(2020) Disrupted Functional Network  
Connectivity Predicts Cognitive  
Impairment in Presbycusis Patients.  
*Front. Aging Neurosci.* 12:246.  
doi: 10.3389/fnagi.2020.00246

**Purpose:** Individuals with presbycusis often show deficits in cognitive function, however, the exact neurophysiological mechanisms are not well understood. This study explored the alterations in intra- and inter-network functional connectivity (FC) of multiple networks in presbycusis patients, and further correlated FC with cognitive assessment scores to assess their ability to predict cognitive impairment.

**Methods:** Resting-state functional magnetic resonance imaging (rs-fMRI) was performed in 40 presbycusis patients and 40 matched controls, and 12 resting-state networks (RSNs) were identified by independent component analysis (ICA) approach. A two-sample *t*-test was carried out to detect the intra-network FC differences, and functional network connectivity (FNC) was calculated to compare the inter-network FC differences. Pearson or Spearman correlation analysis was subsequently used to explore the correlation between altered FC and cognitive assessment scores.

**Results:** Our study demonstrated that patients with presbycusis showed significantly decreased FC in the subcortical limbic network (scLN), default mode network (DMN), executive control network (ECN), and attention network (AN) compared with the control group. Moreover, the connectivity for scLN-AUN (auditory network) and VN (visual network)-DMN were found significantly increased while AN-DMN was found significantly decreased in presbycusis patients. Ultimately, this study revealed the intra- and inter-network alterations associated with some cognitive assessment scores.

**Conclusion:** This study observed intra- and inter-network FC alterations in presbycusis patients, and investigated that presbycusis can lead to abnormal connectivity of RSNs and plasticity compensation mechanism, which may be the basis of cognitive impairment, suggesting that FNC can be used to predict potential cognitive impairment in their early stage.

**Keywords:** presbycusis, cognitive impairment, brain network, resting-state fMRI, functional network connectivity

## INTRODUCTION

Presbycusis, also known as age-related hearing loss, results from lifetime damage to the auditory system and can be defined as progressive bilateral sensorineural high-frequency hearing loss (Gates and Mills, 2005). Presbycusis has become the third leading chronic health disorder affecting elderly over the age of 65 after hypertension and arthritis (GBD 2015 Disease and Injury Incidence and Prevalence Collaborators, 2016), which mainly characterized by slow central processing of acoustic information, impaired localization of sound sources, and reduced ability to distinguish speech under noisy environments (Gates and Mills, 2005; Tavanai and Mohammadkhani, 2017). Lots of robust research evidence suggests that presbycusis not only causes alterations of function and morphology in specific brain areas, but also independently associated with cognitive decline, increasing the risk of dementia, and impaired performance across cognitive domains (Thomson et al., 2017; Ford et al., 2018; Loughrey et al., 2018), this results in a serious adverse impact on their daily life and social interaction of elderly. Early detection and prevention have supposed to be the most potential approaches in dealing with cognitive impairment. Therefore, the recognition of early cognitive impairment is of great importance for patients with presbycusis.

Resting-state functional magnetic resonance imaging (rs-fMRI) does not require subjects to receive any sensory stimuli or perform a specific task, thus, it is widely used in describing abnormal brain neuronal activity and functional connectivity (FC) in various clinical conditions (Biswal et al., 1995). FC refers to measuring the temporal synchronization of neuronal activity between different brain regions within resting-state networks (RSNs), reflecting the functional status of the corresponding brain regions (Geerligs et al., 2015). Therefore, the use of this technology to map the Spatio-temporal covariance structure of spontaneous brain activity networks is increasing, which will provide an in-depth understanding of the neural mechanisms for cognitive impairment in presbycusis. A growing body of research has indicated that auditory and cognitive processing are tightly related and that patients with hearing loss recruit functions of the executive network to maintain communication, leading to cascading cognitive effects that further affect comprehension, perception and working memory (Pelle and Wingfield, 2016; Loughrey et al., 2018). Previous research has found that hearing loss was associated with decreased volume in the temporal lobe, which is responsible for semantic memory and sensory integration, and the atrophy of the temporal lobe may be involved in the early stage of mild cognitive impairment (Fortunato et al., 2016). Another finding suggested that during effortful speech perception in the hearing-impaired showed increased activation of the frontal lobe, which leads to fewer resources of frontal lobes for cognition and indirectly affected the high-level cognitive processes. Moreover, hearing loss can lead to impaired auditory-limbic network FC (Rutherford et al., 2018), and resulted in a cross-modal plastic reorganization of the auditory cortex. Even mild hearing loss affects the transmission

of information within the auditory-linguistic-motor circuits (Bidelman et al., 2019).

Taken together, cognitive impairment in presbycusis most likely depends on system-level disruption of brain networks, namely the internal interactions of different brain regions in one network or the interactions among multiple networks, rather than the dysfunction of a single discrete brain region. However, conventional seed-based FC researches rely on the user's self-defined region of interest (ROI; Lv et al., 2018) and fail to fully investigate the interaction between the brain networks of presbycusis patients. Independent component analysis (ICA) using a data-driven method (McKeown et al., 1998) without prior experimental models or assumptions decompose BOLD signal from the whole brain voxels into spatially and temporally independent components (ICs), which has been widely used in rs-fMRI and is capable of measuring interactions within and between multiple brain networks directly. Among them, resting-state function network connectivity (FNC) can be used to describe the temporal correlation between these RSNs (Wang et al., 2014; Qin et al., 2018). At present, ICA studies on the connectivity changes within and between networks in presbycusis have not been reported, just a few studies focused on intra-network FC alteration (Schmidt et al., 2013; Luan et al., 2019). Therefore, we predict that by exploring RSNs and FNC to elucidate the impairment and compensation patterns of cognitive impairment in presbycusis patients will provide valuable information for rational treatment.

This study aims to systematically explore FC and their interactions within and between RSNs in presbycusis patients and to provide new reliable markers for identifying early cognitive impairments. We will experimentally validate the following hypothesis: first, the cognitive impairment in presbycusis patients is related to the disrupted FC of multiple RSNs; second, in addition to changes within the network, changes between networks may also be associated with cognitive impairment.

## MATERIALS AND METHODS

### Subjects

A total of 40 presbycusis patients were recruited from the otolaryngology department, and 40 age-, gender-, education-, and handedness matched control subjects were selected from community health census or online advertising. Based on the definition of hearing loss, all participants underwent the hearing loss assessment using the speech-frequency pure tone average (PTA) of the 0.25, 0.5, 1, 2, 4, 8 kHz (air conduction) threshold in the better hearing ears. The PTA value of 25 dB HL is the normal listening threshold limit. No significant difference in the auditory threshold between the experimental and control group was observed; and middle ear function was measured by using Madsen Electronics Zodiac 901 Middle Ear Analyzer (GN Otometrics).

Exclusion criteria were as follows: (1) in addition to presbycusis, ear diseases that impacted hearing threshold,

including tinnitus, hyperacusis and Meniere's disease (Lopez-Escamez et al., 2015); (2) a history of otologic surgery, ototoxic drug therapy, noise exposure or hearing aid use; (3) asymmetric hearing loss, with the difference of air conduction threshold exceeding 20 dB, and at least two frequencies between 0.5, 1, 2 and 4 kHz; (4) severe smoking, alcohol abuse, brain damage, Alzheimer's disease, Parkinson's disease, major depression, epilepsy, mental or neurological disorders, major diseases (such as anemia, thyroid dysfunction, cancer); and (5) a contraindication to MRI.

## Neuropsychological Assessment

The neuropsychological assessment of all participants required a comprehensive test of cognitive status, including the use of Mini-Mental State Exam (MMSE; Ardila et al., 2016) and Montreal Cognitive Assessment (MoCA; Lu et al., 2011) to assess general cognitive function, Auditory Verbal Learning Test (AVLT and AVLT-delay; Xu et al., 2020) and Complex Figure Test (CFT and CFT-delay; Shin et al., 2006) for episodic verbal learning as well as visual memory recall, Digit Span Test (DST; Gabel et al., 2019) for verbal working memory. Executive control was assessed by Trail-Making Test A and B (TMT-A and TMT-B; Sánchez-Cubillo et al., 2009) and Clock-Drawing Test (CDT; Viscogliosi et al., 2017), besides mental processing speed and visuospatial abilities were evaluated by Digit Symbol Substitution Test (DSST; Rosano et al., 2013) and Verbal Fluency Test (VFT; Brucki and Rocha, 2004). Also, the Self-Rating Anxiety Scale (SAS; Song et al., 2014) and Self-Rating Depression Scale (SDS; Zung, 1971) were used to assess the symptoms of anxiety and depression. There are a total of 14 cognitive tests and it took almost 60 min for each individual to finish this battery of orderly tests.

## Imaging Data Acquisition

All imaging data acquisitions were performed on a 3.0 Tesla Philips MRI scanner (Ingenia, Netherlands) with an eight-channel phased-array head coil. Resting-state functional images were acquired axially using a gradient echo-planar imaging sequence as following parameters: repetition time (TR) = 2,000 ms, echo time (TE) = 30 ms, slices = 36, thickness = 4 mm, gap = 0 mm, field of view (FOV) = 240 mm × 240 mm, acquisition matrix = 64 × 64, and flip angle (FA) = 90°, the voxel size was 3.75 × 3.75 × 4.0 mm<sup>3</sup>; and this sequence lasted 8 min and 8 s. Structural images were obtained using a three-dimensional turbo fast echo (3D-TFE) T1WI sequence and following scan parameters: TR/TE = 8.1/3.7 ms, slices = 170, thickness = 1 mm, gap = 0 mm, FOV = 256 mm × 256 mm, acquisition matrix = 256 × 256, and FA = 8°. The structural sequence lasted 5 min and 29 s. Besides, all scans were acquired with parallel imaging using sensitivity encoding (SENSE) technique and SENSE factor = 2.

During the scan, the participants were instructed to lie quietly and keep still, with eyes closed but not asleep or think about anything special. Meanwhile, foam padding was used to reduce the involuntary movement of the head, and earplugs were used to reduce the influence of noise on the participants. According to the manufacturer's specifications, the earplugs

(Hearos Ultimate Softness Series, USA) could attenuate scanner noise by almost 32 dB.

## Preprocessing of Functional Imaging Data

GRETNA (Graph Theoretical Network Analysis) was applied to preprocess the functional image data for further analysis (Wang et al., 2015), involving the following steps. First, the first 10 volumes were removed to allow for an equilibrium of the magnetization and adaptation of the participants to the scanning environment. Then the remaining volumes were sliced for timing (slice timing) and corrected for head motion (realignment). Since micromovements from volume to volume can influence the FC, framewise displacement (FD) values were computed for each subject to reflect the temporal derivative of the movement parameters. Time points that exceeded a max FD of 0.5 mm were excluded from subsequent analyses. The corrected volumes were spatially normalized to the Montreal Neurological Institute space with resampled voxel size = 3 × 3 × 3 mm<sup>3</sup>, and finally spatially smoothed with a Gaussian smooth kernel (full width at half-maximum of 6 mm).

## Identification of Resting-State Networks

The group ICA software (Medical Image Analysis Lab, University of New Mexico, Albuquerque, NM, USA<sup>1</sup>) was used to implement the spatial group ICA and identify RSNs. ICA analysis is performed in three phases: (1) data reduction; (2) application of ICA algorithm; and (3) back reconstruction for each subject. The number of ICs over all subjects was estimated using the minimum description-length (MDL) criteria. In phase one, principal component analysis (PCA) was used to reduce computational complexity, then the remaining reduction step was achieved again using PCA based on a selected number of ICs. In phase two, the infomax algorithm was used to run the proper ICA. In the final phase, Single-subject individual time courses and spatial maps were group ICA (GICA) type back-reconstructed and results were converted into z-scores to display.

## Intra-network Functional Connectivity Analysis

Among the 40 components arising from ICA, 12 components (eight meaningful RSNs) were selected as the focus of subsequent analysis through visual inspection based on previous rs-fMRI studies. For each RSNs, a one-sample *t*-test was first performed to obtain z-maps for each group, which were corrected by false discovery rate (FDR) method, and the statistical figure was obtained at the threshold of  $p < 0.05$ . The spatial maps of the components were used as variables for a one-sample *t*-test. Each mask of the control group and presbycusis was further combined into a total mask for each component. Then, the z-maps of RSN were compared between groups using a two-sample *t*-test of voxel restricted within the combination mask. The comparison results were corrected  $p < 0.01$ , with a Monte Carlo simulation for multiple comparisons (AlphaSim

<sup>1</sup><http://icatb.sourceforge.net>

correction<sup>2</sup>), and the regions of significant differences were selected from each RSNs to facilitate further analysis.

## Inter-network Functional Connectivity Analysis

After ICA, the spatiotemporal double regression method was used to obtain the individual level time courses of the identified RSNs. Then, FNC analysis was carried out to study the relationship between different RSNs time courses. During the analysis, a temporal band-pass filter (range from 0.00 to 0.25 Hz) is first applied to the time courses to reduce the effects of low-frequency drift and high-frequency physiological noise. Secondly, the correlations were calculated between any two RSNs time courses of each subject. Then the FNC, also known as temporal correlation, is obtained by calculating the Pearson correlation coefficient of the time courses of selected RSNs and generate the  $13 \times 13$  matrix. A general linear model (GLM) with age, sex as covariates was finally used to analyze which pairs of RSNs were significantly different between controls and patients. The significance threshold was  $p < 0.05$ , corrected for multiple comparisons using FDR.

## Correlations With Neuropsychological Assessment

To further investigate the relationship between connectivity anomalies and cognitive impairment in patients with presbycusis, we performed the correlation analysis between the abnormal connectivity regions detected and neuropsychological assessment scores. That is, for the inter-network FC, the brain region with a significant difference in the two-sample  $t$ -test was selected as the ROIs and the coordinates of ROIs were extracted. Then, the mean  $z$ -scores within ROI were used to illustrate the correlation. Also, for intra-network FC, significant differences among the three groups were detected at the level of 12 components, and its FNC coefficients were used to calculate the correlation with assessment scores.

## Statistical Analyses

To investigate the difference between presbycusis patients and healthy controls for demographic and clinical information, the chi-square test was applied to the categorical variables and independent two-sample  $t$ -test for continuous variables, both conducted by the IBM SPSS 19.0 package,  $p < 0.05$  was considered statistically significant. Then, we used Cohen's  $d$  to describe the effect size (ES) of each clinical variable. Meanwhile, for RSNs and FNC analysis, a two-sample  $t$ -test was performed to conducted group comparison between presbycusis patients and healthy controls, and results were corrected for AlphaSim ( $p < 0.01$ ) and FDR method ( $p < 0.05$ ), separately. Pearson or Spearman correlation was used to exam the relationship between FC and neuropsychological test scores with a statistical significance level  $p < 0.05$ . During all this analysis, SPM8 (statistical parametric mapping) was used to carry out the voxel-level statistical analysis of RSNs, and MATLAB function (MATLAB 2013a) was used for FNC group comparison and

other correlation analysis. Bonferroni correction for multiple comparisons was used in the correlation analysis.

## RESULTS

### Clinical Characteristics and Neuropsychological Data

The clinical characteristics as well as the neuropsychological results of presbycusis patients and the control group were summarized in **Tables 1, 2**. There were no significant differences in the aspect of age, gender, and education level. All participants had a type-A tympanometry curve, suggesting the normal function of the middle ear. No significant difference was observed in PTA between the left and right ear of the presbycusis and the control group. The average hearing thresholds of both ears in presbycusis and control group were shown in **Figure 1**. The average PTA of presbycusis patients was significantly higher than that of the control group ( $p < 0.001$ , 1,000–8,000 Hz). In neuropsychological assessment, patients with presbycusis performed significantly worse on DST and TMT-B scores ( $p < 0.05$ ). The other neuropsychological tests did not show any significant differences between the two groups. No subjects had max FD  $> 0.5$  mm on more than 35 volumes in this study. No significant difference was found in the mean and max FD values between presbycusis patients and controls.

### Resting-State Networks

By using ICA approach, we obtained a cluster of 12 ICs and identified the eight meaningful RSNs (**Figure 2**), which is similar to previously reported research and including the following networks: the subcortical limbic network (scLN; IC2), which located throughout striatum and extends into the thalamus, brainstem, hippocampus, and amygdala. Auditory network (AUN; IC25) mainly consists of superior temporal gyrus and middle temporal gyrus which corresponded to the auditory system. The Default-mode network (DMN; IC3 + 32), includes the anterior region and the posterior region, the anterior region comprises the medial prefrontal cortex and the anterior cingulate cortex, and the posterior region mainly involves the posterior cingulate cortex/precuneus, bilateral inferior parietal cortex, and angular gyrus. The executive control network (ECN; IC21 + 27), primarily contains the bilateral dorsolateral prefrontal cortex and the lateral parietal cortex. Attention network (AN; IC28 + 30) is captured in two components, named as dorsal AN and ventral AN, including the following areas: the bilateral intraparietal sulcus, frontal eye field, ventral parietal cortex, and inferior frontal gyrus (IFG). Sensorimotor network (SMN; IC4 + 22) centered on the bilateral primary somatosensory cortex, mainly including precentral gyrus and postcentral gyrus. Also, visual network (VN; IC6) and cerebellum network (CN; IC26) were in agreement with the anatomical and functional delineations of the occipital lobe and cerebellar cortex, respectively.

### Altered FC Within RSNs

Compared with the controls, presbycusis patients showed significant FC differences in four RSNs including the scLN, DMN, ECN, and AN, all of which revealed the decreased

FC in the presbycusis group (**Figure 3** and **Table 3**). For the scLN, FC decreased in the right middle cingulate gyrus (R\_ middle cingulate gyrus). For the DMN, FC decreased in the left precuneus (L\_Precuneus). For the ECN, FC decreased in the right Inferior Frontal Gyrus (R\_IFG). And, the AN revealed the decreased FC in the right supplementary motor area (R\_SMA). Besides, there were no differences in resting-state FC between controls and presbycusis groups within the AUN, SMN, VN, and CN.

## Altered Inter-network FC

Significant differences in the network connectivity in scLN, AUN, DMN, AN, and VN between presbycusis and control groups for FNC analysis were found (**Figure 4**). Subsequent analysis for significant differences in FNC revealed increased connectivity between scLN (IC2) and AUN (IC25), as well as the VN (IC6) and DMN (IC3) in presbycusis group compared to control group. Relative to the control group, the presbycusis group exhibited significantly decreased inter-network connectivity in the AN (28)-DMN (32).

## Correlation Analysis

Pearson or Spearman correlations were performed between the mean z-scores of 12 ROIs in the eight RSNs and cognitive assessment scores. Before multiple comparisons correction, significant correlations were found between the left precuneus within the DMN and DST scores ( $\rho = 0.501$ ,  $p = 0.001$ ),

as well as between the right IFG within the ECN and TMT-B scores ( $r = -0.341$ ,  $p = 0.042$ ). Moreover, after performing the correlations between the FNC coefficients (three connections) and the cognitive scores in presbycusis patients, only the AN-DMN connection was found to be positively correlated with DST scores ( $\rho = 0.327$ ,  $p = 0.040$ ). Nevertheless, no

**FIGURE 2 |** Functional relevant resting-state networks (RSNs). The spatial maps of 12 independent components (ICs) were selected as the RSNs for further analysis. AUN, Auditory network; DMN, default mode network; ECN, executive control network; AN, attention network; SMN, sensorimotor network; VN, visual network; CN, cerebellum network.

significant correlations persisted after Bonferroni correction. Also, no significant associations between FD value and network connectivity in each RSNs were found in this study.

## DISCUSSION

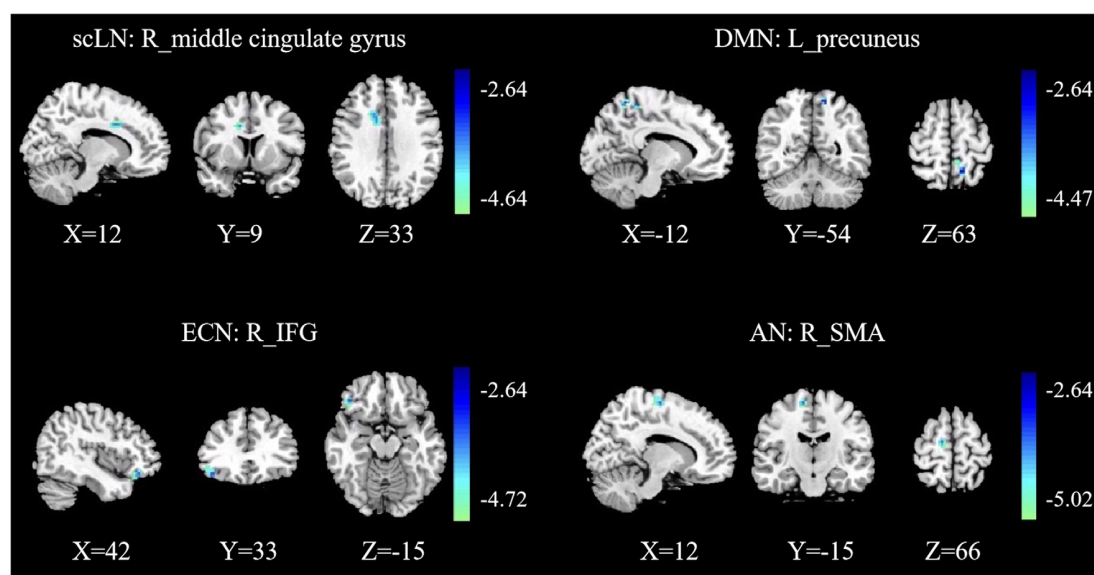

To our knowledge, this study is the first time using the ICA approach to detect the intra- and inter-network FC and their relationship with cognitive function in patients with presbycusis. Four brain networks were found to be abnormal in presbycusis patients compared with the controls, including scLN, DMN, ECN, and AN. Meanwhile, increased or decreased alterations of the inter-network functional coupling were found in the three functional connections in presbycusis patients through FNC analysis. And in presbycusis patients, only DST and TMT-B were found significant in cognitive performance, which may indicate that cognitive impairment is mainly manifested in the level of working memory and executive control function.

Analysis of RSNs internal FC focuses on the interaction of multiple networks in a certain spatial pattern (Beckmann et al., 2005). In this study, presbycusis patients observed reduced FC in the right middle cingulate gyrus for scLN. It is well known that scLN carries a variety of functions, including emotion, behavioral

motivation, cognition, and memory processing (Morgane et al., 2005). A previous study found that in patients with sudden sensorineural hearing loss showed increased nodal betweenness of the limbic network, which may suggest a plastic compensatory mechanism to lessen the consequences of nerve damage caused by hearing loss and help maintain the patient's cognitive abilities (Xu et al., 2016). Our research found reduced FC in the middle cingulate gyrus, suggesting the possibility of cognitive impairment in presbycusis patients. The middle cingulate gyrus forms an important component of the limbic system and is widely connected to neighboring brain regions *via* bundles of white matter fibers (Powell et al., 2018). Moreover, this study believes that the change stems from hearing impairment patients with persistent pressure on speech perception, which leads to reduced adaptive activity in the limbic network involved in the emotional processing of sounds.

As we know, the DMN controls both primary perception and advanced cognition and is responsible for the integration of these two (Zhao et al., 2018). Studies by Chen et al. (2018) indicated that compared with healthy controls, patients with hearing impairment showed reduced spontaneous neuronal activity in the precuneus. Also, decreased FC between the dorsal AN and the precuneus in patients with hearing loss has been emerging understanding. It is however not the hearing loss itself associated with reduced FC but the individually perceived listening effort that occurs as a result of hearing loss (Rosemann and Thiel, 2019). Moreover, the precuneus is functionally involved in episodic memory retrieval, self-awareness and processing, and is a critical element of the DMN (Cunningham et al., 2017; Feldstein Ewing and Chung, 2019). Meanwhile, we also found that the FC in the left precuneus within the DMN was associated with the DST score, implicating the disrupted working memory in presbycusis patients.

The ECN is involved in numerous advanced cognitive tasks and plays an important role in adaptive cognitive control (McHugh et al., 2017). In the current study, decreased FC in the right IFG within the ECN in patients with presbycusis was appeared, and significant correlations between the right IFG and TMT-B scores were found, reflecting the abnormality of the executive control function, which is inconsistent with the previous research. A psychiatric study (Rutherford et al., 2018) identified that hearing loss leads to reduced activation in central auditory pathways, thus resulting in compensatory increased activation in the ECN. Rosemann and Thiel (2019) observed that patients with hearing loss actively recruited frontal lobe regions, which possibly reflect increased efforts in executive function. Our results actually recognized a hypothesized mechanism for the relationship between presbycusis and cognitive impairment: the reallocation of cognitive resources. External acoustic stimuli reduced as a result of hearing loss, so more neural resources are allocated to deal with the attenuation of auditory signals, while few resources correspondingly left that can be used for higher-level cognition. The right IFG is mainly implicated in sensory input processing related to expectation and attention. The decline of its function indicates the impairment of attention and the impairment of language processing (Sherman et al., 2016; Briggs et al., 2019).

**FIGURE 3 |** Group functional connectivity (FC) differences within RSNs. Significant differences between the presbycusis and control groups were found within four RSNs. scLN, subcortical limbic network; DMN, default mode network; ECN, executive control network; AN, attention network; IFG, inferior frontal gyrus; SMA, supplementary motor area; R, right; L, left.

A growing body of evidence suggests that SMA is not only a motor structure but also involves in a wide range of cognitive fields (Bonini et al., 2014; Leek et al., 2016). It is generally believed that the processing of auditory is modulated by movement (Schneider and Mooney, 2018). A previous study discovered that the reduced directed FC from the SMA to the hippocampus revealed impaired sensorimotor function in patients with presbycusis (Chen et al., 2020). Panouillères and Mættænen suggested that in the old adults with hearing loss, the reduction of auditory input from the cochlea to the auditory system leads to a reduction in the recruitment of the articulatory cortex (Panouillères and Mættænen, 2018). This finding supports the hypothesis of auditory-motor decline (Skipper et al., 2017), which is in line with our results. The frontal regions depart from the primary motor cortex, passes through the intermediate premotor and SMA areas, and then head towards the prefrontal areas, thus to form an organizational structure (Fuster, 2006). Therefore, the decreased FC of SMA in presbycusis patients suggested the disruption of this organizational structure, leading to the impaired function of frontal lobe-mediated cognitive processing. The above results suggested that these

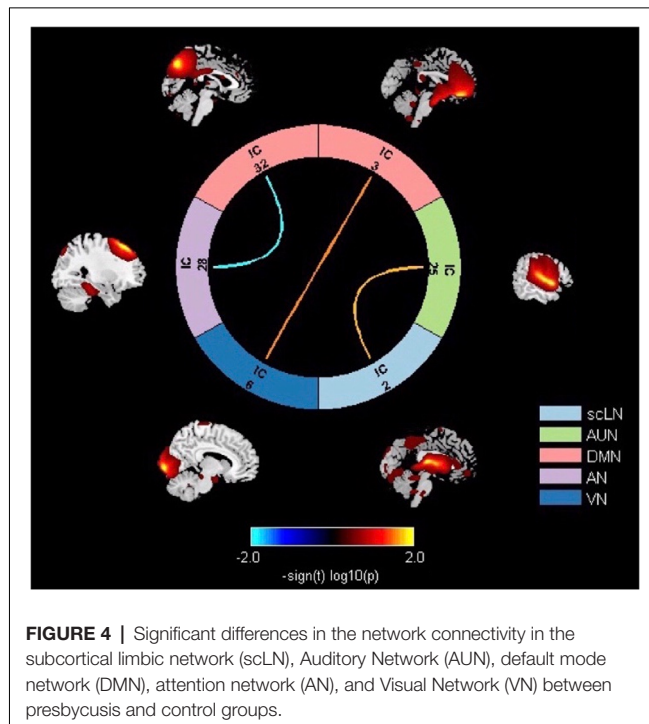

four cognitive-related networks may have certain specificity in cognitive impairment mediated by presbycusis, which will help understand the neuropathological mechanism of presbycusis.

