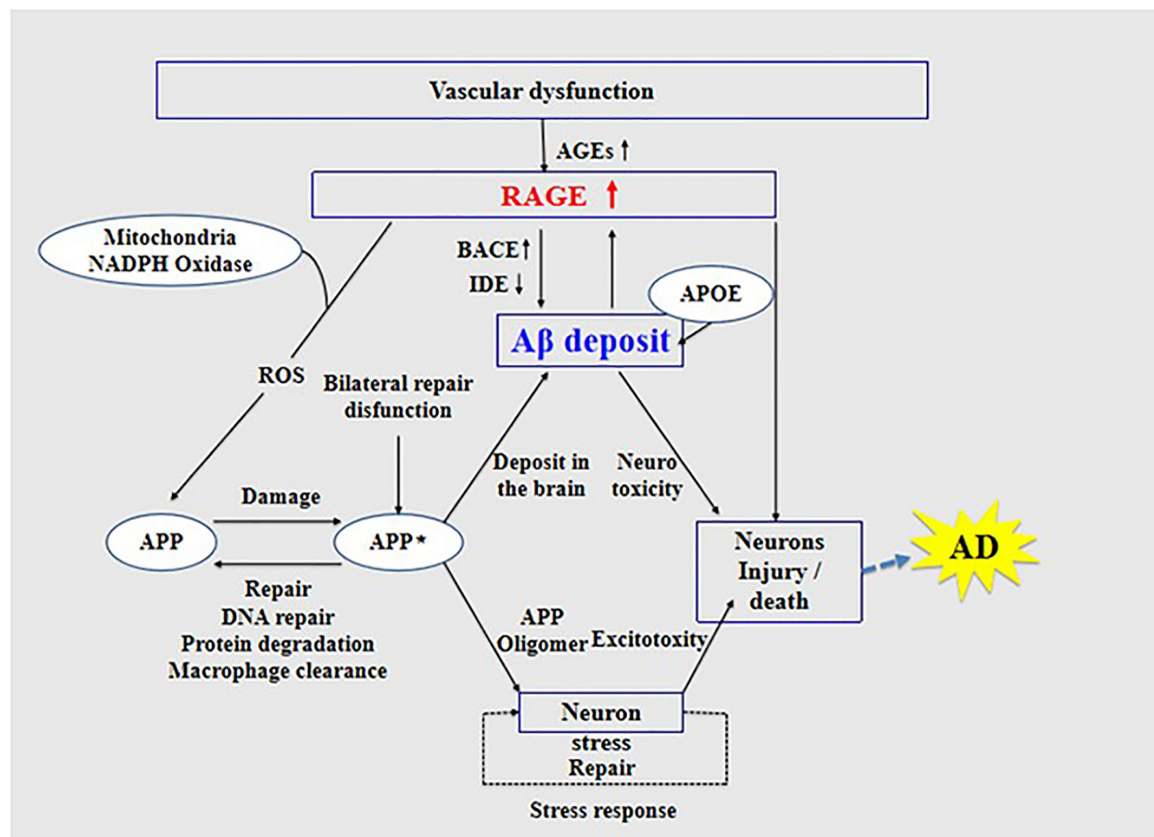

Inhibition of RAGE can prevent A $\beta$  damage in nerve cells and cerebral vasculature. The possible mechanism of RAGE function in AD provides a theoretical basis and new ideas for the early diagnosis of AD and development of new drugs for the prevention and treatment of AD.

## RAGE and RAGE-Targeting Brain Imaging

Many studies have shown that AGEs are important in neurodegenerative diseases (Li J. et al., 2012; Nenna et al., 2015), while *in vitro* and *in vivo* studies have demonstrated the potential of RAGE as a receptor for AGE and as a therapeutic target in neurodegeneration (Sparvero et al., 2009; Deane et al., 2012; Nasser et al., 2015; Ray et al., 2016). Receptor for advanced

glycation end products PET imaging has also been proven to assist in the diagnosis and treatment of neurodegenerative diseases (Kim et al., 2018; Konopka et al., 2018; Goldklang et al., 2019). The full-length human RAGE consists of three domains, namely, the extracellular, the hydrophobic transmembrane, and the cytoplasmic domains, while the main binding domain structure V is located on the extracellular part of the receptor (Bongarzone et al., 2017). Receptor for advanced glycation end products is expressed in a regulated manner, at low levels, in most differentiated adult cells, whereas its expression is high in embryonic cells (Demling et al., 2006). Moreover, RAGE is highly expressed in many inflammation-related pathological states such as vascular disease, diabetes, and neurodegeneration (Hudson et al., 2008; Sparvero et al., 2009). It is important in A $\beta$ -mediated neurotoxicity (Piras et al., 2014), and its signaling pathway is also essential in AGE-induced tau phosphorylation and spatial memory impairment (Choi et al., 2014). Studies using murine models of chronic disease have demonstrated the involvement of RAGE in pathophysiological processes by means of a receptor decoy of soluble RAGE (Bierhaus et al., 2005). Moreover, RAGE was found to be relatively increased on the membrane of neurons and microglia in AD-related neuronal dysfunction (Yan et al., 1996; Cai et al., 2016). Considering the key functions of RAGE, there is a need for molecular imaging agents to measure RAGE expression in neurodegenerative diseases.