Recently, gradually increasing evidence suggested that RSNs are interdependent and continue to interact with each other (Smith et al., 2015). Our results illustrated the increased connectivity for the scLN-AUN, which may be following the conceptual model proposed by Jastreboff (1990). Our results revealed that under the condition of long-term deprivation of auditory ability and insufficient auditory input in presbycusis patients, the compensatory feedback neural activity of the scLN increased, reflecting a certain degree of plastic reorganization within the limbic network. Data from previous animal models also indicated that hearing loss promotes cortical reorganization and morphological alterations (Pelle and Wingfield, 2016). Besides, it also suggested that the auditory cortex is involved in the analysis of inputs from higher-order functions mediated by scLN. Besides, our study also demonstrated the hyper-connectivity for VN-DMN, reflecting the improvement of visual motion or peripheral spatial localization ability of patients with presbycusis, and

**TABLE 3 |** Brain regions with significant differences connectivity within resting-state networks (RSNs) between presbycusis patients and healthy controls.

	Brain regions	BA	Peak MNI coordinates			Peak T-value	Voxels
			x	y	z		
scLN	R_middle cingulate gyrus	32	12	9	33	-3.667	41
DMN	L_precuneus	7	-12	-54	63	-4.1241	41
ECN	R_IFG	47	42	33	-15	-3.8975	47
AN	R_SMA	6	12	-15	66	-4.0499	40

MNI, Montreal Neurologic Institute; scLN, subcortical limbic network; DMN, default mode network; ECN, executive control network; AN, attention network; IFG, inferior frontal gyrus; SMA, supplementary motor area; R, right; L, left.

the compensatory plastic reorganization occurs in the brain network which may be due to the lack of auditory ability. The strengthened functional coupling of the local sensory network including visual and sensory-motor areas in patients with sloping sensorineural hearing loss indicates that the auditory-deprived brain will have integrated compensation for the remaining sensory regions (Wolak et al., 2019).

The decline in attention and the reduction in the volume of the attention-related cortex reflects the impaired function of the AN (Cardin, 2016), which in turn affects the perceptual analysis and the auditory processing of acoustic signals, always occurs in presbycusis patients (Fortunato et al., 2016). Previously investigating the cross-network interaction between the DMN and the DAN, it was found that activities in DMN decreased when performing goal-directed tasks, while activities in DAN increased. This relationship suggested to be anti-correlated (Fox et al., 2009), and our result seems to reinforce this decoupling effect. That is, the FC in AN reduced to stabilize the balance from the external environment, such as auditory input. However, the reduction of perceived auditory tasks in presbycusis leads to the interruption of AN, and decrease the connectivity to key nodes of the DMN. The interruption of AN is also one of the causes of memory impairment (Veldsman et al., 2019). In addition to FNC abnormalities, a negative correlation between the AN-DMN and DST scores was also detected, showing that the dis-coupling probably relates to the disrupted working memory in presbycusis patients, and these disconnections above may also contribute to daily cognitive impairment.

Several limitations should be paid attention to. First of all, although the FC results are consistent with the previous literature, the essence of the interaction between and within different internal connectivity networks has poorly

comprehended. Second, the brain networks involved in this study are limited. Because other networks may play an important role in the pathophysiology of cognitive impairment in the presbycusis, detecting the variation of the FC in multiple networks will provide insight into the neural mechanism in depth. Further researches should focus on the effects of presbycusis on other brain networks and conduct longitudinal research to predict long-term cognitive function. Moreover, no significant results persisted after Bonferroni correction for multiple comparisons in the correlation analyses due to the relatively strict method, which will be considered in further study. Nonetheless, our research is still meaningful to provide some enlightenment for future studies in this field. Finally, the newly reported rs-FC is difficult to reflect the characteristics of temporal variations within the brain network, therefore, dynamic FNC is regarded as the future research direction. Also, the directionality of the interaction between networks cannot reveal by the ICA approach, further studies are needed to assess the specific and directional function in the coupling between brain networks.

To sum up, this study suggested that the structure of intra- and inter-networks FC of presbycusis patients has undergone profound alterations. The alterations involving the primarily auditory system and other high-order cognitive control networks have demonstrated that brain network with extensive plastic reorganization during the abnormal state, which provides meaningful insights for further understanding the neural mechanism of cognitive impairment in presbycusis patients.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the local institutional review board of Nanjing Medical University. The patients/participants provided their written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

## AUTHOR CONTRIBUTIONS

CX and JZ designed the experiment, collected the data, performed the analysis and wrote the manuscript. JC, WY, JH, and XY collected the data. YW and Y-CC contributed to the discussion and manuscript revision.

## FUNDING

This work was supported by the National Natural Science Foundation of China (Grant No. 81601477), Youth Medical Talents of Jiangsu Province (Grant No. QNRC2016062), 14th

The study of cognitive impairment associated with hearing loss has recently garnered considerable interest. Epidemiological data have demonstrated that hearing loss is a risk factor for cognitive decline as a result of aging. However, no previous study has examined the effect of hearing loss in patients with cognitive problems such as Alzheimer's disease. Therefore, we investigated the effect of conductive hearing loss in an Alzheimer's mouse model. Positron emission tomography (PET) and magnetic resonance imaging (MRI) were used to evaluate changes in glucose metabolism and gray matter concentrations in the 5xFAD Alzheimer's Disease (AD) transgenic mouse model with and without conductive hearing loss (HL). Conductive hearing loss was induced using chronic perforation of the tympanic membrane. Behavioral data from the Y-maze and passive avoidance tests revealed greater memory deficits in the AD with HL (AD-HL) group than in the AD group. Following induction of hearing loss, lower cerebral glucose metabolism in the frontal association cortex was observed in the AD-HL group than in the AD group. Although lower glucose metabolism in the hippocampus and cerebellum was found in the AD-HL group than in the AD group at 3 months, the gray matter concentrations in these regions were not significantly different between the groups. Furthermore, the gray matter concentrations in the simple lobule, cingulate/retrosplenial cortex, substantia nigra, retrosigmoid nucleus, medial geniculate nucleus, and anterior pretectal nucleus at 7 months were significantly lower in the AD-HL group than in the AD group. Taken together, these results indicate that even partial hearing loss can aggravate memory impairment in Alzheimer's disease.

## INTRODUCTION

Cognitive impairment associated with hearing loss (HL) has recently attracted considerable interest due to growing evidence suggesting that impaired hearing is a risk factor for cognitive decline (Hardy et al., 2016). Several studies have assessed the relationship between hearing deficits and cognitive impairment. Age-related hearing problems are common among people with dementia

and are associated with poor cognitive function and reduced quality of life (Dawes et al., 2018). Furthermore, hearing loss in later life has been associated with the risk of dementia. The impact of the risk factors for dementia may change during a person's lifespan, and whether or not midlife hearing loss represents a risk factor for dementia remains poorly understood (Osler et al., 2019). Osler et al. have shown that early identification and correction of hearing loss holds promise for the prevention of dementia later in life (Osler et al., 2019). Interventions aimed at improving sensory function may improve the quality of life of patients with dementia (Leroi et al., 2017). Furthermore, middle-aged and old patients with severe or profound hearing impairments also show an increased risk of developing dementia (Kim et al., 2018). However, there are no reports on the effect of hearing loss in patients with cognitive impairment such as Alzheimer's disease (AD). If hearing loss facilitates cognitive decline in the normal population, then patients with AD and hearing loss may be expected to suffer more in the aspect of cognitive function. Therefore, we investigated the behavior, brain function, and changes in hearing in hearing loss-induced AD model mice using behavioral tests, positron emission tomography (PET), and magnetic resonance (MR) imaging.

Although many reports point to a correlation between dementia and hearing impairment, quantitative and functional studies are challenging because the auditory areas in the brain remain poorly understood and are difficult to assess. Deaf animal models provide us with an opportunity to assess the impact of hearing loss interventions on the development of dementia, as well as the corresponding changes in brain plasticity. We have previously demonstrated cross-modal and compensatory plasticity using PET analysis in an animal model (Park et al., 2010). PET is a promising tool for the assessment of neuronal and cortical plasticity (Lee et al., 2001). The cochlear implant is a surgically implanted neuroprosthetic device that provides a sense of sound to a person with severe to profound sensorineural hearing loss (Balkany et al., 1999; Hodges et al., 1999). PET analyses of brain plasticity have provided quantitative results that support increased metabolic activity in auditory areas following cochlear implantation (Lukaszewicz-Moszynska et al., 2014; Strelnikov et al., 2015; Yoshida et al., 2017). Studies have also assessed verbal working memory in children with cochlear implants (Akçakaya et al., 2019).

The aim of this study was to evaluate the effects of conductive hearing loss on Alzheimer's disease. We sought to investigate the following questions: (1) Does conductive hearing loss affect memory ability? (2) Does conductive hearing loss lead to functional changes in imaging studies such as PET and MR? Five familial AD mutation (5xFAD) transgenic mice (which are commonly used as an animal model for AD) were used in the current study (Son et al., 2016; O'Leary et al., 2017; Jeon et al., 2018; Moon et al., 2019). Experimental mice were divided into two groups: Alzheimer's disease with and without hearing loss (AD-HL and AD), and used PET and MR were used to evaluate changes in cerebral glucose metabolism and regional gray matter concentrations after the induction of conductive hearing loss. Memory deficits were assessed using the Y-maze and passive

avoidance tests. To the best of our knowledge, our study is the first to investigate the relationship between AD and hearing loss through the evaluation of cerebral glucose metabolism and regional gray matter concentrations using PET and MR image analysis on animal models.

## MATERIALS AND METHODS

### Animals and Ethics Statement

Five familial AD mutation male mice (2 months of age), which overexpress five familial AD mutations, were used in the current study. These mutations comprise three in human APP (695) with the Swedish (K670N, M671L), Florida (I716V), and London (V717I), and two in human presenilin1, PSEN1 M146L, and PSEN1 L286V. The transgenic mice were purchased from Jackson Laboratory (Bar Harbor, ME, United States). All applicable international, national, and/or institutional guidelines for the care and use of animals were followed. The animal study was approved by the Institutional Animal Care and Use Committee (IACUC) and the Institutional Review Board of the Korea Institute of Radiological and Medical Sciences (KIRAMS 2018-0016, KIRAMS 2015-38), and all experiments were performed in accordance with their guidelines.

### Experimental Design

#### Experimental Group

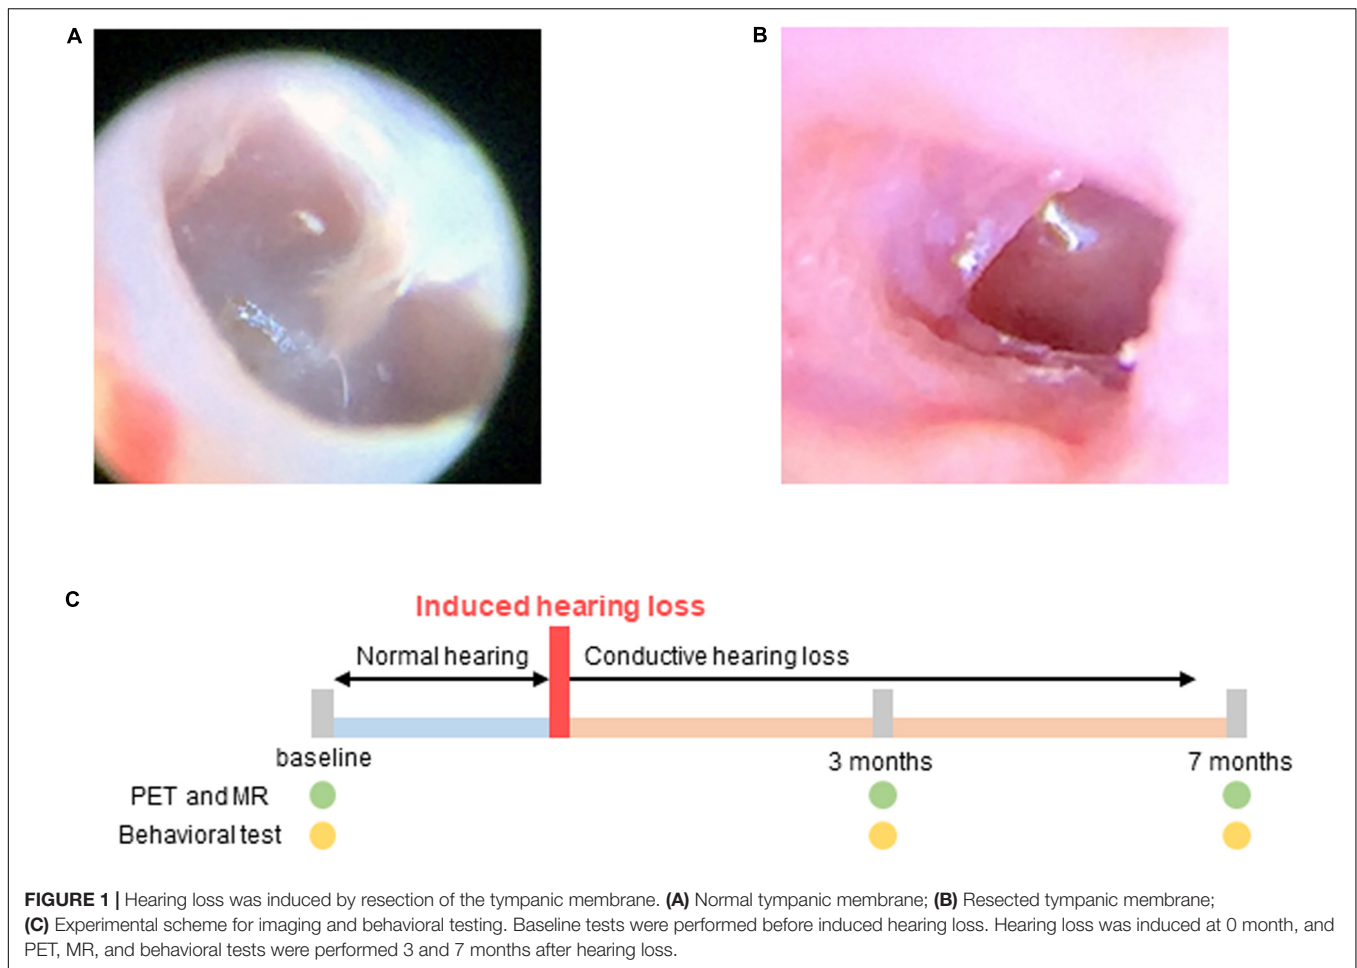

The animals were divided into two groups: the experimental group (AD-HL;  $n = 10$ ) with induced conductive hearing loss and the control group (AD;  $n = 10$ ) with normal hearing. Both groups underwent measurement of hearing thresholds, behavioral tests, and imaging studies.

#### Hearing Loss

Conductive hearing loss was induced in the experimental group using the following procedure: The mice were anesthetized using intraperitoneal injections of ketamine (100 mg/kg) and xylazine (20 mg/kg). The tympanic membrane was resected using a sharp pick under continuous endoscopic visualization (Lieberman et al., 2015). After resection, the movement and balance state of the animals were checked to evaluate inner ear damage. The state of the tympanic membrane was endoscopically examined every week. Resection was repeated when the perforation size was observed to have decreased. The perforation size in the tympanic membrane was maintained until the end of the study (Figure 1).

#### Hearing Evaluation

Hearing levels were assessed using click-evoked ABRs 1 week after surgery, 3 months later, and at the end of the study. Hearing levels were tested by evaluating the auditory brainstem responses (ABRs) to click stimuli (Intelligent Hearing System, Miami, FL, United States). Subdermal needle electrodes were located below both ear and at the vertex. The stimulus rate is 19.3/s using click sound of rarefaction mode. The response was amplified, and band pass filtered (100–3000 Hz), and averaged over stimulation (512 sweeps per stimulation).

## PET Statistical Parametric Mapping (SPM) and MR Voxel-Based Morphometry (VBM) Analyses

PET and MR scans were acquired at baseline and at 3 and 7 months after the induction of hearing loss in order to assess changes in cerebral glucose metabolism and gray matter concentrations (Figure 1C).

Regional cerebral glucose metabolism was measured using the F-18 fluorodeoxyglucose (F-18 FDG) PET scan (Siemens Inveon PET scanner) (Bao et al., 2009). Prior to the PET scan, the mice ( $n = 10$  per group, male) underwent an 8-h fasting period, after which they were anesthetized with 2% isoflurane in 100% oxygen (Forane solution; Choongwae Pharma, South Korea). The body temperatures of the mice were maintained at 36°C using heating pads during the course of the scan. Next, 200  $\mu$ Ci of F-18 FDG was injected through the tail vein of the mice. After 30 min of uptake, emission PET data were acquired for 30 min using an energy window of 350–650 keV. The emission list-mode data were sorted into three-dimensional (3D) sinograms and reconstructed using 3D reprojection algorithms without the use of a filter. The size of the image matrix was  $256 \times 256 \times 159$ , with a pixel size of  $0.155 \text{ mm} \times 0.155 \text{ mm}$  and a slice thickness of 0.796 mm.

Regional differences between groups were identified using voxel-based statistical analysis performed in SPM 8<sup>1</sup>. Statistical parametric mapping analysis on small animals has been described in our previous study (Kim et al., 2008). Briefly, the brain tissue was extracted from the image and a study-specific mouse brain template was constructed using structural images. Individual PET data were spatially normalized onto the mouse brain template using affine and non-linear transformations. The voxel size of the spatially normalized images was  $0.3 \text{ mm} \times 0.3 \text{ mm} \times 0.3 \text{ mm}$ . Finally, a Gaussian smoothing kernel with a full-width at half-maximum (FWHM) value of 3 mm was applied to enhance the signal-to-noise ratio. Count normalization was performed. *t*-tests were used to identify regional differences in cerebral glucose metabolism between the groups ( $p < 0.005$  or  $p < 0.05$ , uncorrected).

T2w 3D MR images were acquired using an Agilent 9.4 T MR scanner (United States). An AD quad 70 RF coil was used, and the matrix size was  $192 \times 192 \times 192$ . The repetition time (RT) was 2500 ms. The effective echo time (TE) was set at 7 ms. The total image acquisition time was 3 h 36 min.

Modulated VBM analysis was performed in SPM eight to compare the regional gray matter concentrations in selected

<sup>1</sup><http://www.fil.ion.ucl.ac.uk/spm>

brain regions between the groups (Wilke et al., 2003). Skull stripping was performed using the BrainSuite (version 16) software (Kazemi and Noorizadeh, 2014). Parameters including the brain surface extractor diffusion iterations, diffusion constant, edge constant, and erosion size were adjusted for skull stripping using individual T2w 3D MR data. A predefined gray matter template (matrix size:  $512 \times 512 \times 512$ ; voxel size:  $0.04 \text{ mm} \times 0.04 \text{ mm} \times 0.04 \text{ mm}$ ) created by the Delora research team was used for spatial normalization (Kazemi and Noorizadeh, 2014; Delora et al., 2016). Individual skull-stripped MR data were spatially normalized onto the template and smoothed with a Gaussian smoothing kernel with a full-width at half-maximum (FWHM) value of 2 mm. Paired *t*-tests were used to identify regional differences in gray matter concentrations between the groups ( $p < 0.005$ , uncorrected).

## Behavioral Analysis

### Y-Maze Test

The Y-maze test was used to measure spatial working memory and reference memory, which were assessed by recording spontaneous alternation behavior (Kraeuter et al., 2019). Activity was recorded for 8 min and analyzed by a computer program (Viewer3, BIOSERVE, St. Augustin, Germany). Alternation was defined as successive entries into three different arms on overlapping triplet sets. Percentage alternation was calculated as the ratio of actual alternation and possible alternation (defined as the total number of arm entries  $- 2$ )  $\times 100$ , as follows:

$$\% \text{ alternation} = \left[ \frac{(\text{No. of alternations})}{(\text{Total arm entries} - 2)} \right] \times 100.$$

### Passive Avoidance Test

The responses to aversive stimuli in the passive avoidance test were used to assess learning and long-term memory (Tucker et al., 1976; Nasri et al., 2012). The setup consisted of two rooms separated by a steel board such that it could automatically be moved up and down to allow movement of the animal from one room to the other. Both the rooms were equipped with a scrambler on the floor, through which electrical stimulation could be delivered to the foot. During the adaptation session (Day 1), the mice were allowed to travel freely between the two rooms for 5 min. On Day 2, the steel board was used to separate the rooms and the mouse was placed in one of the rooms. The room was kept dark for 60 s to allow the mouse to adjust to the darkness, after which the light was turned on and the steel panel was simultaneously removed. As the mouse traveled across to the other room to avoid the bright light, the movement of the mouse triggered the steel panel to shut, and an electrical shock impulse (0.3 mA, 2 s) was transmitted to the grill. After 24 h (Day 3), the mice were subjected to the same trial without the electrical shock stimulus. The time taken by the mice to cross over to the other room was automatically recorded.

## Statistics

Data are presented as mean  $\pm$  standard error of mean (SEM). For behavioral tests, the differences among the groups were analyzed

using the one-way ANOVA test and the difference between two groups were analyzed with Student's unpaired *t*-test in GraphPad Prism five (GraphPad software, CA, United States). A *P*-value less than 0.05 was considered statistically significant.

## RESULTS

### Measurement of the Level of Hearing Loss

The mean hearing level measured using click-evoked ABRs was 20 dB sound pressure level (SPL) at the normal hearing state (Figure 2A). In the control group, the hearing level was increased to 40 dB SPL at 3- and 7-months. In the experimental group, the mean hearing level was 65 dB SPL in both ears after resection of the tympanic membrane (Figure 2B). The final mean hearing levels at 7 months after the induction of hearing loss were  $62.9 \pm 8 \text{ dB SPL}$  on the right side and  $67.1 \pm 7 \text{ dB SPL}$  on the left side (Figure 2C).

### Evidence From PET and MR Imaging

#### Cerebral Glucose Metabolism in the AD Group

SPM analysis of PET scans obtained at baseline and at the 3-month time-point in the AD group revealed decreased cerebral glucose metabolism in the frontal association cortex (FrA;  $P < 0.005$ ; Figure 3A) and the cerebellum (Cb;  $P < 0.05$ ; Figure 3B) at 3 months compared to baseline levels.

#### Comparison Between Cerebral Glucose Metabolism of the AD and AD-HL Groups

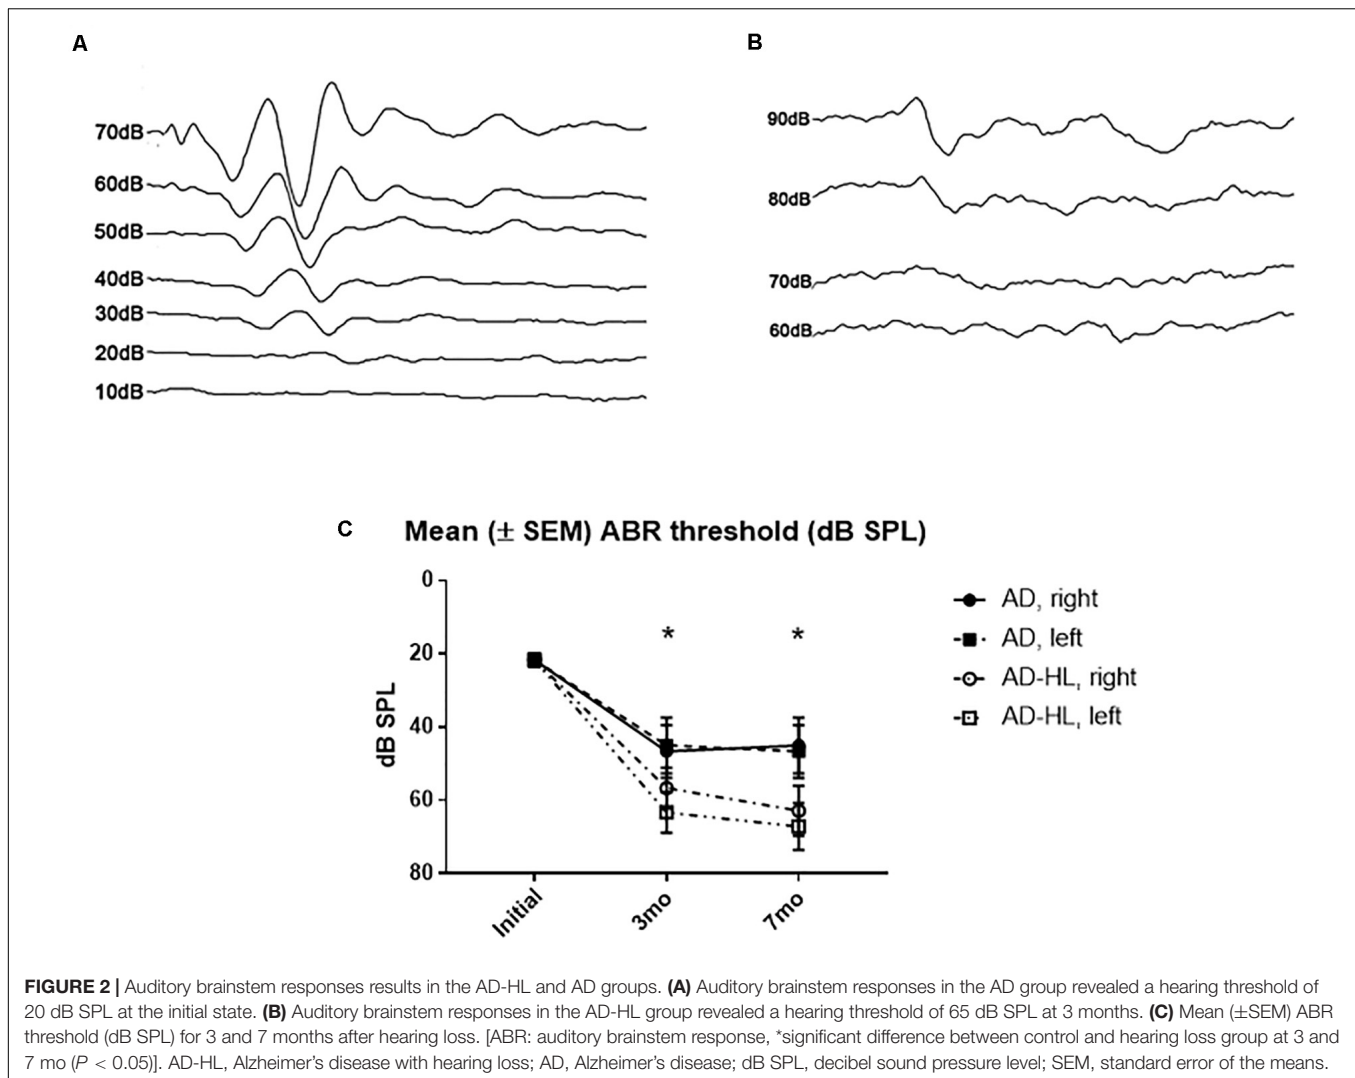

Figure 5 illustrates the results of the SPM analysis comparing PET scans of animals in the AD and AD-HL groups at 3 and 7 months after the induction of hearing loss. Cerebral glucose metabolism in the FrA was lower ( $P < 0.005$ ) in the AD-HL group than in the AD model 3 and 7 months after the induction of hearing loss (shown in Figures 3C,E). We also found lower cerebral glucose metabolism in the hippocampus (CA1) and Cb 3 months after the induction of hearing loss (Figure 3D;  $P < 0.05$ ).

#### Cerebral Gray Matter Concentrations in the AD and AD-HL Mice

Figure 4 illustrates the results of the optimized VBM analysis comparing the MR images of mice in the AD and AD-HL groups. We found no differences in the gray matter concentrations of the two groups at the 3-month time-point after the induction of hearing loss ( $P < 0.005$ ). However, at the 7-month time-point after the induction of hearing loss, the AD-HL group showed lower gray matter concentrations in large areas of the brain including the FrA, simple lobule (Sim, part of the cerebellum), RSA (retrosplenial agranular cortex), cingulate/retrosplenial cortex (Cg/RS), substantia nigra (SNR), retrothmoid nucleus (REth), medial geniculate nucleus (MGV), and anterior pretectal nucleus (APTD) than the AD group ( $P < 0.005$ ).

## Behavioral Analysis

The AD-HL and AD groups underwent behavioral assessment prior to the induction of conductive hearing loss (baseline) when

they were 6 weeks old, and at the 3- and 7-month time-points after induction of hearing loss (in the AD-HL group). None of the animals showed balance or movement problems after resection of tympanic membrane. We assessed the effect of hearing loss on spatial memory using the Y-maze test. The AD group showed an age-dependent decline in working memory. We found no significant difference between the AD and AD-HL groups in the spontaneous alternation as evaluated by the Y-maze (**Figure 5A**) at the 3- and 7-month time-points after hearing loss. However, the AD group tended to show higher spatial memory compared to the AD-HL group.

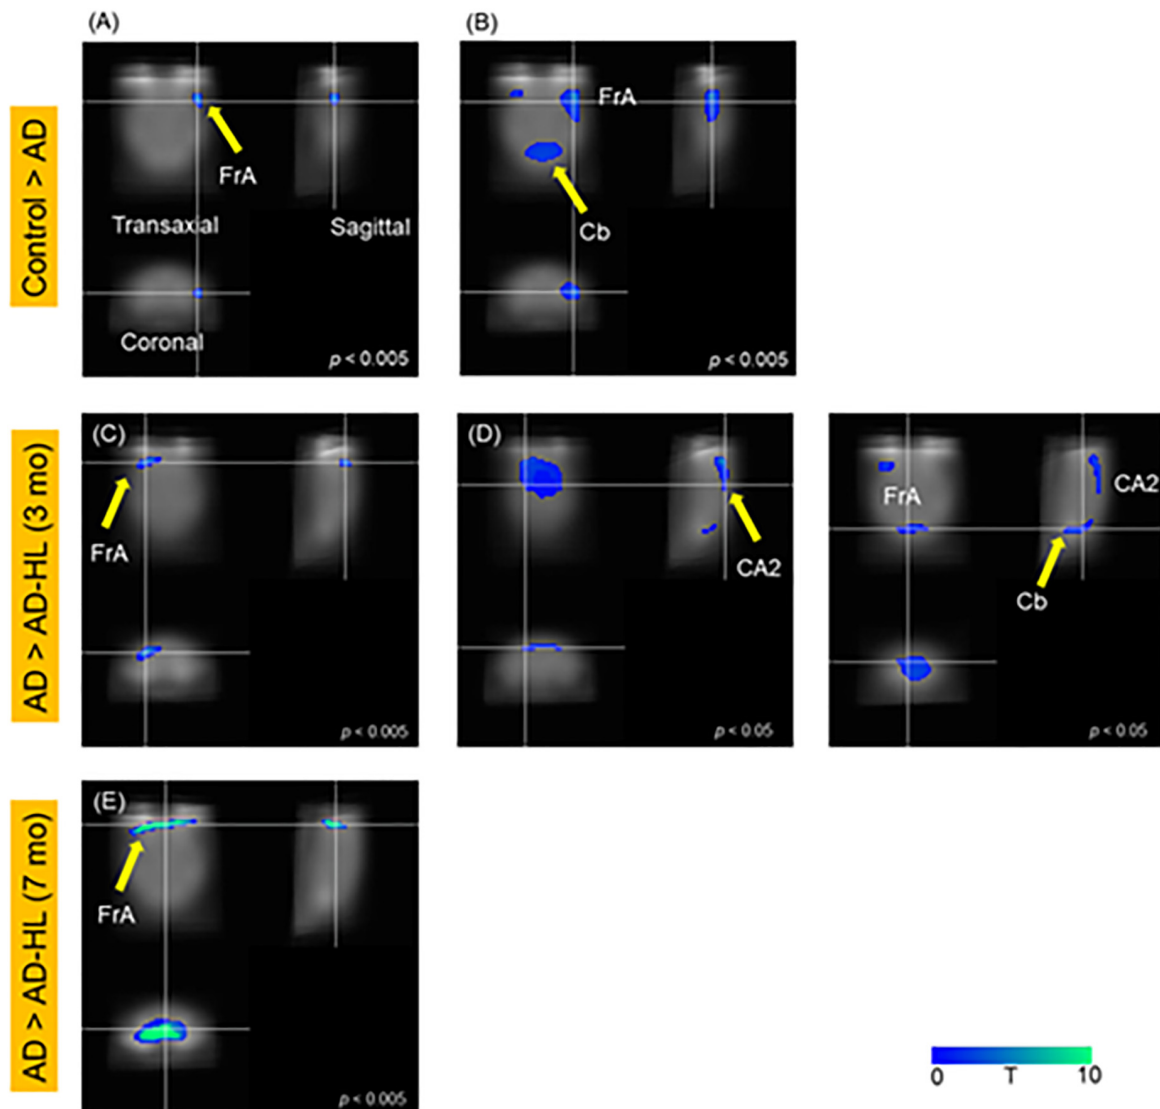

The passive avoidance test was performed to examine the hearing loss-induced memory impairment in the AD-HL group. We found no significant difference in cognitive performance in the passive avoidance test between the two groups prior to the induction of hearing loss. The AD-HL group exhibited significantly higher memory impairment 24 h after the training sessions with the electric shock stimulus than the AD group at the 3-month (mean latency: 210 s in AD vs 87 s in AD-HL,  $p = 0.0037$ ) and 7-month (mean latency: 157 s in AD vs

95 s in AD-HL,  $p = 0.046$ ) time-points following hearing loss induction (**Figure 5B**).

## DISCUSSION

Several meta-analyses, including a meta-analysis of a prospective cohort study, have suggested that hearing impairment significantly increases the risk of developing cognitive disorders (Zheng et al., 2017). The importance of evaluating hearing levels and administering appropriate rehabilitation treatments as part of the cognitive assessment and management plan in individuals with cognitive disorders has also been emphasized (Nirmalasari et al., 2017). Further, age-related hearing loss has been considered to be a possible biomarker and modifiable risk factor for cognitive decline, cognitive impairment, and dementia (Loughrey et al., 2018).

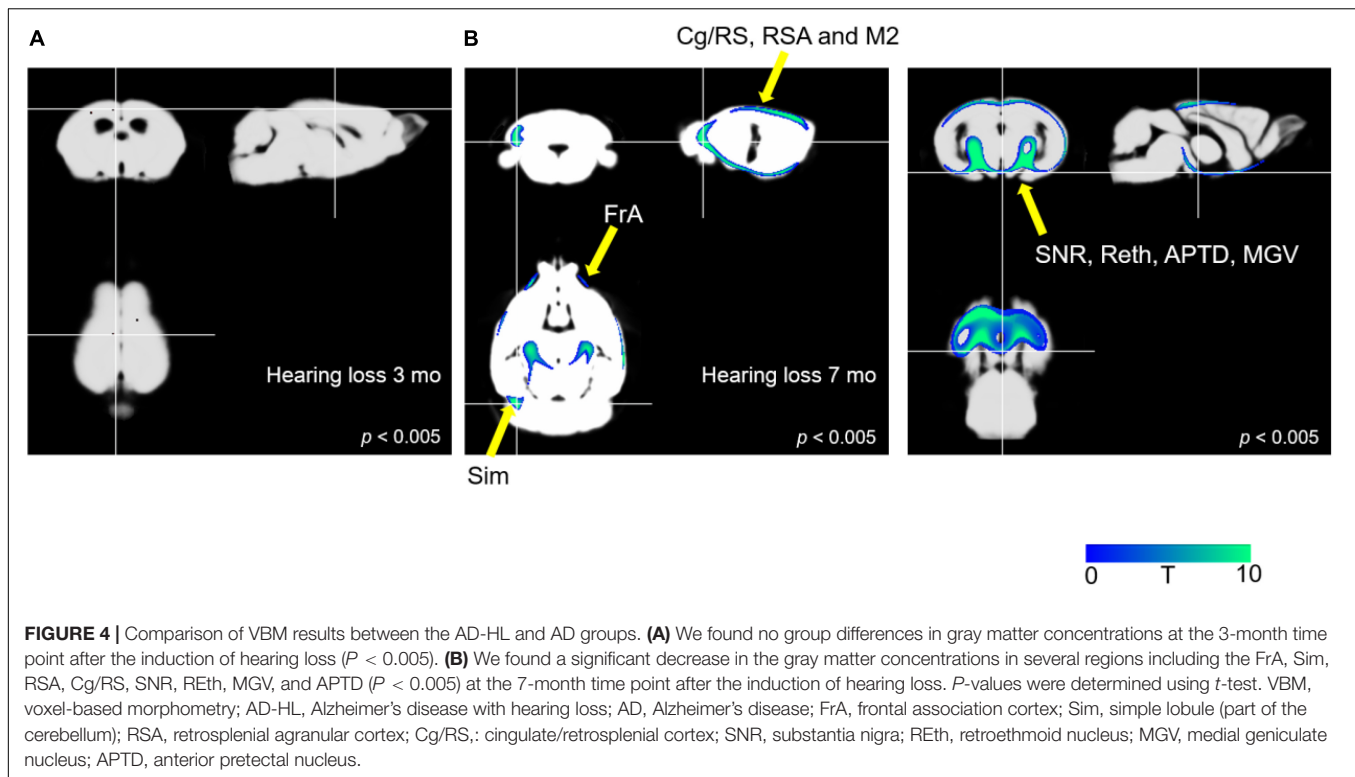

Although meta-analyses and cohort studies have indicated a relationship between hearing loss (hearing impairment or deafness) and cognitive impairment, PET or MR image analyses

**FIGURE 3 |** SPM analysis of PET images; **(A,B)** Control vs AD; **(C,D)** AD vs AD-HL (3 mo); **(E)** AD vs AD-HL (7 mo); We found a decrease in the cerebral glucose metabolism in the **(A)** FrA ( $p < 0.005$ ); and **(B)** Cb ( $p < 0.05$ ) at the 3-month timepoint compared to the baseline levels. We found lower cerebral glucose metabolism in the **(C)** FrA ( $P < 0.005$ ), and **(D)** CA2 region of the hippocampus and Cb ( $P < 0.05$ ) in the AD-HL group than in the AD group at the 3-month timepoint after the induction of hearing loss. **(E)** The cerebral glucose metabolism in the FrA was lower in the AD-HL group than in the AD group ( $p < 0.005$ ) at the 7-month time point after the induction of hearing loss.  $P$ -values were determined using the paired  $t$ -test. SPM, statistical parametric mapping; AD-HL, Alzheimer's disease with hearing loss; AD, Alzheimer's disease; FrA, frontal association cortex; Cb, cerebellum.

or behavioral studies have not been employed to further characterize the relationship until now. Imaging studies using PET have provided a translational platform for clinical use and successful clinical proof-of-concept testing (Platt et al., 2011; Hargreaves and Rabiner, 2014). FDG-PET imaging has been used to visualize the distribution of neural damage or synaptic dysfunction; to identify distinct phenotypes of neurodegenerative disorders such as AD (McKhann et al., 2011), and to identify changes in cerebral glucose metabolism after the onset of deafness, or in brain plasticity after cochlear implantation (Okuda et al., 2013; Strelnikov et al., 2015; Suh et al., 2015; Yoshida et al., 2017). In the present study, we constructed an

AD-HL animal model. This 5xFAD mouse showed peripheral hearing loss with aging (O'Leary et al., 2017). At 4-months-old, the hearing level was normal, but at 14-months-old, the hearing level was much lower than that of the wild type mouse; this has been shown to be an aggravating factor for cognitive decline. Another study was used an animal model of amyloid- $\beta$  infusion to intracerebroventricular space in order to generate a suitable model for AD; in this study, deafness was induced using cochlear ablation. Cognitive behavioral tests were subsequently performed, and amyloid- $\beta$  infused group showed poor performance and greater loss of synapses in the hippocampus (Chang et al., 2019).

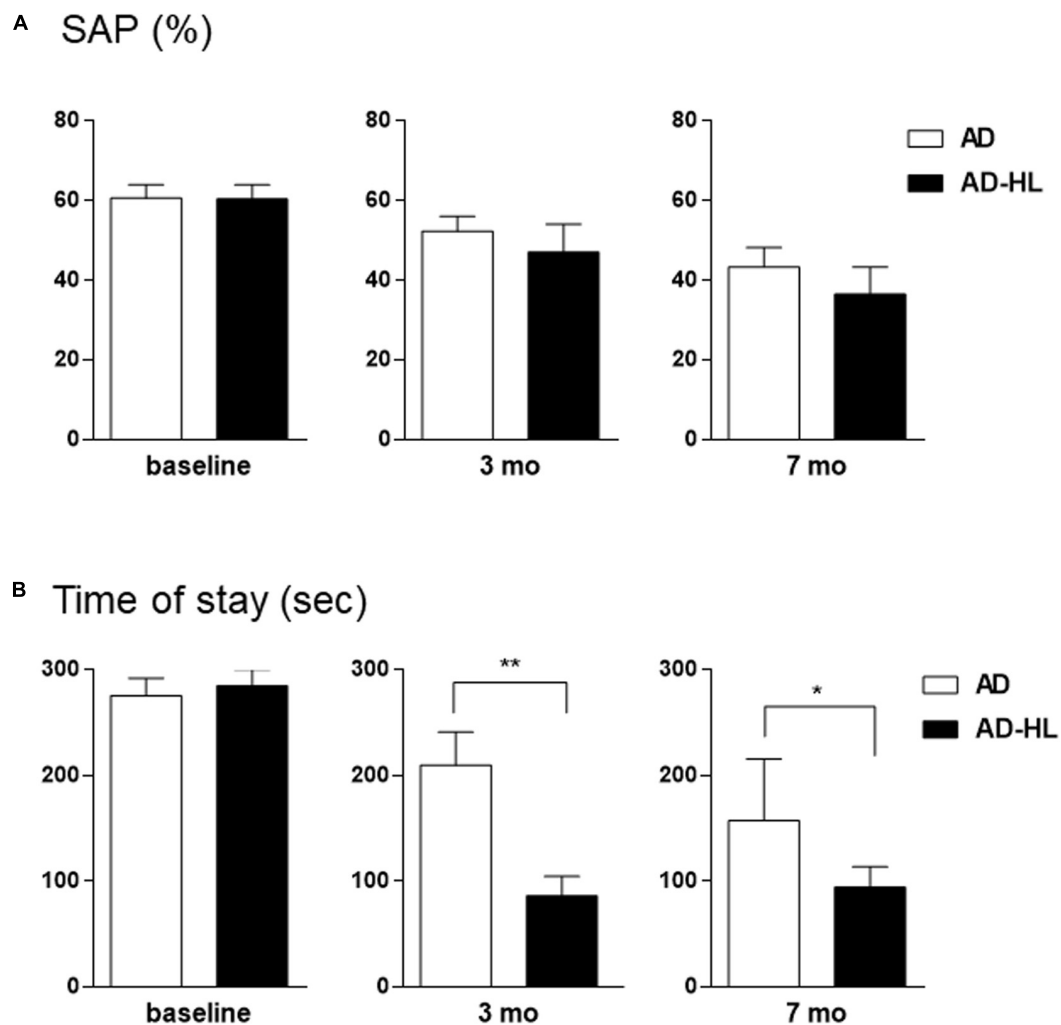

In the current study, we assessed cerebral glucose metabolism, regional gray matter concentrations changes using PET, MR imaging, and behavioral tests. We found reduced glucose metabolism in the FrA ( $P < 0.005$ ), hippocampus, and Cb ( $P < 0.05$ ) in the AD-HL group 3 months after the induction of hearing loss. Interestingly, this functional change was not accompanied by changes in regional gray matter concentrations at the corresponding sites. Memory decline was confirmed using the passive avoidance test. Lower cerebral glucose metabolism levels in the FrA and hippocampus related to memory deficits have also been found in our previous PET study (Park et al., 2013; Lim et al., 2016; Ye et al., 2016). Furthermore, other groups have reported cognitive decline-associated decreases in cerebral glucose metabolism in the Cb (Schreck et al., 2018; Liang and Carlson, 2019; Nishida et al., 2019). In the current study, the decrease in the cerebral glucose metabolism in the FrA persisted at the 7-month time-point. Furthermore, VBM analysis also revealed decreases in gray matter concentrations in the Sim, RSA, and Cg/RS in the AD-HL group. The Cg/RS and RSA are known to be the key brain areas involved in memory, emotion, and attention functions (Zraggen et al., 2012; Milczarek et al., 2018).

However, we noted a discrepancy in the results from PET and MR image analyses. Although we found group differences in the regional gray matter concentrations in several areas of the brain at the 7-month time point, SPM analysis of PET imaging data did not reveal differences in glucose metabolism at the corresponding sites, except in the case of the FrA. This discrepancy could be explained by brain plasticity. Although

the glucose metabolism decreased in the hippocampus and Cb 3 months after the induction of hearing loss, the metabolism in these regions recovered by 7 months, possibly due to brain plasticity. This type of recovery has been previously reported both in humans and cats (Lee et al., 2001; Park et al., 2010). In previous studies, the primary auditory cortex showed hypometabolism after deafness, and then, the hypometabolic area was normalized further after even the ear was still deaf. They explained this phenomenon as an evidence of cross-modal plasticity. Therefore, in our study, CA2 area showed hypometabolism at 3 months after hearing loss; however, the change was normalized at 7 months after hearing loss, even the hearing loss and behavioral deficit were still remained. In addition, the results of the VBM analysis suggest differences in gray matter concentration in several areas of the brain, including the FrA.

Our findings suggest that the decrease in cerebral glucose metabolism in the hippocampus is correlated with memory deficits, such as those affecting long-term memory (Sawangjit et al., 2018). The results of the passive avoidance test support the development of memory deficits induced by hearing loss, especially in terms of long-term memory. Additionally, we found no changes in regional gray matter concentrations in the whole brain at the 3-month time-point, which implies that there were changes only in the glucose metabolism at this time. However, we found significant changes in the gray matter concentrations in memory and motor function-related brain areas at 7 months after the induction of hearing loss. SPM analysis of PET images at 7 months revealed a recovery in the impaired glucose metabolism in the Cb at this time point.

**FIGURE 5 |** Comparison of behavioral changes between the AD-HL and AD groups. **(A)** In the Y-maze, we found no significant group differences in the percentage of spontaneous alternation at any of the tested time-points. However, the AD group tended to exhibit higher spatial memory than the AD-HL group at the 3- and 7-month time-points. **(B)** In the passive avoidance memory test, compared to the AD group, the AD-HL group exhibited significantly higher latency time at the 3- and 7-month time-points, indicating higher memory impairment. Data are represented as mean  $\pm$  SEM. \* $P < 0.05$ , \*\* $P < 0.01$  (vs AD group).  $P$ -values were calculated using  $t$ -test. AD-HL, Alzheimer's disease with hearing loss; AD, Alzheimer's disease; SEM, standard error of the means; SAP, spontaneous alternation percentage.

Interestingly, we did not find significant changes in glucose metabolism or gray matter concentration in the auditory cortex at the 3- or 7-month time-points after the onset of hearing loss. We believe this may be because our mouse model with hearing loss did not constitute complete deafness. In our conductive hearing loss model, the mice could still hear loud sounds. As the auditory system was still functional, loud sounds could evoke activation of the auditory system. However, we found lower cerebral glucose metabolism in the FrA in the AD-HL group than in the AD group. The FrA is composed of the prefrontal cortex and motor function-related areas of the brain excluding the primary motor cortex (Takada, 2016). Neuropsychology and neuropsychology studies have established that the dorsolateral prefrontal cortex is associated with working memory, while the ventral frontal lobe is associated with auditory and audiovisual working memory (Plakke et al., 2015). Our PET findings revealed

decreased glucose metabolism in the dorsolateral prefrontal cortex at the 3-month time-point after induction of hearing loss in the AD-HL mice. However, by the 7-month time-point, the glucose metabolism in the ventral prefrontal cortex, as well as in the dorsolateral prefrontal cortex regions was affected. This finding suggests that auditory areas including the ventral prefrontal cortex were affected despite the fact that we did not induce complete hearing loss.

## CONCLUSION

Our findings reveal memory impairment after hearing loss in the AD mice as evidenced by PET and MR imaging findings. The results from our behavioral tests also support an association between memory impairment and hearing loss. Together, these

results suggest that hearing loss may aggravate memory decline in an animal model of AD.

In sum, we constructed an AD-HL animal model and assessed changes in cerebral glucose metabolism and gray matter concentrations following hearing loss. Our results provide experimental evidence to suggest that even partial hearing loss can aggravate memory impairment in AD. In the future, this model can also be used to identify the onset of memory deficit and brain plasticity following the onset of hearing loss.

# Predictive Value of Odor Identification for Incident Dementia: The Shanghai Aging Study

Ding Ding<sup>1,2</sup>, Zhenxu Xiao<sup>1,2</sup>, Xiaoni Liang<sup>1,2</sup>, Wanqing Wu<sup>1,2</sup>, Qianhua Zhao<sup>1,2</sup> and Yang Cao<sup>3\*</sup>

<sup>1</sup> Institute of Neurology, Huashan Hospital, Fudan University, Shanghai, China, <sup>2</sup> National Clinical Research Center for Aging and Medicine, Huashan Hospital, Fudan University, Shanghai, China, <sup>3</sup> Clinical Epidemiology and Biostatistics, School of Medical Sciences, Örebro University, Örebro, Sweden

**Objective:** This study aimed to evaluate the value of odors in the olfactory identification (OI) test and other known risk factors for predicting incident dementia in the prospective Shanghai Aging Study.

**Methods:** At baseline, OI was assessed using the Sniffin' Sticks Screening Test 12, which contains 12 different odors. Cognition assessment and consensus diagnosis were conducted at both baseline and follow-up to identify incident dementia. Four different multivariable logistic regression (MLR) models were used for predicting incident dementia. In the no-odor model, only demographics, lifestyle, and medical history variables were included. In the single-odor model, we further added one single odor to the first model. In the full model, all 12 odors were included. In the stepwise model, the variables were selected using a bidirectional stepwise selection method. The predictive abilities of these models were evaluated by the area under the receiver operating characteristic curve (AUC). The permutation importance method was used to evaluate the relative importance of different odors and other known risk factors.

**Results:** Seventy-five (8%) incident dementia cases were diagnosed during 4.9 years of follow-up among 947 participants. The full and the stepwise MLR model (AUC = 0.916 and 0.914, respectively) have better predictive abilities compared with those of the no- or single-odor models. The five most important variables are Mini-Mental State Examination (MMSE) score, age, peppermint detection, coronary artery disease, and height in the full model, and MMSE, age, peppermint detection, stroke, and education in the stepwise model. The combination of only the top five variables in the stepwise model (AUC = 0.901 and sensitivity = 0.880) has as good a predictive ability as other models.

**Conclusion:** The ability to smell peppermint might be one of the useful indicators for predicting dementia. Combining peppermint detection with MMSE, age, education, and history of stroke may have sensitive and robust predictive value for dementia in older adults.

**Keywords:** olfactory, odor, dementia, prediction, logistic model, permutation importance method

## INTRODUCTION

Olfactory dysfunction is a common feature of neurodegenerative diseases, especially in dementia (e.g., Alzheimer's disease, dementia with Lewy bodies, and Parkinson's disease dementia), and is considered to be a premotor sign of neurodegeneration (Attems et al., 2014). Previous hospital- and population-based studies have demonstrated the association of olfactory dysfunction with dementia, cognitive decline, or mild cognitive impairment (MCI). Some human studies show a relationship between peppermint aroma stimulation and enhanced memory and functional performance in older people with dementia (Herz, 1997; Collier, 2007; Moss et al., 2008). Furthermore, peppermint's preservation of central nervous system microglia as a mediator of improved cognitive function has also been reported by an experimental *in vivo* study (Koo et al., 2001). At the baseline of our Shanghai Aging Study, we found a lower score on the olfactory identification (OI) test and a reduced ability to identify odors of peppermint, orange, pineapple, cinnamon, coffee, fish, banana, rose, leather, and licorice in participants with MCI compared to those with normal cognition (Liang et al., 2016). We further verified these findings in the 5-year prospective phase and explored the association of inability to smell peppermint with a higher dementia onset risk (HR = 2.67, 95% CI: 1.44, 4.96) by using a multivariable logistic regression (MLR) model (Liang et al., 2020). However, the previous study also did not evaluate the performance (or predictive value) of peppermint in predicting incident dementia.

Variable selection is one of the core concepts in statistical learning, and it impacts the performance of predictive models significantly. Irrelevant or partially relevant variables may reduce the predictive ability of the models. There are many variable-selection methods available in data science, such as recursive feature elimination, principle component analysis, correlation matrix with heat map, feature importance, and some wrapper methods (Hua et al., 2009; Liu and Motoda, 2012). Variable importance is straightforward and can be easily explained to an audience outside of the fields of data science and informatics. In the current study, the permutation importance (PI) method, which permutes the values of a feature of interest and reevaluates the predictive ability of the models (Altmann et al., 2010), was used to evaluate the importance of the OI test, certain odors, and other known risk factors for predicting incident dementia in the prospective Shanghai Aging Study.

## MATERIALS AND METHODS

### Study Setting and Participants

The Shanghai Aging Study is a prospective cohort study aiming to enumerate the prevalence, incidence, and risk factors for dementia and MCI among residents aged  $\geq 60$  in an urban community of central Shanghai. The study design and participant recruitment of SAS are described in detail elsewhere (Ding et al., 2014; Liang et al., 2016; Liang et al., 2020). A flowchart of recruitment for study

participants is shown in **Supplementary Figure S1**. In total, 1,782 recruited participants without dementia completed both cognitive assessment and the OI test at baseline (2010–2011). The participants were contacted between April 1, 2014 and December 31, 2016, to investigate the first wave of dementia incidence. After excluding participants who were lost to follow-up, deceased, or had missing values in the analysis variables, 947 participants were included in the current study. After an average of 4.9 years of follow-up, 75 (7.0%) of the 947 included participants were diagnosed with new-onset dementia with an incidence rate of 16 [95% confidence interval (CI): 13–20] per 1,000 person-years. Participants with incident dementia were older (mean age:  $77.8 \pm 5.6$ ) than participants without incident dementia (mean age:  $69.9 \pm 6.5$ ,  $p < 0.001$ ) at the baseline.

### Collection of Baseline Data

**Demographics and lifestyle:** Demographic and lifestyle characteristics, including age, sex, years of formal education, cigarette smoking, and alcohol consumption, were collected via an interviewer-administered questionnaire (Shu et al., 2004).

**Physical measurements:** Each participant's height and weight at baseline were measured by a research nurse. BMI was calculated as weight in kilograms divided by height in meters squared.

**Medical history:** Participants' medical histories, including physician-diagnosed hypertension, coronary artery disease (CAD), diabetes, and stroke were asked by neurologists from the Department of Neurology, Huashan Hospital (Liang et al., 2020).

**Apolipoprotein (APOE) genotype:** DNA was extracted from blood or saliva samples at baseline. APOE genotyping was conducted by the Taqman SNP method (Smirnov et al., 2009). The presence of at least one  $\epsilon 4$  allele was defined as APOE- $\epsilon 4$  allele positive.