For developing novel RAGE inhibitors as potential AD therapeutics, Han et al. (2014) designed and synthesized a

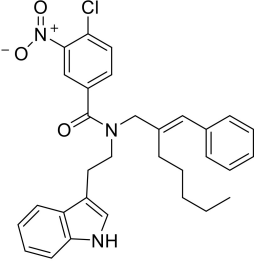

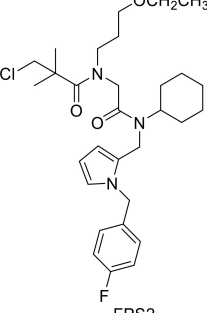

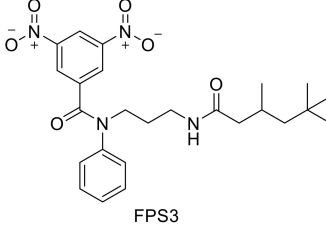

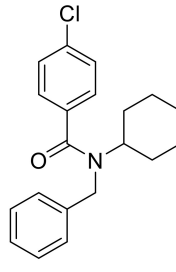

**FIGURE 3 |** Receptor of advanced glycation end products (RAGE) mediates the possible mechanism of Aβ in the pathogenesis of Alzheimer's disease.

series of pyrazole-5-carboxamides to screen for excellent RAGE inhibitors. Screening identified a 4-fluorophenoxy analog with significant brain Aβ-lowering effects, as well as favorable aqueous solubility named 40, which were determined to be excellent RAGE inhibitors. Deane et al. (2012) synthesized a high-affinity RAGE-specific inhibitor, FPS-ZM1, which was selected after screening a second-generation library of compounds designed based on the common structural features of three leading compounds in a primary screen. Compared to other analogs (e.g., FPS1, FPS2, and FPS3), the functional groups of the leading tertiary amides in FPS-ZM1 were altered to reduce the molecular weight to less than 450 Da and decrease the number of hydrogen bonds. FPS-ZM1 has a molecular weight of 327 Da and 1 H-bond (see Table 1). The authors verified its effect using APP<sup>sw/0</sup> mice, an AD model, and found that it can cross the BBB, acts on the V-type region of RAGE, and can still bind to RAGE after crossing the BBB, thereby blocking the role of intracranial RAGE (Lv et al., 2015; Hong et al., 2016). These results indicated the guaranteed binding ability of FPS-ZM1. In addition, FPS-ZM1 was shown to completely restore cerebral blood flow, inhibit neurotoxicity, microglial activity, and the neuroinflammatory response and improve cognitive behavior. Moreover, FPS-ZM1 has a wide safety range, with no toxic effects, even when using doses 500 times higher than the therapeutic dose (Deane et al., 2012). The above suggest that FPS-ZM1 is a potent multimodal

RAGE blocker that effectively controls the progression of Aβ-mediated neurodegeneration and, thus, may be used as a disease-modifying agent for AD.

Based on the importance of the RAGE signaling pathway in AGE-induced tau phosphorylation and spatial memory impairment, research and development of imaging agents with characteristics that can reflect the early pathological mechanism of AD is a highly active field. According to the above characteristics of FPS-ZM1, Cary et al. (2016) synthesized the first small-molecule BBB-permeable PET radioligand for RAGE, [<sup>18</sup>F] RAGER, and conducted a preliminary preclinical study. Micro-PET imaging in rodents and non-human primates indicated that [<sup>18</sup>F] RAGER clusters in the expression area of RAGE, while further molecular docking experiments determined the binding site of RAGER, indicating that [<sup>18</sup>F] RAGER and RAGE distribution area colocalization may have a binding effect. Kong et al. (2016) identified a new [<sup>18</sup>F]-FPS-ZM1 probe targeting RAGE among thousands of small molecules by testing different radiolabeling methods. The probe was radioactively synthesized with a purity of up to 99% and an activity of 30 mCi/ml and was shown to be lipophilic. The authors also studied the probe's hemodynamics and verified its safety by performing animal experiments. They found that the low-molecular-weight [<sup>18</sup>F]-FPS-ZM1 is stable, electrically neutral, lipophilic, and weight independent. Micro-PET imaging and autoradiography

results also indicated that [<sup>18</sup>F]-FPS-ZM1 is a promising RAGE-specific probe.