**OI test:** OI at baseline was assessed using the Sniffin' Sticks Screening Test 12 (SSST-12), which consists of 12 odors (orange, leather, cinnamon, peppermint, banana, lemon, licorice, coffee, cloves, pineapple, rose, and fish) presenting on felt-tip sticks (Wolfensberger, 2000). The SSST-12 kit was purchased from Burghart Medical Technology, Hamburg, Germany (Tinsdaler Weg 175, 2020). OI was defined as an individual correctly naming an odor or odors, either with or without the help of alternative choices. The administration of SSST-12 is described in detail elsewhere (Liang et al., 2016).

**Cognition assessment and consensus diagnosis:** The cognitive function of the participants was assessed using a battery of neuropsychological tests, including the Mini Mental State Examination (MMSE) (Tombaugh and McIntyre, 1992), Conflicting Instructions Task (go/no-go task), Stick Test, Modified Common Objects Sorting Test, Auditory Verbal Learning Test, Modified Fuld Object Memory Evaluation, Trail-Making Test A & B, and Renminbi (Chinese Currency) Test. The normative data and detailed description of the assessment battery are reported elsewhere (Zhang et al., 1990; Ding et al., 2015). Each participant's mood was evaluated using the Zung Self-Rating Anxiety Scale and the Center for Epidemiologic Studies Depression Scale (CESD), and

depression was present if a CESD score  $\geq 16$  (Zung, 1971; Eaton et al., 2004).

Two study neurologists, one neuropsychologist, and one neuroepidemiologist reviewed the functional, medical, neurological, psychiatric, and neuropsychological data of the participants and reached a consensus regarding the presence of dementia using the Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV) criteria (American Psychiatric Association, 1994).

## Prospective Follow-Up

Between April 2014 and December 2016, participants who were diagnosed as dementia-free were invited for a clinical interview as the first wave of follow-up to detect incident dementia cases. Each participant was administered the same neuropsychological battery for the cognition assessment. Procedure and criteria of the consensus diagnosis were identical with that at baseline.

## Statistical Analysis

### Descriptive Analysis

Participants' demographics, lifestyle, medical history, and OI test results are presented using mean with standard deviation (SD) or median with interquartile range (IQR) for the continuous variable and using a percentage for the categorical variables. Difference between groups was tested using the chi-squared test for categorical variables and analysis of variance (ANOVA) or Mann-Whitney *U* test for continuous variables. Correlation was measured using the Pearson correlation coefficient between two continuous variables and using the point-biserial correlation coefficient between a binary and a continuous variable (Demirtas and Hedeker, 2016) and the phi coefficient between two binary variables (Chen and Popovich, 2002). Multicollinearity between the variables is presented using a heat map. A two-sided *P*-value  $< 0.05$  is considered statistically significant.

### Determination of Variable Importance

**Prediction:** In the current study, prediction for dementia incidence was conducted using MLR analysis. Four types of MLR models were constructed in the study. In the first or no-odor model, we only included demographics, lifestyle, and medical history variables (i.e., sex, age, BMI, height, education, smoking, drinking, CAD, hypertension, diabetes, depression, stroke, APOE- $\epsilon 4$ , and MMSE) but not any odor. In the second type or single-odor model, we added only one single odor or OI sum score to the first model. In the third or full model, all 12 odors were included. Weight was excluded in the first three types of models, and OI sum score was excluded in the first and third models because of high collinearity with other variables. In the fourth model, the variables were selected using a bidirectional stepwise selection method (Zhang, 2016).

**Validation:** The K-fold cross-validation method was used during the MLR model learning and validation, which is a standard way to obtain unbiased estimates of a model's goodness of fit and to handle the overfitting problem in statistical learning. In brief, we randomly split the data set into five equal partitions and constructed an MLR model on four partitions

while validating it on the remaining partition. In each iteration, the prediction was made for the one held-out partition. In the end, we got the prediction for the whole data set and used it for validation (James et al., 2013).

**Evaluation:** The metrics, including sensitivity, specificity, accuracy, and area under the receiver operating characteristic (ROC) curve, were used to evaluate the models' predictive ability. Terminology and derivations of the metrics are given in detail elsewhere (Cao et al., 2019). The acceptable, good, and great prediction models for incident dementia are defined as the area under the ROC curve (AUC) of a model greater than 0.7, 0.8, and 0.9, respectively (Marzban, 2004; Mandrekar, 2010).

**Variable standardization:** Because scalability is an important aspect of statistical learning and matters for the models' performance, variable standardization is preferred before training the models (Lantz, 2013). Because the aim of the current study was to evaluate the predictive ability of the models rather than to interpret the associations between the predictors and the outcome, therefore, all features were treated as continuous or discrete numerical variables and were scaled using the standard scaler to have a mean of 0 and a SD of 1 (Zheng and Casari, 2018).

**PI:** For the MLR models, PI was calculated for each variable, which is measured by looking at how much the accuracy decreases when the information on the variable is not available (Altmann et al., 2010). To mask the information on a variable during validation, instead of removing the variable from the data set, the PI method replaces it with random noise by shuffling the values of the variable, i.e., using values from other participants (Breiman, 2001; Fisher et al., 2019). The relative importance of a variable was calculated as the accuracy decrease of the variable relative to the range of the accuracy decreases of all the variables (Gómez-Ramírez et al., 2019).

### Software and Hardware

The descriptive analyses were performed using Stata 16.0 (StataCorp LLC, College Station, TX, United States). The MLR models and PI evaluation were achieved in Python 3.6 (Python Software Foundation<sup>1</sup>) using packages scikit-learn 0.22.1 (Pedregosa et al., 2011) and ELI5 0.10.1 (Korobov and Lopuhin, 2020). All computation was conducted on a computer with a 64-bit Windows 7 Enterprise operating system (Service Pack 1), Intel® Core TM i5-4210U CPU of 2.40 GHz, and 16.0 GB installed random access memory.

## Ethical Consideration and Data Availability

The study is an observational study and was approved by the Medical Ethical Committee of Huashan Hospital, Fudan University, Shanghai, China (approval number: 2009-195). All participants and/or their legal guardian gave their written informed consent for participation in the study. There is no personal identification disclosed in our data. The data are not publicly available but may be available upon reasonable request and with permission of the Ding Ding (dingding@huashan.org.cn).

## RESULTS

### Characteristics of the Participants

Detailed baseline information on the participants is published elsewhere and given in **Supplementary Table S1** (Liang et al., 2020). In general, compared to those who did develop dementia ( $n = 872$ ), participants with incident dementia ( $n = 75$ ) were older (77.8 vs 69.9 years), shorter (156.5 vs 162.0 cm), weighed less (59.1 vs 64.4 kg), and had less education (9 vs 12 years) when recruited. CAD, stroke, and APOE- $\epsilon 4$  positive were more frequently observed in the new-onset dementia cases (**Supplementary Table S1**). The new-onset dementia cases had a lower correct identification rate for most odors and lower OI sum and MMSE scores at the baseline (**Supplementary Table S1**). There was no significant multicollinearity observed between the variables except for the high correlation between height and weight, weight and BMI, and OI sum score and the 12 odors (**Figure 1**).

### Predictive Ability of the Models

The regression coefficients of the full and stepwise models are shown in **Tables 1** and **2**. In the full model, age, APOE- $\epsilon 4$ , peppermint, pineapple, banana, and MMSE are statistically significantly (at the two-sided type one error  $\alpha = 0.05$  level) associated with dementia incidence. However, in the analysis, wrong identification of pineapple is associated with a lower probability of dementia incidence (**Table 1**).

In the stepwise model, age, weight, education, APOE- $\epsilon 4$ , peppermint, banana, pineapple, and MMSE are associated with dementia incidence. Similarly, wrong identification of pineapple is associated with lower probability of dementia incidence (**Table 2**). The predictive abilities of the four types of models are shown in **Table 3**. There is no significant difference in predictive abilities between the no-odor and the single-odor models; both types of models show great ability for predicting dementia incident (AUCs ranging between 0.901 and 0.906). However, the model including licorice shows higher

Cinnamon	-0.182	0.179	0.308
Peppermint	-0.371	0.118	0.002
Banana	-0.341	0.153	0.026
Lemon	0.202	0.168	0.229
Licorice	0.054	0.160	0.737
Coffee	-0.027	0.127	0.828
Cloves	-0.013	0.161	0.934
Pineapple	0.408	0.176	0.020
Rose	-0.244	0.158	0.124
Fish	0.159	0.148	0.280
MMSE	-0.719	0.138	0.000

SE, standard error; BMI, body mass index; CAD, coronary artery disease; OI, olfactory identification sum score; APOE, apolipoprotein; MMSE, Mini-Mental State Examination. Weight and olfactory identification sum score were excluded from the model because of collinearity.  $\beta$  corresponds to the change of women versus men for sex; per year for age and education; per unit for BMI, height, and MMSE; with the feature versus without the feature for smoking, drinking, and comorbidities; and positive versus negative for APOE- $\epsilon$ 4 and individual odor tests.

accuracy (= 0.818), and the model including banana, lemon, or cloves shows higher sensitivity (= 0.920, **Table 3**). The predictive abilities of the full and stepwise models are similar (AUC = 0.916 and 0.914, respectively) (**Figure 2**) and better (although not significant) than those of the no- or single-odor models (**Table 3**).

### Relative PI of the Variables

The relative importance of the variables was evaluated in the full and stepwise models because they showed the best performance for prediction. In the full model, the five most important variables are MMSE, age, peppermint, CAD, and height (**Figure 3**). In the stepwise model, the five most important are MMSE, age, peppermint, stroke, and education. Both results indicate that identification of peppermint odor might be an important indicator for dementia only after MMSE and age. In addition, banana also shows relative higher importance in both models (**Figure 3**). There are also variables with negative importance, which means that, when they were excluded from the model, the accuracy of the prediction increased.

**TABLE 2 |** Multivariable logistic regression coefficients of the stepwise model.

Variable	$\beta$	SE	P-value
Age	1.057	0.186	0.000
Weight	-0.360	0.171	0.036
Education	-0.308	0.132	0.020
Depression	0.248	0.133	0.061
Stroke	0.209	0.121	0.086
APOE $\epsilon$ 4	0.311	0.137	0.023
Leather	-0.255	0.157	0.104
Peppermint	-0.331	0.111	0.003
Banana	-0.310	0.148	0.036
Lemon	0.261	0.158	0.098
Pineapple	0.406	0.166	0.014
Rose	-0.241	0.149	0.107
MMSE	-0.693	0.133	0.000

SE, standard error; APOE, apolipoprotein; MMSE, Mini-Mental State Examination.  $\beta$  corresponds to the change per year for age and education, per unit for weight and MMSE, with versus without depression or stroke, and positive versus negative for APOE- $\epsilon$ 4 and individual odor tests.

When using a simple model that only includes the five most important variables in the stepwise model, we achieved a predictive ability (AUC = 0.901 and sensitivity = 0.880) as great as those of the aforementioned models that include many more variables (**Table 3**).

## DISCUSSION

Although there is a study using random forest and permutation-based methods to select important variables for predicting conversion to MCI (Gómez-Ramírez et al., 2019), to the best of our knowledge, this is the first study investigating the predictive rather than associative value of the odors in the OI test for incident dementia in the elderly. There are several strengths in our study. First, the permuting destroys the interaction effects between variables, which means that it automatically takes into account both the main effect of a variable and the interaction effects with other variables on model performance (Fisher et al., 2019). Second, our data suggest that, not only is MMSE generally applicable to predict dementia in our geriatric population, but the addition of the ability to smell peppermint further improves the precision and accuracy of the model. This has tangible clinical benefits in both informing clinical decision making and translating statistical probability into coherent information for the elderly and their families. Thus, a consensus plan (either medical treatment or preventive intervention) may be more readily reached. Third, cross-validation was used when we evaluated the performance of the models, which minimized overfitting. Finally, different MLR models were constructed and compared, and they presented similar results, which ensure that our conclusion is conservative and robust.

### OI Test and Dementia Prediction

Previous studies reveal that both olfactory and certain cognitive functions are controlled via the orbitofrontal cortex, and reduced

**TABLE 3 |** Performance matrix of the prediction models.

	Sensitivity	Specificity	Accuracy	AUC	95% CI of AUC

<sup>a</sup>Predictors: sex, age, body mass index (BMI), height, education, smoking, drinking, coronary artery disease (CAD), hypertension, diabetes, depression, stroke, apolipoprotein (APOE)- $\epsilon$ 4, and Mini-mental State Examination (MMSE). <sup>b</sup>Other predictors are the same as in the no-odor model. <sup>c</sup>Predictors: sex, age, BMI, height, education, smoking, drinking, CAD, hypertension, diabetes, depression, stroke, APOE- $\epsilon$ 4, MMSE, and the 12 odors. <sup>d</sup>Predictors: age, weight, education, depression, stroke, APOE- $\epsilon$ 4, leather, peppermint, banana, lemon, pineapple, rose, and MMSE. <sup>e</sup>Predictors: MMSE, age, peppermint, stroke, and education.

olfactory ability and manifestation of dementia are associated with brain changes in the hippocampus and entorhinal cortex (Rupp et al., 2006; Maurage et al., 2011; Seligman et al., 2013; Marigliano et al., 2014; Growdon et al., 2015). Olfactory

dysfunction is associated with pathological features of cognitive impairment (Passali et al., 2015; Reijs et al., 2017). Some studies suggest that olfactory dysfunction could be a suitable biomarker for predicting cognitive impairment and development

of dementia (Suzuki et al., 2004; Eibenstein et al., 2005; Devanand et al., 2015; Ottaviano et al., 2016; Roberts et al., 2016; Roalf et al., 2017). Our previous study also indicates that some odors, such as peppermint in the OI test, are associated with incident dementia in the older population (Liang et al., 2020). However, the predictive ability of the models incorporating the OI test was not ideal in previous studies. A large sample size ( $N = 2227$ ) prospective study of middle-aged to older adults (55–86 years) concludes that olfactory function may serve as a marker for screening persons at high risk for cognitive decline and dementia. However, the AUC values in the study are only between 0.55 and 0.62 for the five cognitive tests (Tebrugge et al., 2018). In another prospective study of 757 participant aged 65 years and older, the University of Pennsylvania Smell Identification Test combined with the Selective Reminding Test–total immediate recall shows an improved performance for predicting dementia incidence; however, the AUC is still only 0.77 (Devanand et al., 2015). Although Stanciu et al. (2014) concludes that OI could independently predict conversion to dementia within a 10-year time span, the accuracy of the prediction is not evaluated in that study.

The SSST-12 test comprises 12 common and familiar odorants recognized by a majority of the population (Oleszkiewicz et al., 2019). The number of odors for selection could be as many as 37 in comprehensive olfactory tests (MediSense, 2020); however, it remains uncertain how many items are sufficient for a valid diagnosis or screening (Lotsch et al., 2016). Several studies attempt to reduce the number of odor identification items to 1–5 odors (Doty et al., 1996; Simmen et al., 1999; Hummel et al., 2001; Gilbert et al., 2002; Jackman and Doty, 2005; Mueller and Renner, 2006), and a recent study recommends a three-odor test with cinnamon as the best scoring odor (Lotsch et al., 2016). Although

an inability to identify certain odors has previously been used as a predictor for incident dementia (Adams et al., 2018; Liang et al., 2020), the relative importance of the odors compared to each other or compared to other predictors has not been investigated.

## Peppermint and Dementia

The current study further confirms previous findings that the ability to smell peppermint may play an important role in predicting dementia incidence in the elderly (Adams et al., 2018; Liang et al., 2020). It also reveals that peppermint is the third most important variable in the prediction models, only after MMSE and age. Using a simplified prediction model including MMSE, age, peppermint, stroke, and education, the specificity of the prediction can be as high as 0.88 with an AUC of 0.90.

The relationship between detection of peppermint and dementia has been investigated previously. A human study of peppermint's modulation on long-term potentiation shows a direct correlation between peppermint oils and enhanced memory (Moss et al., 2008). In recall tests of extended memory, improved cognitive function arises in response to exposure to peppermint aroma during both learning and memory retrieval tasks (Herz, 1997). In a randomized single blind trial, researchers used multisensory stimulation, including aromatic cloves or peppermint, to improve functional performance in older people with dementia, and they find a significant effect of the intervention on function, mood, and behavior in people with a diagnosis of moderate/severe dementia (Collier, 2007). However, Fox et al. (2012) study suggests that consumption of peppermint does not mediate alertness or enhance cognitive performance. Although the underlying mechanism of the effects of peppermint on neurological functions is not clear yet, an experimental study shows that *in vivo* exposure of

glial cells to peppermint oil might inhibit heat shock-induced apoptosis of astrocytes in rat and human cell models, suggesting peppermint's preservation of central nervous system microglia as a mediator of improved cognitive function (Koo et al., 2001). Further research investigating compound metabolism is required to optimize quantification of memory performance following peppermint ingestion.

## MLR and PI

There are other statistical learning methods for prediction, such as discriminant analysis, decision tree, K-nearest neighbor, support vector machine, and multilayer perceptron (James et al., 2013). The reasons for using MLR in the current study are that (a) logistic regression is the most widely used method in diagnostic tests and prediction studies for binary outcomes in medical science. The results from a logistic regression analysis can be easily comprehended by clinical researchers (Coughlin et al., 1992; Greiner et al., 2000; Janssens et al., 2005). (b) Coefficients from the logistic regression models can be translated into odds ratios, which are widely used in medical and epidemiology studies (Hilbe, 2009).

Compared to Gini importance, which is model-agnostic and embedded in tree-based statistical learning algorithms, such as random forest (Nembrini et al., 2018), the concept of PI is straightforward. PI measures the importance of a variable by calculating the decrease in the model's prediction accuracy after permuting the variable. A variable is "important" if shuffling its values decreases the accuracy because, in this case, the model relies on the variable for the prediction (Breiman, 2001). Although permuting irrelevant or partially relevant variables may increase the predictive ability of the models, it may result in a negative importance, just as we observe in **Figure 3**. The method is generalizable no matter the predictive model and most suitable for computing variable importance when the number of variables is not large; otherwise, it can be resource-intensive (Altmann et al., 2010; Fisher et al., 2019).

Because using a limited number of variables may have already achieved great prediction for dementia incidence (such as the simple model in **Table 3**), one single variable contributes little to the improvement accuracy of the prediction in a multivariable model; therefore, we only compare relative importance of the variables in this study. It is useful when we want to find common important variables using different statistical learning methods. In our study, all five of the most important variables (MMSE, age, peppermint, stroke, and education) found in the stepwise MLR model are consistent with the statistically significant risk factors derived from previous studies (Snowdon and Nun, 2003; Cullen et al., 2005; Ngandu et al., 2007; Mijajlovic et al., 2017; Liang et al., 2020). The combination gives us real, predictive values that may be useful in clinical practice.

## Limitations

There are also several limitations in the study. First, the sample size is relatively small, and only 75 participants were diagnosed with new-onset dementia after an average of 4.9 years of follow-up. Essentially, the performance of statistical learning

methods relies on the amount of data available. The more observations and variables, the better the models perform. Although we obtain satisfactory accuracy from the models, the generalizability of the findings is limited by the small sample size. Second, nominal variables are treated as discrete numerical features in this study. Although it increases the accuracy of prediction, the interpretability of the models is reduced. Third, about half of the participants who were lost to follow-up were excluded from our analysis data set. We do not know the incidence of dementia among the excluded participants and whether being lost to follow-up was associated with certain cognitive impairments. Although there is no statistically or clinically significant difference between the included and excluded participants in terms of demographic and lifestyle characteristics, the validity of the models is limited by the incompleteness and needs to be examined using data with better representativeness.

## CONCLUSION

The ability to smell certain odors, especially peppermint, might be one of the useful indicators for predicting dementia in the elderly. Incorporating peppermint with MMSE, age, education, and history of stroke, we may predict long-term dementia onset in older adults precisely. Aromatherapy using essential oils, including peppermint, to prevent and/or control symptoms of dementia deserves further investigation.

Lin M-S (2020) CISD2 Attenuates Inflammation and Regulates Microglia Polarization in EOC Microglial Cells—As a Potential Therapeutic Target for Neurodegenerative Dementia. *Front. Aging Neurosci.* 12:260. doi: 10.3389/fnagi.2020.00260

**Background:** Accumulating evidence has demonstrated a significant association between microglia-driven inflammation in the brain and neurodegenerative dementia. We previously showed a significant decline in CISD2 expression in mice models with advanced age. Moreover, we observed that the knockdown of CISD2 led to remarkable inflammation and mitochondrial dysfunction in neural cells. In the present study, we investigated whether CISD2 attenuation influences anti-inflammatory effects and M1-M2 polarization in microglia.

**Materials and Methods:** The knockdown of CISD2 expression by siRNA (siCISD2) in EOC microglial cells was performed to mimic the age-driven decline of CISD2 expression. The extent of the inflammatory reaction, polarization in the M1/M2 spectrum, and NFκB activation were verified in EOC microglial cells exhibiting CISD2 deficiency.

**Results:** In the cellular model of microglia, loss of CISD2 function mediated by siCISD2 exhibited a significant augmentation of proinflammatory signaling, as well as reduced expression levels of Arg-1, Ym1, IL-10, and BCL2. Attenuation of CISD2 expression led to a decrease in the proportion of the M2 phenotype of microglia (compared to M1). Enhanced DNA-binding activity of the NFκB p65 subunit was confirmed in cells transfected with siCISD2, as demonstrated by enzyme-linked immunosorbent assay (ELISA).

**Conclusions:** To the best of our knowledge, this is the first report examining the following phenomena: (1) anti-inflammatory effects of CISD2 in microglia *via* NFκB regulation; and (2) microglial CISD2 assistance in the restoration of M2 microglia phenotype. The anti-inflammatory effects of CISD2 in microglia eventually augment anti-apoptotic effects, which provides a rationale for the development of potential therapeutic target for neurodegenerative diseases and neurodegenerative dementia.

**Keywords:** CISD2, M1/M2 microglia polarization, anti-inflammatory effects, aging, neurodegenerative disease and dementia

## INTRODUCTION

Dementia is a chronic disease leading to disability and dependency among the elderly worldwide. For clinical classification, dementia can be divided into the following major categories: Alzheimer's disease (AD), vascular dementia (VaD), dementia with Lewy bodies (DLB), frontotemporal dementia (FTD), and mixed dementia (Raz et al., 2016). Due to the complexities of neurodegenerative dementia, precise diagnosis remains a challenge in daily clinical practice. Eventually, patients with dementia will present a catastrophic situation for the entire community and society, leading to highly expensive long-term medical care. Moreover, evidence indicates that sustained brain inflammation due to excessive microglial activation contributes to cerebral aging (Hickman et al., 2018; Sanada et al., 2018), neurodegenerative disease (Maragakis and Rothstein, 2006; Hickman et al., 2018), and neurodegenerative dementia (Meraz-Ríos et al., 2013; Bhaskar et al., 2014).

Microglia stabilize and balance the central nervous system (CNS) by mediating immune responses and providing neurotrophic support for neurons (Wake et al., 2011). Embryologically, microglia are derived from the same origin as peripheral macrophages (myeloid progenitors), whereas other resident CNS cells (e.g., astrocytes, oligodendrocytes, and neurons) are derived from neuroepithelial precursors (Zhang et al., 2018). Microglia can be regarded as a specialized macrophage in the CNS owing to the aforementioned close association. Microglia exert biphasic effects that either benefit the neuron survival (M2 phase) or undermine it (M1 phase) under microenvironmental changes. As such, it is representative of the spectrum of M1 (proinflammation)/M2 (anti-inflammation) phenotypes (Song and Suk, 2017; Zhang et al., 2017). In the microenvironment of the CNS, M2 microglia function to maintain CNS homeostasis and neural protection by moving dynamically throughout the entire CNS parenchyma and performing phagocytosis when they encounter pathological changes initiated by pathogens, plaques, protein aggregates, and infectious agents (Thomas et al., 2015). However, under the circumstances of neurodegeneration (non-stressed status) or CNS trauma (injury-challenged status), temporally inappropriate, prolonged, or excessive inflammation indicates the pathological activation of detrimental M1 microglial cells involving the release of cytokines and chemokines (Tator and Fehlings, 1991; Luo et al., 2002). Aberrantly stimulated microglia produce nitric oxide (NO) in conjunction with reactive oxygen species (ROS), which can amplify the inflammatory cascade. In a deleterious pathological cycle, cytokines promote inflammation by inducing the production of additional cytokines, chemokines, NO, and ROS (Li et al., 2006). Sustained microglia-driven inflammation can eventually lead to apoptosis and the killing of oligodendrocytes and neurons, which can impair neuronal functioning and lead to permanent neurological damage (Wood, 1995; Mattson, 2000; Byrnes et al., 2007). Any novel strategies involving the attenuation of microglial inflammatory response could be beneficial in the management of neurodegenerative disease and dementia.

C1SD2 (CDGSH iron-sulfur domain 2) has garnered interest for its protective role against calcium excitotoxicity (Shen et al., 2017), apoptosis (Chen et al., 2009), and inflammation (Lin et al., 2015). C1SD2 has been referred to as a longevity gene, aiding in the preservation of mitochondrial integrity, thereby preventing mitochondrial malfunction and, ultimately, cell death. In response to stress, C1SD2 exerts protective effects against autophagy/apoptosis by enhancing BCL2-BECN1 interactions and by the formation of a complex with BCL2 (Chang et al., 2010). Moreover, C1SD2 attenuates the excitotoxic  $\text{Ca}^{2+}$  surge at the endoplasmic reticulum by binding to BCL2 and the inositol 1,4,5-triphosphate receptor (Chang et al., 2012). Furthermore, overexpression of C1SD2 has been demonstrated to attenuate neuronal loss and  $\beta$ -amyloid-induced mitochondrial dysfunction in the AD mouse model (Chen et al., 2020). Thus, C1SD2 holds promise as a potential therapeutic target for neurodegenerative dementia.

In a previous study, we identified a potential role of C1SD2 in exhibiting the anti-inflammatory effects. In a C1SD2 knockdown model developed with siC1SD2, we observed that C1SD2 deficiency led to a significant increase in iNOS production and a reduction in BCL2 levels in SH-SY5Y cells stimulated with lipopolysaccharide (LPS; Lin et al., 2015). No previous study has been reported on the anti-inflammatory effects of C1SD2 in microglia. In the current study, we sought to delineate the protective effect of C1SD2 in microglial inflammatory reactions associated with neurodegenerative dementia. It is a preliminary investigation into the anti-inflammatory effects of C1SD2 in the EOC microglial cell culture model with a specific aim of determining whether it plays a role in the alternation of microglial M1/M2 polarization.

## MATERIALS AND METHODS

### Cell Lines

Microglia cell lines (EOC 13.31, BCRC 60490) were obtained from the Bioresource Collection and Research Center (BCRC, Hsinchu, Taiwan). EOC 13.31 cell line derived from the brain of a 10-day old female mouse (*Mus musculus*) is dependent on the colony-stimulating factor-1 (CSF-1) for cell proliferation. EOC microglial cells were cultured in 70% Dulbecco's modified essential medium (DMEM), 10% fetal bovine serum (FBS), and 20% LDMAC conditioned medium derived from LADMAC cells (BCRC 60489, a bone marrow monocytic cell line derived from adult mouse, *M. musculus*). LDMAC conditioned medium containing CSF-1 secreted from LADMAC cells was collected from confluent cultures and filtered with 0.2-mm syringe filters before addition to EOC cell cultures.

### Reverse-Transcription Polymerase Chain Reaction and Real-Time Quantitative Reverse-Transcription Polymerase Chain Reaction

Total RNA was prepared by directly lysing the cultured cells in extraction buffer (Trizol/phenol/chloroform) and reverse

transcribing the mRNA into cDNA using oligo-dT and SuperScript II reverse transcriptase (Invitrogen, Carlsbad, CA, USA). The cDNA was subjected to polymerase chain reaction (PCR) for the measurement of mRNA levels of C1SD2, BCL2, and M2 microglia specific markers based on a previous report [Pei et al., 2017; IL-10, Arginase-1 (Arg-1), Chitinase-3-like-3 (Ym1)]; proinflammatory mediators including TNF- $\alpha$ , IL-1 $\beta$ , iNOS, and COX2 (representative of M1 microglia); and the housekeeping gene GAPDH (internal control). The PCR protocol involved 25 cycles of denaturation for 1 min at 94°C, annealing for 1 min at 55°C to 60°C, and extension for 1 min at 72°C. The primers used for PCR are listed in **Table 1**.

For real-time quantitative reverse-transcription (qRT)-PCR, the cDNA samples were analyzed with SYBR Green Gene Expression System (ABI PRISM 7300 HT real-time PCR system; Applied Biosystems, Foster City, CA, USA). Minor groove binding dyes and primers for the detection of the genes of interest and GAPDH were designed by ABI. We further determined the threshold cycle (Ct), and the Ct values of proposed genes were normalized using GAPDH as an internal control. The measurements were performed in triplicates.

## Immunoblotting

Total protein was extracted from cultured EOC microglial cells in a lysis buffer containing 20 mM Tris-HCl, 0.1% sodium dodecyl sulfate (SDS), 0.8% NaCl, and 1% Triton-X 100). Electrophoresis with 12% gradient gel was performed to separate the protein extracts. Proteins that underwent electrophoresis were electro-transferred to a nitrocellulose membrane prepared with blocking reagent and primary antibodies [anti-C1SD2 (1:500; Thermo Scientific, PA5-34545); anti-iNOS (1:2,000; Thermo Scientific, PA3-030A); anti-Arg-1 (1:5,000; Thermo Scientific, PA5-29645); anti-GAPDH (1:500; Millipore, Billerica, MA, USA)] at 4°C for 12 h before washing and incubation with goat-anti-rabbit IgG HRP (horseradish peroxidase)-conjugated secondary antibodies (Merck Millipore, Cat. #12-348) for 1 h. Chemiluminescence detection was performed following the

established protocols (Merck Millipore, WBKLS0500). Bands of interest were visualized and quantified using ImageQuant™ LAS 4000 (GE Healthcare Life Sciences, Marlborough, MA, USA).

## Short Interfering RNA-Mediated RNA Interference

Short interfering RNA (siRNA) specific to C1SD2 mRNA was used to attenuate the expression of C1SD2 in cultured microglia. This method was similar to that used in our previous research conducted on gene knockdown with minor modifications (Lin et al., 2011a,b, 2015, 2019). EOC microglial cells were transfected using a set of siRNAs specific to C1SD2 or scrambled RNA (Silencer® Pre-designed siRNA, Ambion, Austin, TX, USA) using Lipofectamine™ 2000 reagent (Invitrogen, Carlsbad, CA, USA). Briefly, EOC cells were randomly assigned to the experimental groups after being cultured for 5 days. Lipofectamine™ 2000 reagent and siRNA were individually mixed in serum-free medium for 10 min. Lipofectamine transfection reagent was mixed with dissolved siRNA in a serum-free medium for 10 min. Transfected cell mixtures containing 2  $\times$  10<sup>6</sup> cells were added to each plate.

Five hours after transfection, the medium containing Lipofectamine 2000 was replaced with a microglial culture medium and allowed to stand for an additional 7 h. Real-time qRT-PCR was performed for the detection of C1SD2 expression to verify the effectiveness of knockdown.

## Detection of NF $\kappa$ B p65 Activity

NF $\kappa$ B p65 activity was characterized using the NF $\kappa$ B p65 Transcription Factor Assay Kit (ab133112, Abcam, MA, USA) as per the manufacturer's instructions. Briefly, the extracted nuclear protein was collected for characterizing intracellular p65-NF $\kappa$ B activity by using a spectrophotometer reader to measure absorbance at an optical density (OD) of 450 nm. All measured values were derived with Synergy HT (BioTek, VT, USA).

## Statistical Analysis

The normality test of variables was used to determine whether to use parametric tests for variables with a normal distribution or nonparametric tests for variables with a non-normal distribution. The *p*-values of the normality test for variables of the experimental groups exceeded 0.05. Hence, parametric tests were used for mean comparisons among the experiment groups. Independent two-sample *t*-tests were subsequently used to compare the experiment groups. Statistical analysis was performed using GraphPad Prism software 5.0 (GraphPad Software, Inc., La Jolla, CA, USA).

## RESULTS

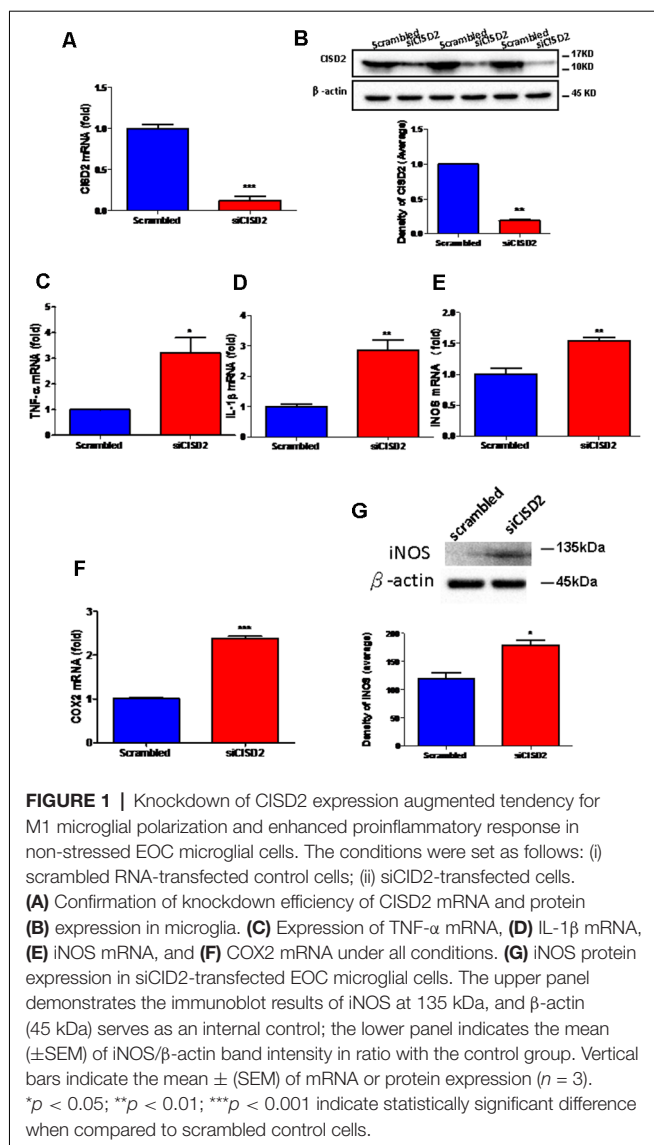

### Knockdown of C1SD2 Expression Augmented Inflammatory Signaling in EOC Microglial Cells and Enhanced M1 Microglia Polarization

High inflammation due to microglial activation has been demonstrated underlying the pathogenesis of various

neurodegenerative diseases in the CNS and neurodegenerative dementia (Thomas et al., 2015; Raz et al., 2016). In our previous study, we demonstrated that the attenuated C1SD2 expression is associated with the aging process and leads to the inflammatory response (Lin et al., 2015, 2019). Hence, we sought to determine whether C1SD2 deficiency in microglia results in the inflammatory cascade as well as the likelihood that these detrimental insults influence microglia polarization. The C1SD2 expression was attenuated in the microglial EOC cell lines *via* siC1SD2-mediated knockdown to delineate the inflammatory mechanism involving C1SD2 and evaluate the possibility of influencing polarization in the microglia M1/M2 spectrum.

The knockdown efficiency of C1SD2 siRNA in the EOC microglial cell line was confirmed by real-time qRT-PCR ( $p < 0.001$ , labeled as \*\*\*, **Figure 1A**) and western blot analysis ( $p < 0.01$ , labeled as \*\*, **Figure 1B**). Each experiment was performed in triplicate.

We observed that mRNA expression levels of proinflammatory mediators were higher in siC1SD2-transfected EOC microglial cells than those in scrambled RNA-transfected cells as determined by real-time qRT-PCR (TNF-α,  $p < 0.05$ , labeled as \*, **Figure 1C**; IL-1β,  $p < 0.01$ , labeled as \*\*, **Figure 1D**; iNOS,  $p < 0.01$ , labeled as \*\*, **Figure 1E**; and COX2,  $p < 0.001$ , labeled as \*\*\*, **Figure 1F**). As shown in **Figure 1G**, western blot analysis confirmed that C1SD2 deficiency significantly increased the protein production of iNOS (\* $p < 0.05$ ) in EOC microglial cells.

These results indicate a trend toward M1 microglia-associated inflammatory effects observed with C1SD2 attenuation. Thus, C1SD2 inactivity could be associated with the proinflammatory effects of M1 microglia underlying the pathological mechanism of neurodegenerative disease and dementia.

## C1SD2 Deficiency Reduced the Proportion of M2 Phenotype in EOC Microglial Cells

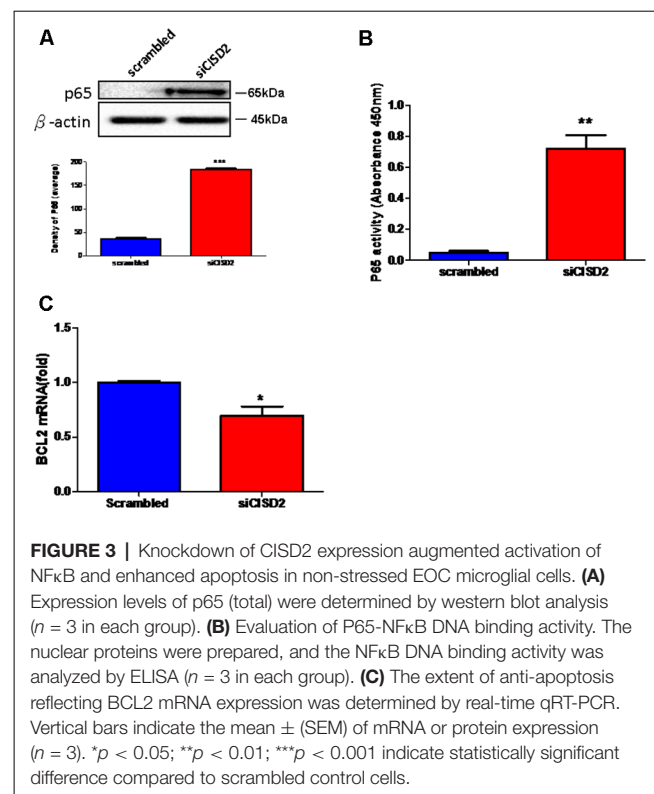

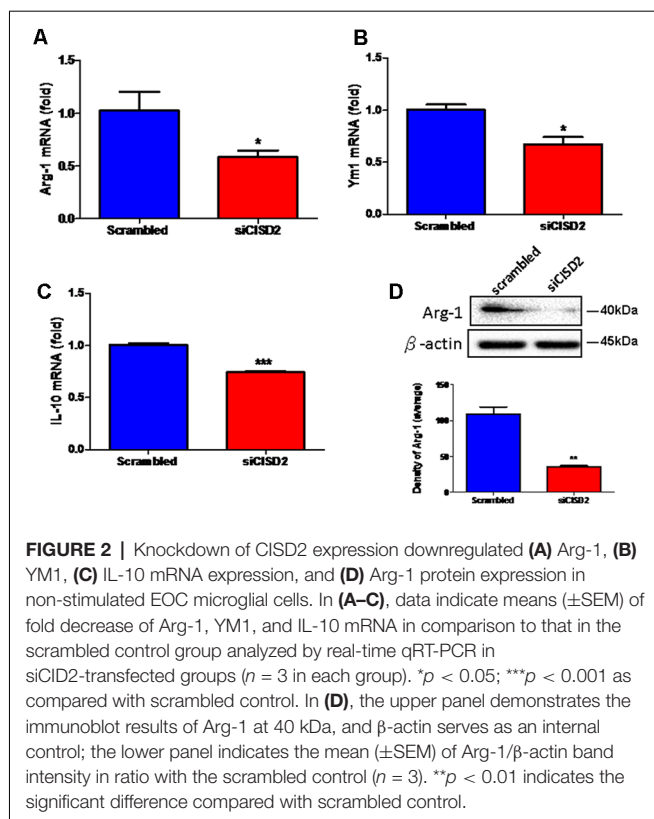

Under pathological conditions in the CNS, such as aging, and neurodegenerative disease, neuroprotective M2 microglia underwent excessive stimulation, switched to the detrimental M1 phenotype, and subsequently produced various proinflammatory mediators that might lead to irreversible neurological deficits. We observed that C1SD2 deficiency in EOC microglial cells led to a broad range of proinflammatory reactions. Next, we sought to determine whether C1SD2 attenuation halts protective M2 microglia polarization.

Real-time qRT-PCR analysis demonstrated that the mRNA expression of Arg-1, Ym1, and IL-10 was reduced in siC1SD2-transfected EOC microglial cells (Arg-1,  $p < 0.05$ , labeled as \*, **Figure 2A**; Ym1,  $p < 0.05$ , labeled as \*, **Figure 2B**; and IL-10,  $p < 0.001$ , labeled as \*\*\*, **Figure 2C**, respectively) compared to the cells subjected to scrambled RNA-transfection. Western blot analysis was used to examine Arg-1 protein expression in EOC microglial cells. Each experiment was performed in triplicates. The siC1SD2-transfected cells demonstrated a marked decrease in the protein expression of Arg-1 ( $p < 0.01$ , labeled as \*\*, **Figure 2D**) compared to that in the scrambled RNA-transfected cells.

These findings demonstrate that the knockdown of C1SD2 tends to reduce the relative proportion of M2 microglia. Thus, it can be concluded that C1SD2 deficiency impairs anti-inflammatory effects manifesting as either an enhancement of the detrimental effects associated with M1 or M2-associated protective effects under non-stressed conditions. These results illustrate the protective effects of microglial C1SD2 exhibiting anti-inflammatory functions and leading to the enhancement of M2 polarization.

## C1SD2 Deficiency Augmented Inflammatory Response *via* NFκB Activation and Promoted Cellular Apoptosis in EOC Microglial Cells

Finally, we wanted to confirm whether the proinflammatory response induced by C1SD2 attenuation involved NFκB signaling

in microglial cells. As shown in **Figure 3A**, western blot analysis demonstrated a significant elevation of the total expression of p65 protein in the siC1SD2-transfected group (\*\* $p < 0.001$ ), compared to that in the control group that was subjected to scrambled RNA-transfection. Enzyme-linked immunosorbent assay (ELISA) was used to verify the NFκB p65 subunit DNA-binding activity to evaluate the nuclear translocation of NFκB p65. It was observed that P65-NFκB DNA binding activity was significantly higher in siC1SD2-transfected EOC microglial cells (\*\* $p < 0.01$ , **Figure 3B**) than that in the scrambled RNA-transfected cells. Moreover, real-time qRT-PCR analysis demonstrated that the mRNA expression of BCL2 was significantly decreased in siC1SD2-transfected EOC microglial cells ( $p < 0.05$ , labeled as \*, **Figure 3C**), compared to that in scrambled RNA-transfected cells.

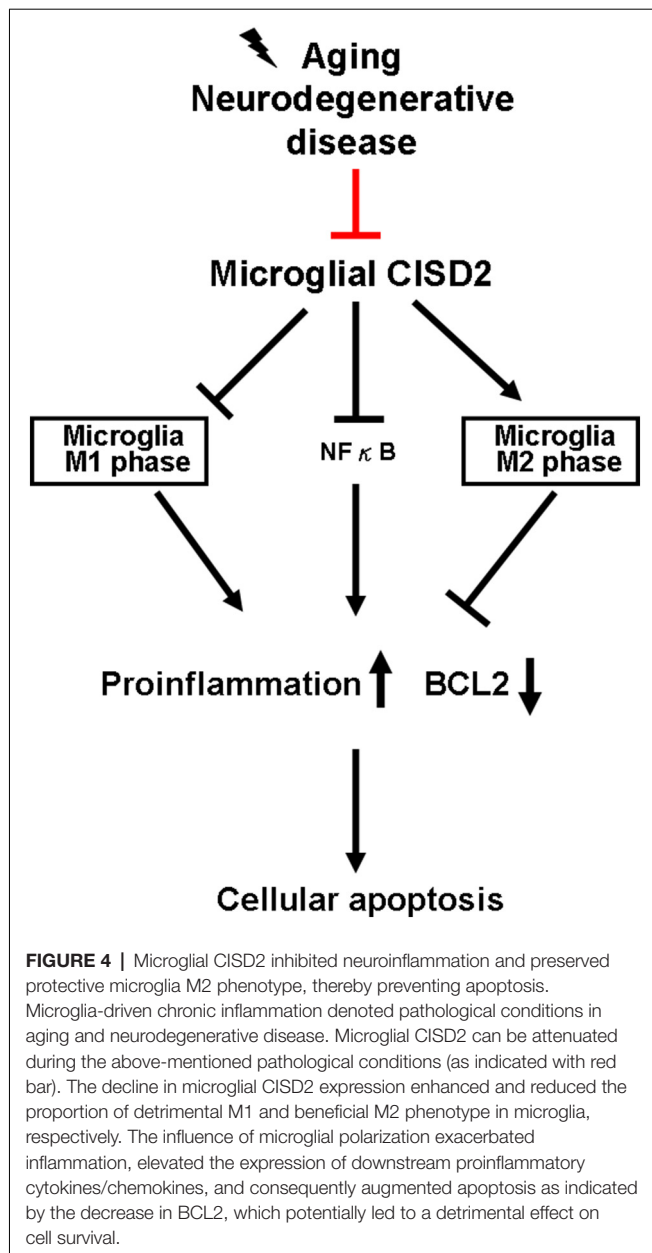

In conclusion, these results strongly indicate that microglial C1SD2 inhibits the inflammatory response *via* NFκB signaling and possibly by the preservation of M2 polarization in microglia. We postulate that BCL2-associated apoptosis initiated by age-driven C1SD2 decline in microglia, which potentially impairs cell survival, can likely be attributed to NFκB activation and neuroinflammation following the downregulation of microglial C1SD2.

## DISCUSSION

As many protective molecules in nature exhibiting biphasic effects (Lin et al., 2011a,b), microglia-mediated neuroinflammation has been described as a double-edged

sword (Hu et al., 2015). It demonstrates protective and restorative effects in the nonpathological and healthy CNS. However, it may also exacerbate and destroy under excessive inflammation under microenvironments of non-stressed (as a proxy for chronic inflammation driven by aging and neurodegenerative disease) and injury-challenged CNS (as a proxy for high-grade impact from neurotrauma). During the early stages of neural pathological conditions of the CNS (e.g., aging and neurodegenerative disease), protective M2 microglia tend to be dominant in the spectrum of proinflammatory/anti-inflammatory phenotypes. During low-grade inflammation, the activated M2 microglia scavenge fatal pathogens to confer neuronal protection. However, when the damage exceeds the range of homeostasis, a decline is observed in the proportion of activated M2 microglia. Accordingly, a delayed reactivation of detrimental M1 microglia can lead to a deleterious inflammatory cycle (Karve et al., 2016), which can be detrimental to neuronal survival and potentially cause CNS disease, such as dementia. **Figure 4** presents a schematic illustration showing the proposed sequence of events associated with the anti-inflammatory effects of C1SD2 in microglia, as determined in this study.

During the process of aging, the cerebral immune system remains relatively active resulting in the upregulation of inflammatory genes associated with the aging brain. Under such an immunocompetent response, cerebral microglia are primed to be activated and remain resistant to immune adaptive regulation (Norden and Godbout, 2013). This type of sustained microglial dysfunction can cause low-grade chronic neuroinflammation

in the brain and thereby exacerbate the cerebral aging process (Simen et al., 2011). Unlike normal aging, neurodegenerative diseases (due to genetic or environmental influences) can lead to misfolding and accumulation of native cerebral proteins, such as prion, tau,  $\beta$ -amyloid,  $\alpha$ -synuclein, and huntingtin. Conformational changes in these proteins are resistant to proteolysis resulting in the formation of so-called inclusion bodies in the brain (Jucker and Walker, 2011). When stimulated by toll-like receptors, the aggregation of such atypical proteins promotes the release of microglial-derived inflammatory mediators at high concentrations resulting in long-lasting inflammatory stimuli. Such effects are observed in AD, multiple sclerosis (MS), and Parkinson's disease (PD; Ross and Poirier, 2004). Thus, microglia-driven inflammatory cascades have

definitively been linked to aging, neurodegenerative diseases, and neurodegenerative dementia.

The precise function of C1SD2 has not been elucidated. Interestingly, C1SD2 expression is attenuated during non-stressed or injury-challenged conditions *in vivo* and *in vitro* (Lin et al., 2019). We observed a significant reduction in C1SD2 expression with age in the mouse brain and spinal cord (Lin et al., 2019). In mouse models, spinal cord injury has been demonstrated to attenuate the expression of C1SD2 (Lin et al., 2015). Moreover, we previously observed that C1SD2 deficiency exacerbated inflammatory responses and mitochondrial dysfunction in cultured cells (with or without injury). Specifically, C1SD2 expression was lower in non-stressed 35 DIV astrocytes than in 7 DIV cells, and the expression of iNOS along with RANTES (regulated on activation, normal T cell expressed and secreted) was higher (Lin et al., 2019). In LPS-stimulated C1SD2 knockdown SH-SY5Y cells, the deficiency of C1SD2 led to elevated iNOS levels and significant mitochondrial dysfunction (Lin et al., 2015, 2019). Resident immune cells (i.e., microglia) would be the apparent focus while investigating inflammatory cascades in the CNS.

Priming and activation in microglia can promote the proinflammatory signaling associated with aging, neurodegenerative disease, and traumatic CNS injury (Norden et al., 2015). Data obtained in this study demonstrated that C1SD2 deficiency (induced by the knockdown of C1SD2 expression) augmented the detrimental effects associated with the M1 phase and led to neuroinflammation and apoptosis in non-stimulated EOC microglial cells. Hence, we postulate that C1SD2 exerts anti-inflammatory effects in microglia under non-stressed microenvironments (as a proxy for microglial inflammation driven by aging and neurodegenerative dementia). The attenuation of microglia-mediated inflammatory cascades can be beneficial under such pathological conditions. The beneficial effect of the dementia-C1SD2-microglial anti-inflammation axis provides a strong rationale for further development of C1SD2-based anti-inflammatory therapies for patients with the aforementioned disorders.

Our data provide novel evidence that the anti-inflammatory effect of microglial C1SD2 is associated with the regulation of NF $\kappa$ B signaling. At present, the molecular mechanism underlying the anti-inflammatory effects of C1SD2 has yet to be elucidated. When located in the cytoplasm and mitochondrial intermembrane space, the activation of NF $\kappa$ B, in addition to a role as well-recognized proinflammatory mediator, has been linked to inflammation, mitochondrial dysfunction, and eventual cellular apoptosis (Albensi, 2019). Thus, it can be interpreted that the attenuation of C1SD2 owing to primary insults from neurotrauma or inflammation from CNS disease inhibits the protective effects against NF $\kappa$ B in cytoplasm and mitochondria leading to a remarkable inflammatory response and mitochondrial dysfunction. Furthermore, evidence has been obtained stating that calcium regulates the expression of TNF- $\alpha$  (Canellada et al., 2006) and modulates macrophage-driven inflammatory cascades (Racioppi et al., 2012). We posit that anti-inflammatory effects may be attributed to the regulatory role of C1SD2 in calcium metabolism (Chang et al., 2012).

It has been suggested that C1SD2 combines with BCL2 to antagonize the apoptotic mediator Beclin 1 (Chang et al., 2012). NF $\kappa$ B also regulates apoptotic effects *via* the combination or dissociation of Beclin 1/Bcl2 complex (Salminen et al., 2012). Moreover, elevated activity of NF $\kappa$ B transcription factors has also been demonstrated to modulate the expression of BCL2 (Chen et al., 2015). In this study, C1SD2 was demonstrated to mediate the upstream regulation of NF $\kappa$ B, as observed by the DNA-binding activity of the NF $\kappa$ B p65 subunit. Collectively, the results indicate that C1SD2 plays an upstream regulatory role in the functions of NF $\kappa$ B and BCL2. Advanced inflammation and mitochondrial dysfunction are highly likely to result in cell damage and negative cell survival. This may explain why C1SD2 deficiency leads to potent inflammatory and apoptotic signaling.

As located in the outer membrane of mitochondria, C1SD2 deficiency has been demonstrated to cause mitochondrial dysfunction and may undermine mitochondrial integrity. Note that mitochondrial dysfunction has been shown to inhibit M2 microglial polarization (Nakagawa and Chiba, 2014). It has been reported that M1 macrophages undergo aerobic glycolysis and pentose phosphate pathway (PPP) in obtaining a supply of energy. Conversely, M2 macrophages use acetyl-CoA and participate in the mitochondrial TCA (tricarboxylic acid) cycle (Culmsee et al., 2019). Thus, C1SD2 deficiency-driven mitochondrial dysfunction contributes to a decrease in TCA cycle activities and augments aerobic glycolysis and the PPP pathway. In so doing, it leads to the promotion of the M1 phenotype along with the reduction of the M2 phenotype.

Some limitations have been attributed to this study. First, based on some previous novel findings involving non-immune cells (SH-SY5Y), we used the cell culture model developed with EOC microglial cell line to evaluate the mechanisms in this study. In future studies, it would be prudent to examine this putative mechanism in primary cultured microglia or *via in vivo* research using animal or human tissue. Moreover, the mechanism underlying the effect of C1SD2 knockdown on M1/M2 microglia

polarization will have to be verified using morphological analysis conducted *in vitro* or *in vivo*, such as staining for microglia M1/M2 profile marker. We demonstrated the involvement of C1SD2 in the regulation of inflammatory genes under basal conditions in the present study using siC1SD2 to attenuate C1SD2 expression. Confirmation of this mechanism will be considered in further studies demonstrating the overexpression of C1SD2 in microglia.

## CONCLUSION

The results obtained in this study demonstrate that C1SD2 exerts anti-inflammatory effects, which may be induced by the suppression of NF $\kappa$ B activation and the preservation of the protective M2 phenotype in non-stressed microglia. C1SD2 deficiency in microglia could be one of the mechanisms underlying cell apoptosis, perhaps occurring *via* inflammation. C1SD2-based anti-inflammatory therapy is a strong candidate for the treatment of neuroinflammation-driven aging and neurodegenerative diseases.

doi: 10.3389/fnagi.2020.00222

**Background:** The human brain has high energy requirements that continuously support healthy neuronal activity and cognition. A disruption in brain energy metabolism (BEM) may contribute to early neuropathological changes such as accumulation of  $\beta$ -amyloid and tau in vulnerable populations. One such population is amnesic mild cognitive impairment (aMCI) where some individuals are at risk for developing dementia, i.e. Alzheimer's disease (AD). Recent advances in imaging technology are providing new avenues to measure BEM accurately using  $^{31}\text{P}$ phosphorus magnetic resonance spectroscopy ( $^{31}\text{P}$  MRS) at ultra-high-field (UHF) magnetic strength 7-Tesla. This study investigates whether a methodology using partial volume-coil  $^{31}\text{P}$  MRS at 7T over parieto-occipital lobes can accurately quantify high-energy phosphate and membrane phospholipid metabolites in aMCI. A secondary objective was to explore BEM and membrane phospholipid indices' correspondence with cognitive performance in domains of executive function (EF), memory, attention, and visuospatial skills in aMCI, a heterogeneous population.