Several studies have documented other PET imaging probes for early AD diagnosis, such as those aimed at various targets, including Aβ, tau, and others. Tau-targeting imaging probes such as [<sup>18</sup>F]-THK-5351, [<sup>18</sup>F]-THK-5117, and [<sup>18</sup>F]-AV-1451 show a high uptake in the patients' cortex (Harada et al., 2015; Lemoine et al., 2015; Passamonti et al., 2017; Kobayashi et al., 2018; Valotassiou et al., 2018), which means that they can accurately detect NFTs, thus helping in the early diagnosis of AD. At the same time, [<sup>11</sup>C] PiB, an analog of thioflavin-T and a benzothiazole derivative, was the first probe specifically targeting Aβ (Rabinovici et al., 2007; Lim et al., 2014; Lemoine et al., 2015; Kobayashi et al., 2018). Since then, many new probes targeting Aβ have appeared, including [<sup>18</sup>F]-florbetapir, [<sup>18</sup>F]-florbetaben, and [<sup>18</sup>F]-flutemetamol, all showing high affinity and specificity for Aβ (Valotassiou et al., 2018). These tau and Aβ-targeting probes can also be used for quantification analysis to further validate the role of RAGE in the pathogenesis of AD (Fang et al., 2018). As RAGE overexpression precedes Aβ plaque formation (Luzi et al., 2020), [<sup>18</sup>F]-FPS-ZM1 PET/CT imaging is expected to be more sensitive than traditional Aβ imaging. It can monitor changes in cerebrovascular function over time and thus provide accurate,

reliable, and reproducible non-invasive *in vivo* quantitative data for local or whole-brain pathological changes.

Although many tracers have been developed to aid in the diagnosis and treatment of AD, including those targeting tau, P2X7, phosphodiesterase PDE10A, and synaptic vesicle glycoprotein 2A (McCluskey et al., 2020), only few RAGE-targeting imaging tracers are currently available apart from [<sup>18</sup>F]-FPS-ZM1, and they all have certain limitations in the diagnosis of AD. Available RAGE probes include the <sup>99m</sup>Tc-F(ab')<sub>2</sub> anti-RAGE fragment developed by Tekabe et al. (Shan, 2004; Tekabe et al., 2010), which has only been applied in atherosclerosis and peripheral arterial disease, but not in AD. Another probe was developed by Hoppmann et al. (2008) on the basis of a multigenic family of Ca<sup>2+</sup>-modulated proteins, namely, S100, as RAGE ligands. However, compared with the high affinity and specificity of FPS-ZM1 for RAGE, this probe lacks stability and has low affinity for RAGE (Wolf et al., 2011). Recently, another RAGE-targeting probe, <sup>64</sup>Cu-Rho-G4-CML, was developed by Konopka et al. (2018), which may be the best RAGE-targeting imaging agent currently available for cancer. However, its size prevents it from crossing the BBB, rendering it ineffective for neurological assessments (Konopka et al., 2018). Compared with these three probes, [<sup>18</sup>F]-FPS-ZM1 is expected to be more potent and

could greatly improve early diagnosis, prevention, screening, and evaluation of AD and could help develop an imaging agent with appropriate characteristics that can reflect the early pathological mechanism of AD (Table 2).

## CONCLUSION

There is currently no breakthrough drug treatment for AD, which has become a serious social and economic problem. Although the progression of AD cannot be prevented or reversed, the availability of radioactive tracers for RAGE PET imaging will allow us to monitor RAGE brain expression levels in AD. Receptor for advanced glycation end products has an important role in the development of AD, but the kind of state RAGE exists in AD and the way it acts on A $\beta$  and tau have yet to be determined. It is unclear whether increased RAGE expression affects the behavior and pathophysiology of AD models. Thus, an in-depth study of the mechanism of action of RAGE is essential for the further understanding of neurological diseases.

In this review, we introduced the RAGE-targeting probe [ $^{18}\text{F}$ ]-FPS-ZM1. Compared with probes targeting A $\beta$  and the tau protein, [ $^{18}\text{F}$ ]-FPS-ZM1 has advantages in exploring the

involvement of RAGE in AD pathogenesis. Due to its high specificity and affinity for RAGE, [ $^{18}\text{F}$ ]-FPS-ZM1 is believed to provide accurate and reliable *in vivo* data for studying local or whole-brain pathological changes. Thus, [ $^{18}\text{F}$ ]-FPS-ZM1 could greatly promote the early diagnosis and evaluation of AD and provide a way to reflect the early pathological mechanism of AD.

## AUTHOR CONTRIBUTIONS

YK, BS, JW, and YG guided the study. YK, CL, YZ, JQ, and CZ wrote the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

This study was supported by the National Natural Science Foundation of China (Project Nos. 81571345 and 81701732), Shanghai Municipal Science and Technology Major Project (No. 2018SHZDZX01), and ZJLab, Shanghai Municipal Key Clinical Specialty (shslczdzk03402).