**Methods:** 19 aMCI participants enrolled in the study completed cognitive assessment and  $^{31}\text{P}$  MRS scan. BEM indices were measured using three energy indicators: energy reserve (PCr/t-ATP), energy consumption (intracellular\_Pi/t-ATP), and metabolic state (PCr/intracellular\_Pi) along with regulatory co-factors of BEM-intracellular  $\text{Mg}^{2+}$  and pH; whereas the ratio of phosphomonoesters (PMEs) to phosphodiesteres (PDEs) – membrane phospholipid indicator.

**Results:**  $^{31}\text{P}$  MRS scan showed thirteen well-resolved peaks with precise quantification of the phosphorus metabolites at UHF. The higher BEM indices were associated with lower cognitive performance of memory [(energy reserve indicator: CVLT  $p = 0.004$ ), (metabolic state indicator: CVLT  $p = 0.007$ )], executive function [(metabolic state indicator: TOSL ( $p = 0.044$ ), and attention [(pH: selective auditory task,  $p = 0.044$ )]. The finding of an inverse relationship observed in the parieto-occipital lobes suggests an association between neuronal energy markers with cognition in aMCI.

**Conclusion:** The significant contribution of this preliminary research was to establish the feasibility of utilizing a methodology at UHF to accurately measure high-energy phosphate and membrane phospholipid metabolites in a population with heterogeneous outcomes. This work offers a novel approach for future work to further elucidate early dementia biomarkers or precursors to the downstream accumulation of amyloid and tau using the combination of MRS-PET imaging modalities in AD.

**Keywords:** brain energy metabolism, membrane phospholipid, amnesic mild cognitive impairment (aMCI), Alzheimer's disease (AD), adenosine triphosphate (ATP),  $^{31}\text{P}$  magnetic resonance spectroscopy,  $^{18}\text{F}$  fluorodeoxyglucose positron emission tomography ( $^{18}\text{F}$ FDG PET)

## INTRODUCTION

Mild cognitive impairment (MCI) represents a heterogeneous clinical condition that is definable and objectively classifiable; however, its nature is unstable. MCI appears to follow one of three courses: (1) static condition with little to no change; (2) revert back to normal cognitive function; and (3) advance to dementia, especially Alzheimer's disease (AD) (Albert et al., 2011; Petersen et al., 2014). Motivated by the very nature of this heterogeneity, MCI may present with an ideal group to examine whether the relationship between cognitive and brain energy metabolism (BEM) exists. Such preliminary efforts may help elucidate some possible predictors that could subsequently be investigated in longitudinal studies and compare with cognitively normal and AD population in a pilot trial testing a new methodology at ultra-high-field (UHF) MRI.

Traditionally in MCI, cognitive decline is presented as single or multiple-domain deficits in which either one or more cognitive function decline is observed (Alichniewicz et al., 2012; Cerami et al., 2014; Giau et al., 2019). A subset of the MCI population is classified as amnesic MCI (aMCI). This aMCI subgroup manifests significant memory problems with or without alterations in other cognitive domains for their age, but they remain functionally independent (Petersen et al., 2001). An estimated 30% of MCI subjects are of the aMCI-type with this type showing a higher predilection to subsequently evolve into criteria to meet diagnosis of AD (Cerami et al., 2014). The conversion rate of AD/dementia diagnosis is much higher in the general category of MCI, ranging from 10–15% per year in the clinical setting and 6–10% in population-based studies when compared to age-matched healthy comparison group. In the latter group, the conversion rate is estimated to be about 1–2% per year (Petersen et al., 1999; Farias et al., 2009; Shimada et al., 2019). A meta-analysis in 25 studies supported an overall reversion rate from MCI back to cognitively normal as approximately 24% (Malek-Ahmadi, 2016). Given the heterogeneity of MCI, it is important to point out that although this group may be at greater risk of developing dementia than the normal population, a significant proportion of this population still does not show AD's frank symptoms to reach diagnostic criteria. Overall, this varying range of MCI progression to dementia, or reversal back to normal, supports a plausible hypothesis that the biological mechanisms involved are heterogeneous and unstable. As such, this classifiable

group may provide a valuable population to explore the early biomarkers of neuronal function that affect cognition before the diagnosis of dementia.

Due to the heterogeneity, unstable nature, and wide range of cognitive behavior in individuals with MCI, research is focused on further elucidating novel biomarkers occurring inside the brain cells in this vulnerable complex group. These novel biomarkers are speculated to contribute to our knowledge about possible early pathomechanistic disruptions that could later inform which individuals go on to develop AD and who do not. Previous work established that extracellular deposits of  $\beta$ -amyloid peptides and intracellular deposits of tau aggregates are associated with the pathology of MCI and AD (Mufson et al., 2012). Moreover, only the burden of intracellular tau is strongly correlated with the degree of cognitive decline in MCI and AD (Bejanin et al., 2017). The correlation between tau and cognition observed in postmortem human brain is replicated in *in vivo* studies using a positron emission tomography (PET) tau-radiotracer  $^{18}\text{F}$ -AV-1451 scan (Bejanin et al., 2017). However, little is known about the initial process that disrupts the internal biological mechanisms causing tau hyperphosphorylation leading to the aggregation of tau in the form of neurofibrillary tangles and the relationship of these early biological markers with cognition in MCI.

Growing evidence in MCI and AD pathology supports a role of neuroenergetics, a study of BEM along with depletion of neurotransmitters and neuroinflammation as significant contributing factors to the early disease pathophysiology and progression even before the accumulation of  $\beta$ -amyloid and tau (Ogawa et al., 1996; Heneka et al., 2015). It is intriguing to know that the human brain weighs only 2% of the body weight, whereas it consumes about 25% of the glucose and 20% of the body's oxygen to produce energy in adenosine triphosphate (ATP) (Zlokovic, 2011). The energy produced supports various cellular events such as  $\text{Na}^+/\text{K}^+$ -ATP activities to maintain membrane potential, integrity, and metabolite exchange for neuronal firings (Albers and Siegel, 1999). In sum, the high-energy requirements of the brain make it a highly vulnerable organ to BEM disturbances, especially in the transitory stage such as MCI. It has been speculated that disruptions in BEM and neurochemicals may represent early disease markers in MCI who may convert to AD/dementia with prominent cognitive decline and is observed versus non-converters.

The hypothesis of BEM alterations in MCI can be supported by two recent studies using  $^{18}\text{F}$ -FDG-PET to measure brain glucose metabolism. Earlier longitudinal study of 3 years in 45 MCI (37 aMCI and 8 non-amnesic) using  $^{18}\text{F}$ -FDG PET showed a distinct pattern of neurometabolic changes in terms of reduced glucose metabolism in the temporoparietal brain areas in individuals associated with cognitive deterioration who progressed toward AD (Cerami et al., 2014). In the 3-year follow-up, 14 MCI (11 aMCI and 3 non-amnesic MCI) with normal glucose metabolism in the brain never converted to dementia, whereas 24 MCI of the 45 enrolled (18 aMCI and 6 non-amnesic MCI) with region-specific reduced glucose metabolism in the brain showed increasing cognitive decline to the point where they converted to AD/other dementias (Cerami et al., 2014). Similarly, in a different retrospective longitudinal study of 4 years in 30 aMCI using  $^{18}\text{F}$ -FDG PET, patients without typical hypometabolism in temporoparietal areas did not convert to AD, and cognitive function remained stable over the period of follow-up (Cerami et al., 2018). Thereby, emphasizing that brain metabolism plays a crucial role in regulating cognitive behavior, paving the path to explore the relationship of BEM-cognitive correlates in aMCI.

In addition to  $^{18}\text{F}$ -FDG-PET, magnetic resonance spectroscopy (MRS) represents an emerging brain imaging field that shows promise in providing a platform to investigate BEM, neuroinflammatory, and excitotoxicity markers at the microscopic level inside the brain cells. These microscopic changes have the potential to later affect the macroscopic neural structure, such as the brain's anatomy and physiology, subsequently leading to brain atrophy, which are well studied in MCI and AD (Godlewska et al., 2017). Specifically, the high-energy phosphate metabolites a methodology to investigate BEM at the molecular level is investigated by using a novel non-invasive imaging technology—phosphorus ( $^{31}\text{P}$ ) MRS. This technology aids in the quantification of high-energy phosphate metabolites [ATP, phosphocreatine (PCr), and inorganic phosphate (Pi)] and membrane phospholipid metabolites [phosphoethanolamine (PE), phosphocholine (PC), glycerophosphoethanolamine (GPE), and glycerophosphocholine (GPC)] (Ross and Sachdev, 2004) crucial to understand BEM and membrane phospholipid metabolism. Recent work by Rijpmma et al. (2018) using whole-brain  $^{31}\text{P}$  MRS at 3Tesla observed that the Pi/PCr ratio and the membrane phospholipid metabolites, especially PE, GPC, and GPE, were lower in mild AD compared to age-matched healthy controls. One possible explanation of decreased Pi/PCr findings in AD may be due to a reduction of creatine kinase (CK) activity, an enzyme of mitochondria, thereby increasing PCr (David et al., 1998; Rijpmma et al., 2018). Moreover, a  $^{31}\text{P}$  MRS study at 1.5T showed an association between higher levels of PE and PC in the prefrontal cortex with the severity of cognitive decline measured using the Cambridge Cognitive scale, which included domains of memory, orientation, language, attention, praxis, calculation, abstract thinking, and visual perception subtests (Forlenza et al., 2005). Similarly, other studies in AD have identified higher levels of PE and PC membrane phospholipid metabolites either in temporoparietal

areas (Brown et al., 1989) or over diffuse cortical areas (Pettegrew et al., 1988).  $^{31}\text{P}$  MRS methodology may aid in fine-tuning the characterization of MCI group who will progress to dementia or not in addition to hallmark proteinopathies-accumulation of amyloid and tau.

Over the last two decades, the  $^{31}\text{P}$  MRS technique has been used in brain imaging at lower magnetic strength. Nonetheless, we have at least two main unanswered questions in MCI: (1) Can BEM metabolites be measured in the early stage with higher resolution compared to the existing work using lower magnetic strength and, (2) Is there a correspondence between BEM and cognitive performance in this group? The main challenge is to quantify the high-phosphate energy metabolites accurately and precisely. At lower magnetic strength, like 3T or less, neurochemicals or neurometabolites with only high signal-to-noise ratio (SNR) and abundant in nature can be assessed (Oeltzschner et al., 2019). However, recent advancements in MRI technology to use UHF magnets have enabled the robust application of the  $^{31}\text{P}$  MRS technique (Godlewska et al., 2017). UHF increases the SNR with a higher spectral resolution with enhanced sensitivity of neurochemicals and neurometabolites, which are present in minute concentrations (Mekle et al., 2009; Pradhan et al., 2015; Oeltzschner et al., 2019). To date, no study has used the UHF methodology of  $^{31}\text{P}$  MRS in understanding the relationship of high-energy phosphate and membrane phospholipid metabolites relationship with cognition in an aMCI group.

The present pilot study in aMCI by 7T  $^{31}\text{P}$  MRS had two goals. The first goal was to conduct a preliminary study to determine the feasibility of quantifying various high-energy phosphate and membrane phosphorus metabolites identifiable at 7-Tesla using a partial volume-coil in the parieto-occipital lobes of an aMCI cohort. The current study represents the first known project to test whether a methodology, previously shown to separate similar metabolites in the healthy young adult brain (Ren et al., 2015), heart (Rodgers et al., 2014), and muscles (Ren et al., 2013) could be adapted to measure BEM using  $^{31}\text{P}$  MRS at 7 Tesla in participants classified as aMCI. We selected parieto-occipital lobes as the region of interest based on two previous MCI studies (Ashraf et al., 2015; Corriveau-Lecavalier et al., 2019). Ashraf's et al. (2015) research supported increased metabolism (hypermetabolism) in the occipital cortex in MCI compared to healthy controls using  $^{18}\text{F}$ -FDG PET. Similarly, a longitudinal study in 26 MCI by Corriveau-Lecavalier et al. (2019) found that parietal lobe hyperactivation in 13 MCI was an early indicator in individuals who progressed to dementia. In MCI, based on Ashraf's and Corriveau's findings in the parietal and occipital lobes separately, we hypothesized that there may be compensatory hyperactivation, which may be a proxy of higher cerebral blood flow and energy metabolism during the early phases of biological changes, which may be associated with worsening of cognitive performance.

Our next goal was to investigate the relationships across BEM indices measured using the metabolite ratios of PCr/t-ATP (reflective of energy reserve), (Pi/t-ATP (reflective of energy consumption), and PCr/Pi (reflective of a metabolic state) and its regulatory co-factors (intracellular  $\text{Mg}^{2+}$  and

pH) followed by *membrane phospholipid metabolite index* (PMEs/PDEs) in the parieto-occipital lobes with the cognitive performance of executive function (EF) (complex abstraction, innovation, inhibition and switching, conceptual reasoning, and working memory), memory (episodic), attention, and visuospatial skills. In this research, we define the energy reserve indicator the ratio of PCr to ATP, where PCr is the immediate energy reserve replenishing consumed ATP for maintaining ATP homeostasis during the neuronal activity. In contrast, Pi to t-ATP ratio reflects the relationship between metabolic substrate and product and for energy consumption ( $\text{ATP} \rightarrow \text{Pi} + \text{ADP}$ ) and reproduction ( $\text{Pi} + \text{ADP} \rightarrow \text{ATP}$ ). Pi tends to accumulate when cellular ATP consumption temporarily exceeds the ATP production by mitochondria at a steady state, and increased Pi in turn tends to increase the potential of energy production. The ratio of PCr to Pi is a metabolic state indicator because both PCr and Pi increase the turnover rate or production of ATP. This index was previously termed the oxidative phosphorylation index to measure mitochondrial function (Chance et al., 1981). Based on Ashraf's and Corriveau's studies in MCI, we hypothesized that higher BEM and membrane phospholipid metabolite indices in parieto-occipital lobes would be associated with lower performance on cognitive measures. Overall, in aMCI, which is considered a heterogeneous clinical condition, this work represents a preliminary effort to test a methodology at UHF to measure BEM metabolites precisely followed by exploring the BEM-cognitive performance correlates.

## MATERIALS AND METHODS

### Protocol Approvals and Consent

The study was approved to include individuals with memory complaints between the age of 50 and 80 years by the Institutional Review Board of The University of Texas Southwestern Medical Center and The University of Texas at Dallas. Informed consent and HIPAA forms were signed as per the ethical standards of the Committee on Human Experimentation under Declaration of Helsinki, 1981.

### Participants

Nineteen aMCI participants were recruited using a multi-stage phone screen, including questions related to demographics and medical history along with a review of medications list, an imaging screen, and a memory screen called Clinical Dementia Rating (CDR) scale. Individuals with a history of metal in the body, neurological diseases, substance abuse, psychiatric problems, or any medication that stimulated or slowed the brain's electrical activity were excluded. Eligible participants included for the cognitive screen and assessment were selected irrespective of gender and ethnic factors. All selected participants were right-handed and native English speakers with a minimum of 12 years of education and CDR scale score of 0.5, that is, subjective memory complainers.

### Characterization of aMCI Participants

The qualified individuals on the phone screen with subjective memory complaints (CDR of 0.5) were diagnosed as aMCI based on the established objective memory decline as per either Petersen's or the Alzheimer's disease Neuroimaging Initiative (ADNI) criteria, respectively. The comprehensive ADNI aMCI criteria implemented were: (1) subjective memory complaints; (2) CDR 0.5; (3) objective memory loss measured by logical memory subtest (Wechsler Memory Scale-III); (4) normal daily living activities and cognitive functions assessed using Lawton instrumental activities of daily living scale; (5) clinical dementia rating scale score of 0.5; (6) Mini-Mental Status Examination (MMSE) of 24–30; and (7) absence of dementia. In the Petersen's criteria, all the characteristics mentioned above in ADNI were the same except objective memory loss was assessed using California Verbal Learning Task (CVLT) and individuals who scored  $-1.5$  standard deviation (SD) below the age and education-adjusted mean were included in the study as aMCI. Cognitive screens such as logical memory and CVLT along with geriatric depression scale (short form) were included during the 3-h cognitive assessment protocol. Only participants with no or mild depression were included in the study. **Table 1** summarizes all the screening measures and questionnaires administered to eligible aMCI participants.

### Cognitive Screen and Assessment

The cognitive screening measures included were MMSE, logical memory, and CVLT along with geriatric depression scale (**Table 1**). The other measures included in the present analyses were the cognitive domains of EF (complex abstraction, innovation, switching and inhibition, reasoning, and working memory), memory (episodic memory), attention (selective attention), and visuo-spatial skills. After the cognitive screening, individuals who met the criteria of aMCI and completed other cognitive assessments were invited to complete a 45-min  $^{31}\text{P}$  MRS scan at 7-Tesla. **Table 3** summarizes all the neurocognitive measures implemented in this part of the study. The demographics/characteristics of the participants are presented in **Table 4**.

### $^{31}\text{P}$ Phosphorus Magnetic Resonance Spectroscopy ( $^{31}\text{P}$ MRS) Data Acquisition Protocol

$^{31}\text{P}$  MRS was performed at 7-Tesla MR system (Philips Healthcare, Cleveland, OH, United States), using a double-tuned  $^1\text{H}/^{31}\text{P}$  partial volume-coil consisting of two-tilted partially overlapping 10 cm loops with a plastic housing fit to the shape of the head posterior. All the aMCI participants were positioned head-first and supine in the MRI scanner to acquire spectral data from the parieto-occipital lobes. Prior to this MRS data acquisition, axial, coronal, and sagittal T2-weighted turbo spin echo MR images were recorded for planning the shimming voxel. Typical imaging parameters included field-of-view  $180 \times 180$  mm, repetition time (TR) 2.5 s, echo time 80 ms, turbo factor 15, in-plane spatial resolution  $0.6 \times 0.7$  mm<sup>2</sup>, slice thickness 8 mm, gap 2 mm, bandwidth 517 Hz, number

**TABLE 1 |** Screening measures and questionnaires in amnesic mild cognitive impairment (aMCI).

	Measures	Description
Screening Measures	Clinical Dementia Rating Scale (CDR) (Morris, 1993)	Assesses six domains of cognitive and functional performance in memory, judgment and problem solving, community affairs, orientation, personal care and hobbies. Score: 0.5
	Logical Memory (ADNI Criteria, WMS-III, Wechsler, 1997b)	The ability to recall a short story as it is read out immediately and after 25 min interval was assessed. Score: Delayed memory recall of 9–11 for 16 years of education or 5–9 for 8–15 years of education.
	California Verbal Learning Task (Petersen's et al., 2001)	The ability to recall a list of sixteen (16) words in four categories immediately after the list was read followed by delayed recall after 20 min interval was assessed. Score: –1.5 standard deviation below the mean for age and sex adjusted scores. Assesses the ability to examine functions of registration, attention and calculation, recall and language. Score: 24–30
	Mini Mental Status Examination (Folstein et al., 1975)	Assesses the activities of daily living in the areas of ability to use phone, shopping, food preparation, housekeeping, laundry, mode of transportation, responsibility for own medications, and ability to handle finances. Score: 8
	Activities of daily living: Lawton Instrumental Activities of Daily Living Scale (Lawton et al., 2003)	
Questionnaires	Subjective memory perception Depression	Multifactorial Memory Questions (MMQ) (Troyer and Rich, 2002)
		Assessed individual's self-perception of memory in three subscales using 57 items questionnaire 1. MMQ-Contentment (MMQ-C): Self-satisfaction of memory 2. MMQ-Ability (MMQ-A): Self-perception of memory 3. MMQ-Strategy (MMQ-S): Using of memory strategies in daily life functions.
		Geriatric Depression scale (Yesavage et al., 1982)
		Assessed the depression of the individuals using 15 items questionnaire. Score: $\leq 6$

of acquisitions one, and acquisition time 2.1 min. Second-order  $^1\text{H}$ -based automatic volume shimming was applied.

Quantitative  $^{31}\text{P}$  MR spectra were acquired using a non-localized block-shaped excitation pulse with  $B_1$  59  $\mu\text{T}$ , and pulse width 0.2 ms with an estimated flip angle  $55^\circ$ ,

**TABLE 2 |** Independent variables: energy and membrane phospholipid metabolite indices in amnesic mild cognitive impairment.

Index	Ratios	Definition
<b>BEM indices</b>		
Energy reserve indicator	$\text{PCr}/\text{t-ATP}$	Energy reserve indicator is the ratio of $\text{PCr}/\text{t-ATP}$ as $\text{PCr}$ is the immediate energy reserve metabolite replenishing energy demands during the neuronal activity
Energy consumption indicator	$\text{Pi}/\text{t-ATP}$ : $\text{Extracellular-Pi}/\text{t-ATP}$ $\text{Intracellular-Pi}/\text{t-ATP}$	Energy consumption indicator is the ratio of $\text{Pi}/\text{t-ATP}$ as $\text{Pi}$ is rapidly consumed to release energy in the form of $\text{ATP}$ to support ongoing metabolic and neuronal activity.
Metabolic state indicator	$\text{PCr}/\text{Pi}$ $\text{PCr}/\text{Intracellular-Pi}$	Metabolic state indicator is the ratio of $\text{PCr}/\text{Pi}$ as both $\text{PCr}$ and $\text{Pi}$ increase the turnover rate or production of $\text{ATP}$ . Previously this index was termed as oxidative phosphorylation index to measure mitochondrial function (Chance et al., 1981).
Regulatory co-factors	Magnesium ( $\text{Mg}^{2+}$ ) Intracellular pH	
<b>Membrane phospholipid index</b>		
Membrane phospholipid index	$\text{PMEs}/\text{PDEs}$	Membrane phospholipid index is the ratio of $\text{PMEs}$ (the major precursors of phospholipids contributing to membrane synthesis) to $\text{PDEs}$ (major products of phospholipid breakdown) indicating neuronal and non-neuronal membrane integrity (Ross and Sachdev, 2004).

*BEM*, brain energy metabolism; *PCr*, phosphocreatine; *t-ATP*, total adenosine triphosphate; *Pi*, inorganic phosphate- internal or external;  $\text{Mg}^{2+}$ , magnesium; *PMEs*, phosphomonoesters; *PDEs*, phosphodiester.

which was previously calibrated. B1 calibration of partial volume-coil is presented in the **Supplementary Figure S1**. The transmitter frequency was centered at 700 Hz upfield from the resonance of  $\text{PCr}$ . A short delay time of 0.5 ms was applied prior to free induction decay (FID) data collection to filter out broad-membrane phospholipids signal. The sampling point was 4 k, zero-filled to 8 k prior to Fourier transformation. For quantitative comparison of different metabolite  $^{31}\text{P}$  peaks, fully relaxed spectra were recorded at long TR of 25 s with and eight scan average. For  $\text{Mg}^{2+}$  measurement, to minimize measurement error due to potential  $T_1$  effects and time-of-the-day-dependent  $\text{Mg}^{2+}$  fluctuation, additional  $^{31}\text{P}$  spectra were also acquired at short TRs ranging from 1 to 5 s

**TABLE 3 |** Dependent variables: neurocognitive battery administered to amnesic mild cognitive impaired participants.

Cognitive domain	Measures	Description
<b>Executive function</b>		
1. Complex abstraction	Test of Strategic Learning (TOSL) (Chapman et al., 2002) WAIS-III similarities (Wechsler, 1997a)	Assesses the ability to condense and synthesize complex information written as summary from a complex text. Scores represents number of abstracted ideas. Assesses the ability to think abstractly and to find similarities among words or ideas that may not appear to be similar on the surface.
2. Innovation	Test of Strategic Learning (TOSL) (Chapman et al., 2002)	Assesses the ability to construct as many interpretations as possible from a lengthy text to measure idea fluency.
3. Inhibition and switching	Trails B (Delis et al., 2001)	Assesses the ability to alternate between a number and letter by drawing a continuous line to measure the speed of processing.
4. Conceptual reasoning	Delis–Kaplan executive function system (DKEFS) card sort (Delis et al., 2001)	Assesses the ability to draw similarities between two sets of cards by drawing reasons behind the selection of cards was assessed.
5. Working memory	Digit Span Backwards Test (WMS-III, Wechsler, 1997b)	Assesses the ability to repeat a series of numbers backward.
<b>Memory</b>		
Episodic memory	Memory for facts: Test of Strategic Learning (TOSL) (Chapman et al., 2002)	Assesses the ability to recall details of a lengthy text.
Attention	Selective Auditory Learning Task (Hanten et al., 2007) Digit Span Forward Task (WMS-III, Wechsler, 1997b)	Assesses the ability to focus and pay attention to high-priority stimulus, while simultaneously blocking or inhibiting unwanted or low-priority information was assessed. Assesses the ability to pay attention and remember a series of number in the same sequence.
Visuospatial skills	Trails A (Delis et al., 2001)	Assesses the ability to visually search for numbers in ascending order and draw a continuous line to measure the speed of processing.

with 32 scan averages for a duration of 30 min. The chemical shifts of all  $^{31}\text{P}$  metabolites were referenced to PCr at 0 ppm. Gaussian apodization (6 Hz) was applied to each FID prior to Fourier transformation using the scanner software (SpectroView, Philips Healthcare). Precautions were taken to avoid signal contribution from the neck muscles by positioning the head chin-up, aligning the parieto-occipital region of the brain at the coil iso-center, and placing a supporting cushion pad underneath the neck.

### $^{31}\text{P}$ MRS Data Analysis

First, the preprocessing of the raw data, including zero filling, apodization, Fourier transformation and phase correction, was performed at the scanner using the software package SpectroView from Philips Healthcare. The data post-processing, including baseline correction and spectral fitting, was done with an in-house program written in MATLAB. The fitting was based on the Voigt lineshape model (a combination of Gaussian and Lorentzian lineshape). Thirteen resonance phosphorus peaks were fitted: PCr, ATP ( $\alpha$ -,  $\beta$ -, and  $\gamma$ -spins) nicotinamide adenine dinucleotide (total NAD), uridine diphosphate glucose (UDPG and its analogs), inorganic phosphate (intracellular and extracellular), five phospholipid metabolites including PE, phosphocholine (PC), GPE, GPC, and an macromolecular

metabolite peak. These metabolites were generally well-dispersed in the acquired spectra at 7-Tesla, allowing accurate quantification based on lineshape fitting analysis of individual  $^{31}\text{P}$  peaks. Total-ATP (t-ATP) was calculated by averaging the  $\alpha$ -,  $\beta$ -, and  $\gamma$ -ATP resonances. The brain  $^{31}\text{P}$  spectra revealed two distinct peaks for Pi, assigned intra- and extracellular Pi, the latter including contributions from both interstitial and intravascular spaces (Ren et al., 2018). For the membrane phospholipid metabolite index, phosphomonoesters (PMEs) were calculated by summation of PE and PC, whereas phosphodiesteres were by summation of GPE and GPC. The metabolite concentrations, BEM index, and membrane phospholipid metabolite index (PMEs/PDES), were measured from the integral of each individual metabolite peaks in the fully relaxed  $^{31}\text{P}$  spectra, whereas the cellular pH and  $\text{Mg}^{2+}$  concentration were derived from the chemical shift measurements in the summed spectra at various TRs, which provided high-SNR spectral data. **Table 2** summarizes the definitions of all the indices.

### Evaluation of $\text{Mg}^{2+}$ and Intracellular pH Concentration in the Parieto-Occipital Regions of the Brain

Free magnesium ( $\text{Mg}^{2+}$ ) concentrations in the parieto-occipital regions of the brain were calculated using the chemical shift difference between  $\alpha$ - and  $\beta$ -ATP ( $\delta_{\alpha-\beta}$  in ppm) with PCr as a

reference point ( $\delta_{\text{PCr}} = 0$ ) (Ren et al., 2015).

$$[\text{Mg}^{2+}] = k_d \frac{\delta_{\text{ATP}} - \delta_{\alpha-\beta}}{\delta_{\alpha-\beta} - \delta_{\text{MgATP}}} \quad (1)$$

where  $k_d$  (dissociation constant of  $\text{MgATP}$ ) = 0.05 mM and the limiting shift constant  $\delta_{\text{ATP}} = 10.82$  ppm and  $\delta_{\text{MgATP}} = 8.32$  ppm.

pH was calculated from the chemical shift of the corresponding Pi (internal) peaks ( $\delta_{\text{Pi}}$ , in ppm) in reference to PCr ( $\delta_{\text{PCr}} = 0$  ppm) (Ren et al., 2015).

$$\text{pH} = \text{pKa} + \log \frac{\delta_{\text{Pi}} - \delta_a}{\delta_b - \delta_{\text{Pi}}} \quad (2)$$

where pKa (deprotonation constant) = 6.73,  $\delta_a = 3.275$  ppm (for acidic protonated species  $\text{H}_2\text{PO}_4^-$ ) and  $\delta_b = 5.685$  ppm (for basic protonated species  $\text{H}_2\text{PO}_4^-$ ) were used in the data analysis.

## Statistical Analysis

A linear regression model was used to investigate the relationship of BEM indices using PCr/t-ATP (reflective of energy reserve), Pi/t-ATP (reflective of energy consumption), PCr/Pi (reflective of a metabolic state), regulatory co-factors ( $\text{Mg}^{2+}$  and pH), and the membrane phospholipid index (PMEs/PDEs) in the parieto-occipital brain region with cognitive performance across the domains of EFs, memory, attention, and visuo-spatial skills. Specifically, all the indices and individual metabolite along with intracellular pH were first transformed by using  $f(x) = \log(x-a)$ , whereas intracellular  $\text{Mg}^{2+}$  was transformed using where  $f(x) = -\log(b-x)$  where “x” is the raw score of the specific metabolite for each participant, and “a” or “b” are metabolite-specific constants. The metabolite-specific constants were used to symmetrize each metabolite distribution and reduce undue leverage of the single participants in the regression. Once the indices,  $\text{Mg}^{2+}$ , and pH values were transformed, the linear regression model was used to test the association with neurocognitive measures across the domains of EFs, memory, attention, and visuo-spatial skills.

## RESULTS

### Brain Phosphorous Metabolites at 7T

Figure 1 shows a typical  $^{31}\text{P}$  MR spectrum acquired from the human brain parieto-occipital lobes using a partial volume-coil at 7T. A total of 13 metabolites are clearly identifiable.

### Relationship of BEM and Membrane Phosphate Metabolite Indices in the Parieto-Occipital Lobes With Cognitive Performance in aMCI

We investigated the relationships across BEM indices measured using PCr/t-ATP (reflective of energy reserve), Pi/t-ATP (reflective of energy consumption: extracellular-Pi/t-ATP and intracellular-Pi/t-ATP), and PCr/Pi (reflective of a metabolic state) and its regulatory co-factors (intracellular  $\text{Mg}^{2+}$  and pH) followed by membrane phospholipid metabolite index

(PMEs/PDEs) in the parieto-occipital lobes with cognitive performance of EF (complex abstraction, innovation, inhibition and switching, conceptual reasoning, and working memory), memory (episodic), attention, and visuo-spatial skills. Age and education had no appreciable effects on the high-energy phosphate and membrane phospholipid indices, nor on the cognitive measures in our sample (Supplementary Table S1). Therefore, we did not adjust for age and education in our final analyses of BEM indices and cognitive performance.

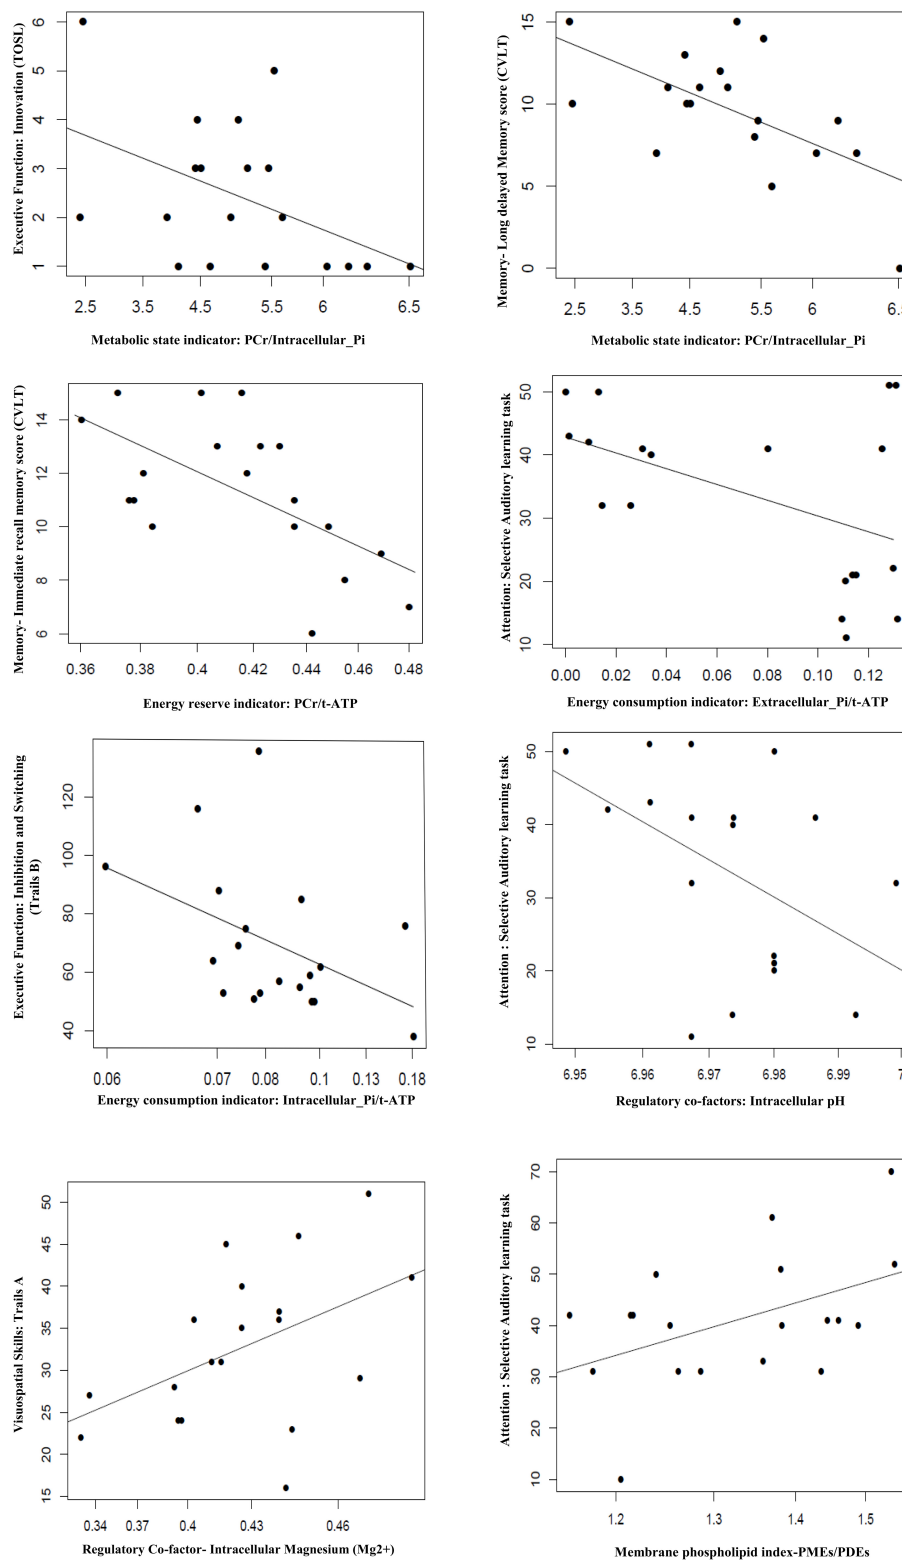

### BEM Index: Cognitive Correlation

In the BEM index and neurocognitive relationship, we found four significant results. First, the extracellular-Pi/t-ATP ratio was inversely related with performance of attention [selective auditory attention-trail 2: ( $b = -0.0018$ ,  $t = -2.254$ ,  $p = 0.038$ )]; whereas intracellular-Pi/t-ATP ratio was trending to be inversely proportional with the performance on the EF domain of inhibition and switching [Trails B: ( $b = -13.867$ ,  $t = -2.029$ ,  $p = 0.0585$ )]. Second, the energy reserve indexed by PCr/t-ATP was inversely related with performance on immediate recall of cognitive memory screen [CVLT: ( $b = -0.0138$ ,  $t = -3.272$ ,  $p = 0.004$ )]. Finally, the regulatory co-factors of BEM index intracellular pH was also inversely associated with attention [selective auditory attention-trail 2: ( $b = -285.95$ ,  $t = -2.172$ ,  $p = 0.044$ )], whereas  $\text{Mg}^{2+}$  was positively associated with visuo-spatial skills [Trails A: ( $b = -12.471$ ,  $t = 2.219$ ,  $p = 0.040$ )].

In view of a previous study by Rijpma et al. (2018) in AD for observation of a reduced level of PCr/Pi, an indicator of metabolic state, we also investigated the relationship of PCr/Pi ratio with cognition. A significant inverse relationship was found between the PCr/Pi index and performances on EF of innovation [TOSL: ( $b = -0.78$ ,  $t = -2.18$ ,  $p = 0.044$ )], and delayed recall of cognitive memory screen [CVLT: ( $b = -2.43$ ,  $t = -2.278$ ,  $p = 0.007$ )].

See Figure 2 and Table 5 for details.

**FIGURE 2 |** Association of BEM, membrane phospholipid indices, and regulator co-factors in the parieto-occipital brain region with cognitive performance in amnesic mild cognitive impairment ( $p \leq 0.05$ ). TOSL, Test of Strategic Learning; CVLT, California Verbal Learning test; intracellular\_Pi, inorganic phosphate (intracellular); extracellular\_Pi, inorganic phosphate (extracellular); PCr, phosphocreatine; t-ATP (total adenosine triphosphate: sum of  $\alpha$ -ATP,  $\beta$ -ATP, and  $\gamma$ -ATP); PMEs, phosphomonoesters; PDEs, phosphodiesterases.

## Membrane Phospholipid Metabolite Index: Cognitive Correlation

The membrane phospholipid metabolite index (PMEs/PDEs) was positively associated with cognitive domain of attention [selective auditory attention-Trail 1: ( $b = 5.92$ ,  $t = 2.14$ ,  $p = 0.047$ )].

See **Figure 2** and **Table 5** for details.

## DISCUSSION

The present exploratory pilot study investigated two main goals in aMCI, a heterogeneous and unstable clinical population. This group is at higher risk of developing AD/dementia than the cognitively normal population, although many with aMCI may not progress. Our main goal was to establish a methodology and test the feasibility to measure BEM related high-energy phosphate and membrane phospholipid metabolites precisely at UHF magnetic strength 7-Tesla using a partial volume-coil  $^{31}\text{P}$  MRS technique in the parieto-occipital region of the brain in a population with variability as defined by its nature. Our results showed that we were able to resolve 13 of  $^{31}\text{P}$  peaks with well-separated spectral resolution of high-energy phosphate and membrane phospholipid metabolites. The enhanced spectral resolution suggests this methodology may provide a feasible way to further explore BEM in more extensive comparative studies with healthy controls and those affected with AD in the future at UHF magnetic strength. Next, we investigated if the BEM indices derived from measuring the high-energy phosphates and membrane phospholipid metabolites at 7T showed a correspondence with cognitive performance (BEM-Cognitive correlates). Overall, we hypothesized an inverse relationship across BEM indices—energy reserve, energy consumption, and metabolic state—along with regulatory co-factors pH and  $\text{Mg}^{2+}$  and membrane phospholipid index with cognitive performance supported by previous work from Ashraf et al. (2015), Croteau et al. (2018), and Corriveau-Lecavalier et al. (2019). Our results support our assumptions of an inverse relationship in aMCI with the exception of  $\text{Mg}^{2+}$  and the membrane phospholipid index, which were positively associated with visuospatial domain and attention, respectively.

## Population of Interest

An increasing body of research is focused on investigating pathophysiologic changes in the *in vivo* human brain with the goal to track and diagnose the onset of dementia as

early as possible, particularly in populations at higher risk, such as aMCI. Although this cohort has an elevated risk for developing Alzheimer's, the evidence that many will not develop dementia may make this an informative population to study, as a preliminary step. Due to variability of the disease progression, identification of early biological markers is an important goal in developing effective therapeutics. In prior research, seeking to better understand BEM, the research to date focused predominantly on either healthy controls or disease populations like AD at lower magnetic strength, with a knowledge gap regarding the potential role of BEM on cognition in aMCI. The current work expands on these efforts by reporting on the first, albeit small, pilot study in aMCI to explore the feasibility of acquiring precise data at UHF magnetic strength 7T using  $^{31}\text{P}$  MRS to study BEM-cognitive correlations.

## Methodological Approach to Measure BEM: $^{31}\text{P}$ MRS at 7T in aMCI

Our first goal of this study was to identify a distinct spectral display of high-energy phosphate and membrane phospholipid metabolites using  $^{31}\text{P}$  MRS at 7T. The results revealed it was possible to resolve and identify a high-quality spectral display with improved SNR of the high-energy phosphate and membrane phosphorus metabolites in the parieto-occipital lobes using the UHF MRI. What is interesting to note is that the spectral resolution of brain phosphorus metabolites in this study was similar to previous studies in healthy young adult brains and muscle (Ren et al., 2015) and heart (Rodgers et al., 2014) at 7T. Moreover, the use of 7T allowed clear separation of multiple phosphorus metabolites with similar chemical shifts in the spectra collected from the parieto-occipital region. With improved SNR in the summed spectra, we were able to fully resolve PMEs into PE and PC, PDEs into GPC and GPE, and Pi into intra- and extracellular compartments, along with observation of NAD(H) and UDP(G). At UHF MRI, the  $\alpha$ - and  $\beta$ -ATP signal appeared to be an easy-to-fit single peak on the spectral display due to improved SNR of the phosphorus metabolites. It is worthy to note that the  $\alpha$ -ATP chemical shift can be affected by the NAD(H) signal, a shift that cannot be resolved at a lower magnetic field. Thereby, the easy-to-fit singlet of  $\alpha$ - and  $\beta$ -ATP allowed us to calculate the concentration of free  $\text{Mg}^{2+}$ , an important regulatory co-factor of BEM in the *in vivo* human brain. Overall, the  $^{31}\text{P}$  MRS data acquisition methodology with improved SNR provided indirect help in accurately measuring the regulatory co-factors (intracellular  $\text{Mg}^{2+}$  and pH), which are essential metabolic sensors to provide neuronal environmental cues alterations in health and disease progression (Rabhi et al., 2017). This capability was previously limited due to the use and insensitivity of lower magnetic strengths such as 1.5-Tesla (Smith et al., 1995; Lotti et al., 1996; Forlenza et al., 2005) or 3-Tesla (Mandal et al., 2012; Rijpmma et al., 2018).

Another methodological contribution of this study was the resolution of Pi into two separate peaks, intracellular and extracellular compartments (Ren et al., 2018). The extracellular Pi pool includes the signal of Pi from both the vascular and

interstitial space plus the space occupied by cerebrospinal fluid (CSF). One hypothesis that could be explored in subsequent studies is whether brain atrophy leads to increased extracellular space and reduced intracellular space, assuming invariant extracellular-Pi is a crucial biomarker as the disease emerges and progresses. Prior work in MCI and AD supported the postulation that low level of serum or blood phosphorus, that is, phosphorus levels, was significantly associated with higher cerebral amyloid deposition when compared to healthy controls matched for age, sex, and apolipoprotein ε4 genotype and memory scores of MMSE (Park et al., 2017). Park et al. (2017) findings motivated us to explore a relationship between phosphorus metabolites in the brain with cognition in MCI. Building on this prior evidence, the current work expands the knowledge by going one step further in measuring phosphorus metabolites, an indicator of BEM directly using <sup>31</sup>P MRS at 7T, followed by exploring the relationship of these phosphorus metabolites with cognition in aMCI.

To date, research in MCI has focused largely on the macroscopic pathological contributing factors associated with neurodegeneration, such as the accumulation of amyloid and structural alteration (Mufson et al., 2012; Oeltzschner et al., 2019). However, there is a desire to better understand the microscopic biological mechanisms taking place inside the cells of the *in vivo* human brain, now that researchers have access to more advanced imaging technology and analytics. As protocols develop and are tested to measure intracellular mechanisms, it may improve the predictive capabilities of which profiles progress toward the disease compared to non-converters. Our preliminary work using <sup>31</sup>P MRS at 7T opens the door to employ this new methodology to advance our understanding of the biological mechanisms like BEM, that is, bioenergetics and membrane phospholipid metabolism occurring inside the brain cells in aMCI, a heterogeneous cohort.

## BEM-Cognitive Correlates

Our second goal of the study was to investigate the association of BEM and membrane phospholipid metabolite indices in the parieto-occipital brain regions, with the cognitive performance

of EFs, attention, memory, and visuospatial skills. We measured BEM indices using PCr/t-ATP (reflective of energy reserve), Pi/t-ATP (reflective of energy consumption: extracellular-Pi/t-ATP and intracellular-Pi/t-ATP), and PCr/Pi (reflective of a metabolic state), along with co-regulatory factors intracellular pH and Mg<sup>2+</sup> concentrations in the parieto-occipital lobes (see Table 2 for details). The membrane phospholipid index ratio of PMEs (the significant precursors of phospholipids contributing to membrane synthesis) to PDEs (significant phospholipid products breakdown) indicated neuronal and non-neuronal membrane integrity (Ross and Sachdev, 2004) measured in the parieto-occipital lobes. An inverse relationship was observed with BEM indices and cognitive performance except for Mg<sup>2+</sup> and membrane phospholipid index, which were significantly associated with visuospatial domain and attention, respectively.

The results of the inverse relationship of BEM indices and cognition support that individuals with higher BEM in the parieto-occipital lobes performed lower on cognitive domains of memory and EF. We offer one plausible hypothesis that subsequent research could explore is whether these low cognitive performers with higher BEM indices may represent individuals at greater risk of progressing toward AD in longitudinal work. This possibility is based on prior work on brain metabolism using <sup>18</sup>FDG-PET (Ashraf et al., 2015; Croteau et al., 2018). The present work complements prior findings showing glucose hypermetabolism in MCI when compared to age-matched healthy controls, in parietal (Croteau et al., 2018) and occipital lobes (Ashraf et al., 2015). Although these two studies focused on different brain regions, they both offered a similar explanation for their findings; that is, the glucose hypermetabolism in parietal and occipital lobes represented a compensatory mechanism in MCI compared to healthy controls.

A compensatory mechanism can be interpreted as a process whereby the brain is adapting to neural changes attributed to a variety of factors, such as brain aging or neurodegenerative processes (Bobkova and Vorobyov, 2015). This adaptive mechanism was explained as “neuroplasticity” in Ashraf’s study.

It is important to note that, at some point, the compensatory phenomenon of the brain's systems, such as higher BEM observed in our study, may not have been adequate to support the same level of cognitive performance as cognitively normal individuals (Croteau et al., 2018). To date, impairments across EF, memory, and attention are thought to rely on the anterior brain networks of the frontal, temporal, and anterior part of the parietal lobes (Kim et al., 2019) with limited understanding of investigating early neurometabolic changes in the posterior part of the brain-parietal and occipital lobes. Thus, the current work lays a foundation to examine the correlates of BEM in posterior part of the brain, that is, parieto-occipital regions of the brain with cognition in aMCI, a group where some are at risk of developing dementia while others are stable either in the condition or revert to normal.

In contrast to the inverse relationship of BEM indices with cognitive performance, two independent variables (regulatory co-factor:  $Mg^{2+}$  and membrane phospholipid index) also showed significant association with specific cognitive domains but in different directions in aMCI. One was a higher  $Mg^{2+}$  concentration and associated with the higher performance on the visuospatial task, and other was a positive association of membrane phospholipid index (PMEs/PDEs) with the performance on the attention task. One possible explanation of the deviation of the inverse relationship of  $Mg^{2+}$  in the parieto-occipital lobes with cognition is that the posterior parietal and occipital brain regions are part of the dorsal stream of the visual system that aids in recognizing objects in space with detection and analyzing the movements (Hebart and Hesselmann, 2012). Thereby, a visuospatial task, which is primarily controlled by the parietal and occipital lobes, could depend on higher energy requirements in the form of higher  $Mg^{2+}$  level, an essential co-factor for ATP synthesis. Whereas the other significant positive correlation of the membrane phospholipid index with the cognitive domain of attention in the region of interest may again support the theory of neuroplasticity/compensatory mechanism as proposed by Ashraf's et al. (2015) in MCI. We speculate that neuroplasticity of the parietal and occipital lobe may have higher turnover of membrane phospholipid index to support failing anterior lobe network. In general, though this study generates a lot of hypothesis that needs to be tested in future studies, still it adds to the existing knowledge that BEM and membrane phospholipid indices are associated with cognition in a cohort with mixed progression and reversion rate.

In sum, this study represents an early step to elucidate the methodologies of BEM and membrane integrity using partial volume-coil  $^{31}P$  MRS at UHF magnetic strength 7T in aMCI. We were able to show the feasibility of measuring the high-phosphate energy and membrane phospholipid metabolites with higher sensitivity and spatial resolution when compared to the strength of lower magnetic fields, such as 1.5T and 3T, in a heterogeneous population. This pattern of findings supports the viability of  $^{31}P$  MRS at 7T to explore further the brain's energy requirements and its association with cognition to motivate additional research. We propose that future research using volume-coil  $^{31}P$  MRS at 7T could enhance our understanding of the role of mitochondrial contributions, which play an essential role in BEM linked to brain

pathology in at risk populations in whom the disease may or may not progress from healthy aging to AD. Moreover, the potential of such an approach is strengthened by the finding of a relationship between BEM and membrane phospholipid indices in parieto-occipital lobes with cognitive performance across the domain of EF, memory, attention, and visuospatial skills in cognitively compromised brain of aMCI.

## Limitations

We interpret the findings of this study in aMCI cautiously due to its limitations. First, the study sample size was small and lacked a cognitively normal age-matched control group or AD cohort for comparison. However, even with our small sample size and lack of a control group, we were able to show that BEM and membrane phospholipid indices, an indicator of neurometabolic changes in the parieto-occipital brain areas, are associated with performance of cognition especially in the area of memory, EF, and attention in aMCI significantly. This study focused on exploring a relationship of BEM-cognitive correlates at a single point of time. Future research is needed to follow individuals with aMCI longitudinally to see if early markers could be identified to better predict who is at risk for developing AD/dementia and who is less likely to progress. Second, the use of partial volume-coil  $^{31}P$  MRS limited our ability to support the theory of the compensatory mechanism in the early stages as the BEM indices of the anterior part of the brain, that is, frontal and temporal were not measured. Nonetheless, the use of the partial volume-coil in this research helped us to understand the relationship of a BEM and cognition in aMCI, specifically in brain regions that have been shown to probable predictor sites in the brain in subset of MCI individuals that progress toward AD using  $^{18}F$ FDG-PET (Ashraf et al., 2015; Croteau et al., 2018).

## CONCLUSION

Our findings show a highly resolved spectral display of high-energy phosphate and membrane phospholipid metabolites using  $^{31}P$  MRS at 7Tesla in aMCI. We also observed an inverse relationship between higher BEM indices with the lower performance of EFs, memory, and attention. The salient contribution of this pilot study is that it adds to the growing body of evidence that BEM can be measured accurately and appears to be associated with cognitive performance in this heterogeneous cohort. It also lays the foundation for future efforts to investigate if BEM mechanisms synergistically with amyloid and tau proteins, which are the hallmarks of the disease as potentially understand upstream triggers that aggravate the pathophysiological mechanism of the disease. Finally, longitudinal follow-up of an aMCI population would be of interest to test predictive ability of BEM, deploying imaging technology at 7 Tesla, as to which individuals will develop dementia and which will not, based on changes at the molecular level. This novel approach offers a novel research approach to advance our understanding of early biomarkers of those at risk for dementia to complement current endeavors.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by IRB, The University of Texas Southwestern Medical Center and The University of Texas at Dallas. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

ND has been involved in the analysis and writing of the whole manuscript. JR has been involved in instrumental in the analysis of MRS data along with ND. JS, biostatistician was involved in the analysis, whereas AR helped in the recruitment of MCI participants. SC was the principal investigator of the study and mentored in the writing of the manuscript. All authors contributed to the article and approved the submitted version.

Alzheimer's disease (AD) is a debilitating neurodegenerative disease characterized by the accumulation of two proteins in fibrillar form: amyloid- $\beta$  (A $\beta$ ) and tau. Despite decades of intensive research, we cannot yet pinpoint the exact cause of the disease or unequivocally determine the exact mechanism(s) underlying its progression. This confounds early diagnosis and treatment of the disease. Cerebrospinal fluid (CSF) biomarkers, which can reveal ongoing biochemical changes in the brain, can help monitor developing AD pathology prior to clinical diagnosis. Here we review preclinical and clinical investigations of commonly used biomarkers in animals and patients with AD, which can bridge translation from model systems into the clinic. The core AD biomarkers have been found to translate well across species, whereas biomarkers of neuroinflammation translate to a lesser extent. Nevertheless, there is no absolute equivalence between biomarkers in human AD patients and those examined in preclinical models in terms of revealing key pathological hallmarks of the disease. In this review, we provide an overview of current but also novel AD biomarkers and how they relate to key constituents of the pathological cascade, highlighting confounding factors and pitfalls in interpretation, and also provide recommendations for standardized procedures during sample collection to enhance the translational validity of preclinical AD models.

**Keywords:** Alzheimer's disease, translational research, biomarkers, cerebrospinal fluid, screening tools

## INTRODUCTION

Due to an increasingly elderly population, patients with Alzheimer's disease (AD) constitute a growing public health problem, thus developing methods for early diagnosis of the disease will become pertinent as there of yet exists no cure. The disease typically manifests through a progressive decline in cognitive and behavioral functions that severely impact the ability of AD patients to independently perform daily tasks. As a result, the associated socioeconomic cost and burden to the healthcare system are very high, with annual healthcare expenditure exceeding billions of dollars. Based on the early findings by Alzheimer et al. (1995), we now know that the neuropathological hallmarks of AD include intracellular neurofibrillary tangles (NFTs) composed of misfolded tau protein, and extracellular amyloid plaques comprising aggregated amyloid- $\beta$  (A $\beta$ ). The pathological

protein accumulation in AD follows a predictable spatiotemporal pattern where certain areas become affected before others, including the entorhinal cortex (EC) and the hippocampus (Serrano-Pozo et al., 2011). In late stage AD, up to 90% of cells are lost in EC layer II (Gomez-Isla et al., 1996). The initial A $\beta$  deposits present as plaques in the temporal neocortex, before progressing to the EC and the hippocampus (**Box 1**; Thal et al., 2002). Meanwhile, initial tangle formation begins in the most lateral portions of EC layer II, followed by the hippocampus, before appearing in areas of the neocortex (**Box 1**; Braak and Braak, 1991). The anatomical and temporal progression of A $\beta$  and tau pathology, and subsequently neurodegeneration, has led to the postulation that A $\beta$  acts as an initiator of the disease progression that results in tau-mediated neurodegeneration (Freudenberg-Hua et al., 2018).

Many variants of the amyloid cascade hypothesis have been proposed over the years; and this hypothesis argues that the deposition of A $\beta$  is the initial and causative step for developing AD (Hardy and Higgins, 1992). According to this hypothesis, A $\beta$  deposition causes disruption of calcium homeostasis in cells, resulting in molecular lesions, NFTs, oxidative stress, inflammation, excitotoxicity, and eventually cell death. The main counter argument for this hypothesis has been that amyloid plaque burden has a low correlation with the severity of clinical symptoms of AD, unlike that of NFTs and neurodegeneration (Terry et al., 1991; Arriagada et al., 1992). In line with this, amyloid plaque deposition commonly plateaus with time, despite declining cognition in AD (Engler et al., 2006). Therefore, the majority in the AD research field now focus on soluble, intracellular A $\beta$  oligomers as a possible initiator of the development of the disease (**Figure 1**).

Amyloid- $\beta$  can exist in multiple assembly forms, ranging from monomeric to oligomeric and fibrillar forms (**Figure 1**). As a monomer, A $\beta$  does not seem to be toxic, whereas oligomeric or fibrillar forms have been found to be potent blockers of long-term potentiation (LaFerla et al., 2007). Research suggests that levels of soluble A $\beta$  oligomers are better correlated with disease severity than amyloid plaques mainly consisting of insoluble A $\beta$  fibrillar species (Arriagada et al., 1992; Lue et al., 1999; McLean et al., 1999; Naslund et al., 2000; Haass and Selkoe, 2007). When produced intracellularly, A $\beta$  oligomers expose flexible hydrophobic surfaces that might contribute to trapping vital proteins and, in this way, they can subtly damage and predispose vulnerable neurons to the formation of intracellular tau aggregates (Campioni et al., 2010). Thus, tau pathology in AD appears to be a downstream, effect of the presence of A $\beta$  oligomers (**Figure 1**). In line with this, a link has been made between increased amounts of intracellular A $\beta$  and neurodegeneration, while clearing of intracellular A $\beta$  has been shown to revert AD-related memory deficits in animals modeling AD (Billings et al., 2005). An explanation for the weak correlation between cognitive decline and plaque load could be that insoluble fibrillar A $\beta$  species might serve as reservoirs for smaller oligomeric A $\beta$ , thus sequestering these away from neurons (Mucke and Selkoe, 2012; **Figure 1**).

The manner in which pathology progresses in model systems and human patients with AD has mostly been

investigated separately resulting in little or poor translational value. As such, the translational aspect of staging the AD molecular disease cascade between preclinical models and human AD patients has remained inadequate. Despite intense investigation into disease cause and mechanisms of neurodegeneration, there is currently no cure or unequivocal evidence as to the exact nature of its underlying cause. Still, there seems to be consensus as to the fact that the success of treatments is primarily contingent on whether they can target disease-related pathology at early onset. This suggests that we are urgently in need of better tools for early onset diagnosis, before evolving pathology severely affects brain function, as well as better tools for monitoring pathological progression.

This effectively means, to translate discoveries made in preclinical models to the clinic, we must bridge the gap between model systems and patients with AD by improving the robustness and predictive validity of screening tools. For instance, the current dominant view is that A $\beta$ 42 accumulates extracellularly first, and thereby leads to the formation of amyloid plaques. However, several studies of brain tissue from animal models and human patients have begun to challenge this notion. In this paper, we explore potential early screening tools for the diagnosis of AD and also provide links between the extensive research done in preclinical models to human clinical applications. Specifically, we review how screening in AD patients can become more precise by the use of novel cerebrospinal fluid (CSF) biomarkers and by following recommendations for standardized procedures during CSF sample collections. We also focus on how intracellular events of A $\beta$  and tau aggregation eventually lead to extracellular deposition and the presence of neuropathological hallmarks, and how current tools can predict, diagnose and potentially treat models and patients at various timepoints of the disease.

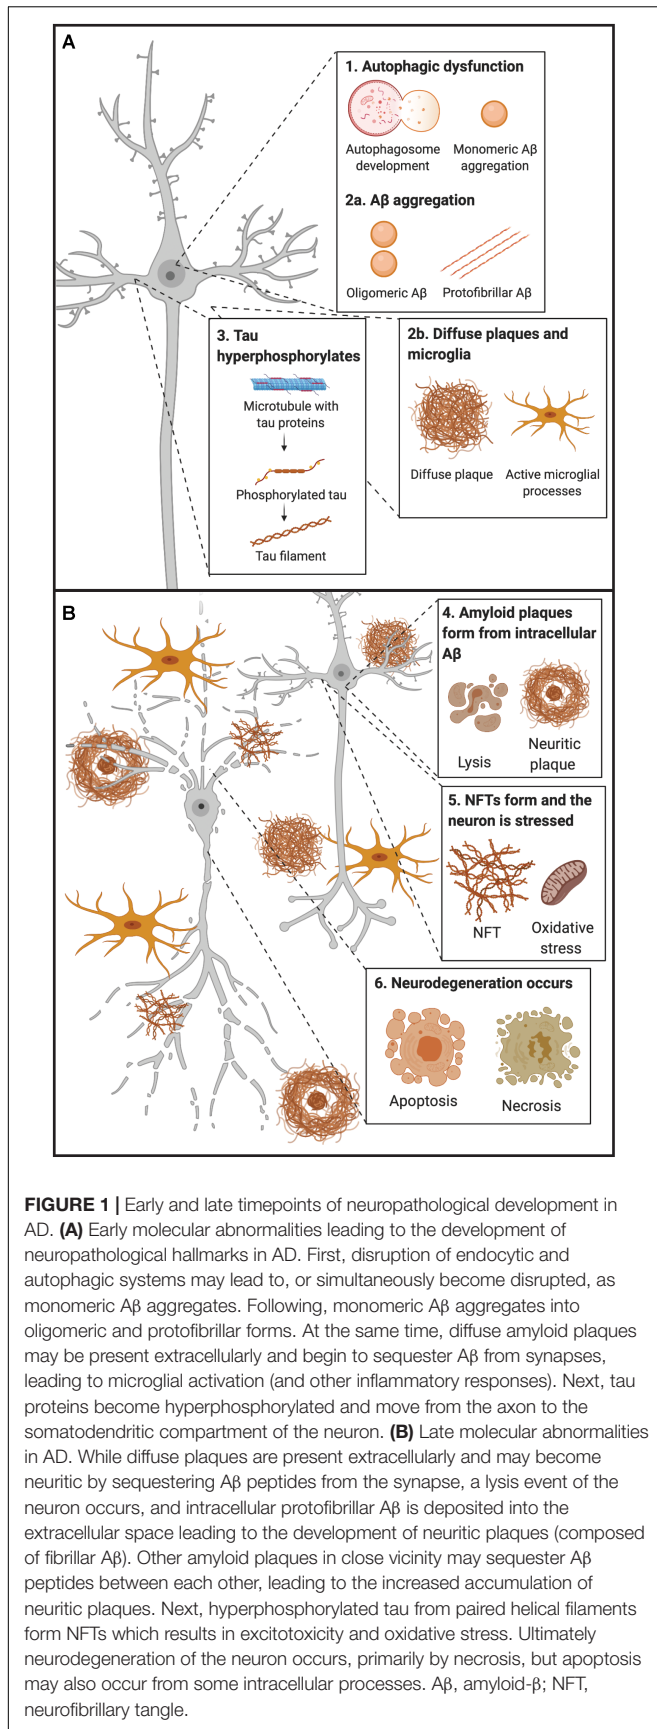

## AD BIOMARKERS – TYPE AND DEFINITION

When defining an AD biomarker, many agree that it is a measurable indicator within a patient that can help to test and monitor the progress of pathology (Hane et al., 2017). The ideal fluid biomarker for AD would be consistent, reproducible, non-invasive, simple to measure, inexpensive, and easy to implement into the clinic and the primary care setting (Davies et al., 1998; Wang et al., 2012; Bjerke and Engelborghs, 2018; Molinuevo et al., 2018). Such biomarkers should be able to identify the clinical disease stage of the patient and also monitor treatment effects. Conventionally, patients with overt dementia are diagnosed with around 85% specificity (but at much lower rates in patients with early stage AD), but the ideal biomarker should exceed this rate (Davies et al., 1998). There is thus an urgent need for a specific marker for early detection in these patients. Various biomarkers that can detect early AD in both preclinical models and patients have been proposed. For instance, it would be preferable to have a biomarker that can detect intracellular events prior to the deposition of amyloid plaques and NFTs. In line

**Thal A $\beta$  staging****Stage I****Stage II****Stage III****Stage IV****Stage V****Braak NFT staging****Stage I-II****Stage III-IV****Stage V-VI**

**BOX 1 |** Spatiotemporal pattern of A $\beta$  and NFT deposition during the AD disease cascade in the human and mouse brain. Stages of A $\beta$  deposition in the AD brain (Gomez-Isla et al., 1996). Stage I is characterized by exclusively neocortical A $\beta$  deposits (neocortex: green) (Gomez-Isla et al., 1996). This includes A $\beta$  deposits in frontal, temporal, parietal, and occipital cortices (Gomez-Isla et al., 1996). Stage II shows additional allocortical A $\beta$  deposits (green) in entorhinal cortex, CA1, cingulate cortex, amygdala, presubiculum, and the fascia dentata (Gomez-Isla et al., 1996). In stage III, there are additional A $\beta$  deposits in diencephalic nuclei and striatum (green) including thalamus, hypothalamus, the basal forebrain, caudate nucleus, putamen, claustrum, the lateral habenular nucleus, and white matter (Gomez-Isla et al., 1996). In stage IV there are A $\beta$  deposits in distinct brainstem nuclei (substantia nigra, superior and inferior colliculi, inferior olivary nucleus, intermediate reticular zone, central gray of the midbrain, CA4, and the red nucleus; green) (Gomez-Isla et al., 1996). In stage V there are A $\beta$  deposits in the cerebellum and additional brainstem nuclei (pons, locus coeruleus, reticular formation, raphe nuclei, parabrachial nuclei, and the dorsal tegmental nucleus; green) (Gomez-Isla et al., 1996). Stages of NFT deposition in the AD brain (Thal et al., 2002). Stages I-II show alterations which are confined to the superficial entorhinal cellular layer (pre- $\alpha$ ; layer II/layer IIa) (Thal et al., 2002; Freudenberg-Hua et al., 2018). The next stage is an aggravation of stage I (Thal et al., 2002). Stages III-IV lead to severe involvement of the entorhinal and transentorhinal layer pre- $\alpha$  (pink) (Thal et al., 2002). Stage IV is characterized by layer pre- $\alpha$ , pri- $\alpha$  (layer V) (Freudenberg-Hua et al., 2018), and pre- $\beta$  (layer III; layer IIb) (Thal et al., 2002; Freudenberg-Hua et al., 2018) involvement. CA1, the basolateral nuclei of the amygdala, the reunions nucleus, the antero-dorsal thalamic nucleus, putamen, and nucleus accumbens are densely filled with NFTs (Thal et al., 2002). Stages V-VI are marked by isocortical destruction (pink) (Thal et al., 2002). In stage V, the deep layer pri- $\alpha$  is severely involved. Layers pre- $\beta$  and pre- $\gamma$  (layer III) (Freudenberg-Hua et al., 2018) are also affected (Thal et al., 2002). Virtually all components of the hippocampal formation are involved, and the isocortex is severely affected (Thal et al., 2002). By stage VI, the subcortical nuclei show a much more pronounced involvement (Thal et al., 2002), and considerable nerve cell loss is seen in layers pre- $\alpha$  and pri- $\alpha$  (Thal et al., 2002). Grayscale represents the recency of involved regions for each stage of neuropathology. Human brain regions adapted from Jürgen et al. (2016); mouse brain regions adapted from Allen brain atlas (Sunkin et al., 2013).

with this, when diagnosing patients based on physical symptoms, reduced memory recall manifests in many diseases other than AD (Hane et al., 2017), highlighting the need for preclinical markers specific to AD.

Furthermore, AD has a long preclinical phase (**Figure 2**) consisting of three stages. In the first stage, monomeric and oligomeric A $\beta$  aggregates inside neurons and subsequently onto neuronal surfaces and synapses as the concentration in the CSF reservoir diminishes. At this stage, current methods cannot detect the changes caused by A $\beta$  aggregation in neurons and synapses (Hane et al., 2017). During the second stage, certain CSF biomarkers such as increased CSF tau, hypometabolism in the posterior cingulate, and cortical thinning become detectable (Hane et al., 2017). In the third stage, the patient experiences subtle symptoms while CSF A $\beta$  decreases and CSF tau increases (Hane et al., 2017). Therefore, biomarker trajectories may differ as a function of the stage to which patients belong along the neuropathological cascade.

## Neuroimaging Biomarkers in AD Imaging Amyloid and Tau Burden

Substantial advances have been made in the detection AD biomarkers using neuroimaging. In terms of imaging amyloid burden, positron emission tomography (PET) scans with radiolabeled tracers specific to A $\beta$  have become fairly common in AD research. PET amyloid ligands allows for quantification of amyloid deposition in patients, and binding of these ligands predates the development of clinical symptoms of AD by 7–15 years (Jack et al., 2013; Roe et al., 2013). [ $^{11}\text{C}$ ]Pittsburgh Compound-B (PiB), a derivative of the fluorescent benzothiazole dye thioflavin T, enables for non-invasive imaging of fibrillar A $\beta$  deposits (Klunk et al., 2004; Johnson et al., 2009). Importantly, this imaging tool is only able to detect extracellular A $\beta$  deposition, and not intracellular A $\beta$  accumulation. The Alzheimer's Disease Neuroimaging Initiative (ADNI) suggests that PiB can predict cognitive decline and brain atrophy in patients with mild cognitive impairment (MCI; represents a transition toward diagnosable dementia) (Weiner et al., 2010). Amyloid imaging is now usually performed by the use of fluorine-based tracers ( $^{18}\text{F}$  or FDG) and points to the parietal cortices as the earliest sites of amyloid deposition (**Figure 2**; Dickerson et al., 2009). The specific brain regions (posterior cingulate, retrosplenial cortex, and precuneus) are heavily connected with the medial temporal lobes (MTLs) (Ranganath and Ritchey, 2012), which are sites of early AD-related neuropathology. Tau imaging, by the use of selective PET tracers, is able to detect tau depositions that follow Braak staging of NFT pathology (**Figure 2**; Schöll et al., 2015; Cho et al., 2016; Maass et al., 2017). PET ligands have also been developed that are specific for paired-helical filament tau (Leuzy et al., 2019; Scholl et al., 2019). Post-mortem studies of AD patients indicate that, unlike amyloid plaque deposition, NFT density correlates with neurodegeneration and cognitive impairment (Duyckaerts et al., 1987; Braak and Braak, 1997). However, disentangling primary age-related tauopathy (PART) and AD may be a great challenge as there is considerable overlap in the MTL.

**FIGURE 2 |** Chronobiological biomarkers to Alzheimer's disease clinical stage. This disease model displays that biomarkers become abnormal in a temporally ordered manner as the disease progresses (Jack et al., 2010). Amyloid plaque biomarkers are dynamic early in the disease, prior to the appearance of clinical symptoms, and have largely reached a plateau by the time clinical symptoms appear (Jack et al., 2010). Biomarkers of neuronal injury, dysfunction, and degeneration are dynamic later in the disease and correlate with clinical symptom severity. MRI is the last biomarker to become aberrant. None of the biomarkers are static, and rates of change in each biomarker vary over time and follow a non-linear time-course, which is hypothesized to be sigmoid shaped (Jack et al., 2010). A sigmoid shape as a function of time implies that the maximum effect of each biomarker varies over the course of disease progression (Jack et al., 2010). Figure adapted with permission from Leclerc and Abulrob (2013). MCI, mild cognitive impairment; CSF, cerebrospinal fluid; Aβ, amyloid-β; PET, positron emission tomography; FDG, fluorine-based tracers; MRI, magnetic resonance imaging; t-tau, total tau; p-tau, phosphorylated tau.

### FDG-PET – Cerebral Glucose Hypometabolism

Positron emission tomography imaging has been used to examine brain glucose abnormalities in aging, MCI and AD (de Leon et al., 1983). FDG can be used as a metabolic marker and reduced hippocampal metabolism has been observed in patients with MCI and AD (Mosconi et al., 2005; **Figure 2**). FDG-PET is a sensitive biomarker for neuronal and synaptic degeneration (Zimmer et al., 2017), and in line with this, research indicates that cerebral glucose hypometabolism is a downstream marker of neurodegeneration. Thus, this imaging method is able to detect patients at a later timepoint in the course of AD. Studies (Kuhl et al., 1982) have demonstrated that in older ages cerebral glucose metabolism decreases, and that the MTLs, the posterior cingulate cortex and the precuneus show the least age-dependent change. These regions express significant hypometabolism in AD (Márquez and Yassa, 2019), and Mosconi et al. (2008) showed that FDG-PET could be used to differentiate healthy subjects from AD patients with 98 to 99% specificity. Recent work by ADNI 2 PET Core has examined how FDG-PET and amyloid PET can be combined to track progression of AD. For instance, they demonstrated that amyloid PET is negatively associated with

temporoparietal metabolism (Landau et al., 2012). Amyloid PET is associated with cognitive change in healthy subjects, whereas FDG-PET imaging is able to demonstrate cognitive change in MCI patients (Jagust et al., 2015). This is consistent with the spatiotemporal progression model of AD (**Figure 2**), where amyloid progression precedes neurodegeneration.

### Imaging Connectivity – Resting-State Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) techniques use blood-oxygenation-level-dependent (BOLD) contrast, which is associated with neuronal population activity. Resting-state fMRI studies examine the correlation of the BOLD signal and anatomical regions of interest at a temporal scale by analyzing spontaneous fluctuations in brain connectivity (Biswal et al., 1995; Fox and Raichle, 2007). In preclinical stages of AD, resting-state fMRI signals have been linked to metabolic changes (indexed by PET) and found to precede neurodegeneration (Sheline and Raichle, 2013). Therefore, this imaging tool is able to detect patients at some point immediately before or after amyloid plaque deposition, prior to the development of NFTs

and associated neurodegeneration. Most of these analyses have focused on the default mode network (Gusnard et al., 2001; Raichle et al., 2001), a network consisting of the MTL, the medial prefrontal cortex, posterior cingulate cortex, anterior cingulate cortex, parietal cortex, and precuneus (Greicius and Menon, 2004; Buckner et al., 2008). These regions overlap with the spatial pattern of amyloid and tau pathology (Buckner et al., 2008). In addition to changes in the default mode network, some studies have suggested that connectivity within the MTL may also be disrupted in AD (Yassa et al., 2011), such as the connectivity between EC and hippocampus [dentate gyrus (DG) and cornu ammonis field 3 (CA3)].

### Cortical Thinning and Volume Loss – Structural MRI

Compared with functional imaging modalities, structural MRI provides an overview of anatomical changes in high resolution. Research has shown that in AD patients there is a decrease in brain volume associated with cortical thinning and gyral loss (Figure 2; Uylings and de Brabander, 2002), especially in the prefrontal cortex and hippocampus (Jack et al., 2000; Raz et al., 2005). Thus, this imaging tool can detect patients in which neurodegeneration has begun to occur. Studies in aged rodents and monkeys have demonstrated that hippocampal cells do not undergo frank cell loss with healthy aging (Rapp and Gallagher, 1996; Rasmussen et al., 1996; Rapp et al., 2002); in contrast, this is observed in the prefrontal cortex (Peters et al., 1994; Smith et al., 2004; Stranahan et al., 2012). Recently, cortical thinning of the EC has been shown to be a sensitive marker for structural alterations in both patients with MCI and AD (Holland et al., 2012a). EC thickness has been found to diminish prior to, and thereby predict, hippocampal atrophy (Desikan et al., 2010, 2011, 2012; Eskildsen et al., 2013). Several recent studies using the ADNI data have shown that older adults with CSF A $\beta$  and phosphorylated-tau (p-tau) present with volume loss in EC (Desikan et al., 2012; Holland et al., 2012b).

### White Matter Integrity – Diffusion Tensor Imaging

Studies using diffusion tensor imaging (DTI) in MCI and AD patients show a decrease in brain white matter integrity but with most prominent changes in MTLs (Bozzali et al., 2002; Naggara et al., 2006; Xie et al., 2006; Huang et al., 2007; Chua et al., 2008). DTI studies have focused primarily on the fornix as this region links the limbic system with the rest of the brain. Fornix lesions have been found to reproduce memory and learning deficits linked to hippocampal damage in rats (Sutherland et al., 1982; McDonald and White, 1993) and monkeys (Gaffan et al., 1984; Gaffan, 1992, 1994). The perforant path connects EC layer II neurons to the hippocampal DG and CA3 (Witter, 2007) and is critical for normal hippocampal function (Hyman et al., 1986). The integrity of this pathway is reduced in aged rats with memory loss (Geinisman et al., 1992; Smith et al., 2000). Perforant path lesions also result in EC layer II neuronal loss (Peterson et al., 1994), i.e., at the site where neurodegeneration is first observed in AD patients. Thus, similarly to structural MRI, this imaging tool can detect AD patients at the timepoint at which neurodegeneration has occurred. *In vivo* biomarkers, such as those derived from brain imaging, are crucial for

accurate diagnosis of AD, but does not support diagnosis during preclinical stages. Additionally, molecular imaging is expensive and not easily accessible to the clinical population.

### CSF Biomarkers in AD

The current approach to diagnosing AD patients involves assessing patient history, clinical examinations, and detection of underlying pathology using biomarkers during stages of the disease (Ramesh et al., 2018b), with the latter having a diagnostic accuracy between 82 and 84% (Engelborghs et al., 2008). The clinical staging of AD usually lasts about 9–10 years (Heyman et al., 1996), however, researchers have found that the neuropathology of AD starts 20–30 years before the onset of clinical symptoms (Selkoe, 2001; Sperling et al., 2011). Thus, it is likely that, with current means, clinical diagnosis is only feasible at a late stage of the disease. Imaging tools are invaluable methods to diagnose AD patients, but additional methods are needed to detect AD pathology at an earlier stage of the disease cascade, where intervention may be able to delay, even, halt disease progression. By developing better screening and detection tools, early interventions at the preclinical stages of the disease should be possible.

Clearance of abnormal proteins by drainage into the CSF is an endogenous neuroprotective function of the brain. Clinical AD diagnosis is conducted by sampling CSF and analyzing aberrant protein levels within the sample. CSF fills the ventricular system in the brain and spinal cord (Barten et al., 2017) and research evidence suggests that the composition of CSF at any given time reflects true biochemical changes that occur in the brain (Lee et al., 2019). Most of the CSF is generated by the choroid plexus but a significant fraction derives from the interstitial fluid (ISF) in the brain and spinal cord parenchyma. ISF is the circulating CSF that bathes brain tissue (Barten et al., 2017), whereas the choroid plexus connects to nearby permeable capillaries with tight junctions and produces CSF using the aquaporin-1 water channel as well as directional ionic transporters (Speake et al., 2001; Brinker et al., 2014). In terms of CSF production and volume, studies have shown that it can change with age, disease, and time of day. For instance, CSF production increases from 0.4 to 1.4  $\mu$ L/min between 8 and 12 weeks of age in the rat (Karimiy et al., 2015). Interestingly, CSF volume has been found to increase during neurodegeneration (Barten et al., 2017), which may be related to the increase in atrophy and substance loss of the brain. It is therefore vital to keep these changes in CSF production in mind when comparing healthy subjects to AD patients, and when comparing preclinical with clinical findings.

### Temporal Course of AD Biomarkers

Amyloid- $\beta$  level changes is the first biomarker abnormality seen in AD patients, which can either be in the form of an upregulation in plasma and CSF in cognitively normal individuals (Figure 2). The increased levels seen in CSF A $\beta$ 40 and A $\beta$ 42 in AD patients is thought to reflect extracellular A $\beta$  deposits prior to the accumulation of amyloid plaques (Murphy and LeVine, 2010). However, it is important to note that A $\beta$  oligomers can form intracellularly before being deposited extracellularly, and currently this cannot be detected with existing biomarkers.

Moreover, A $\beta$  deposition detected by PET ligands can be seen as early as 15 years prior to onset of AD symptoms (Figure 2; Shen et al., 2018). The next stage of biomarker alteration include neuronal injury, shown by increased levels of CSF total tau protein (t-tau) and tau phosphorylated at threonine 181 (p-tau181/p-tau), and brain atrophy revealed by structural MRI, and synaptic loss and neurodegeneration detected by DTI or FDG-PET (Figures 2, 3; Shen et al., 2018).

## Core CSF Biomarkers for Diagnosis

Currently, CSF biomarkers are the only variety of fluid markers used for diagnosis of early AD, however, they have proven difficult to implement in the clinic due to their limited accessibility and the invasive nature of CSF collection (Lee et al., 2019). There are three core CSF biomarkers for AD diagnosis; A $\beta$ 42, t-tau, and p-tau (Shen et al., 2018). Using a combination of the core AD biomarkers is a better approach compared to using the biomarkers individually, especially for differential diagnosis (Engelborghs et al., 2008). Lower concentrations of CSF A $\beta$ 42 and higher concentrations of t-tau have been used to distinguish AD patients from healthy age-matched controls and to predict the conversion of MCI to AD (Frölich et al., 2017). To develop a non-invasive and effective measure of preclinical stages in AD, early abnormal AD biomarkers in preclinical models and patients need to be translated and assessed, followed by methodological developments of screening tools that are successful in system models that mirror the disease progression seen in patients.

## CLASSIFICATION OF AD BIOMARKERS

Alzheimer's disease biomarkers may be open to different interpretations, however, there is an international classification system proposed by the National Institute of Aging (NIH) and the Alzheimer's Association (NIA-AA) that can aid in grouping them. In 2018, CSF biomarkers could be used in conjunction with neuroimaging for the first time to diagnose AD patients (Lee et al., 2019). The A/T/N system (Table 1) is a suggested grouping by Jack et al. (2016) based on the framework from the NIH and NIA-AA, where the A refers to the A $\beta$  pathology measured either by PET or CSF A $\beta$ 42, the T represents tangle pathology and is assessed by either PET or CSF p-tau, and the N stands for neurodegeneration or neuronal injury detected by either FDG-PET, structural MRI, or CSF t-tau (Jack et al., 2016). Imaging techniques have found amyloid PET to be most reliable, whereas MRI and FDG-PET scans often are unable to distinguish AD more from other neurodegenerative disorders (Johnson et al., 2012). It is important to note that fluid biomarkers are more available and affordable compared to MRI and PET (Lee et al., 2019).

## A $\beta$ as a Biomarker for AD

Amyloid- $\beta$  production occurs at the C-terminal fragment of amyloid precursor protein (APP) by cleavage of APP by  $\beta$ -secretase (BACE1) to form C99, followed by cleavage of C99 by presenilin (PSEN) 1 or PSEN2, two enzymatic components of  $\gamma$ -secretase (Haass and De Strooper, 1999). Following

**TABLE 1 |** AT(N) biomarker grouping of the NIA-AA framework.

Biomarker class	CSF marker	Imaging marker
Amyloid (A)	CSF A $\beta$ 42 or A $\beta$ 42:A $\beta$ 40 ratio	Amyloid PET
Tau (T)	CSF p-tau	Tau PET
Neurodegeneration (N)	CSF t-tau	Anatomic MRI; FDG-PET

Adapted from Jack et al. (2016). NIH, National Institute on Aging; NIA-AA, Alzheimer's Association; CSF, cerebrospinal fluid; A $\beta$ , amyloid- $\beta$ ; p-tau, phosphorylated tau; t-tau, total tau; PET, positron emission tomography; MRI, magnetic resonance imaging; FDG, fluorine-based tracers.

production, A $\beta$ 42 aggregates and accumulates intracellularly and/or extracellularly until a critical threshold is reached, where CSF A $\beta$ 42 decreases as the peptide sequesters in amyloid plaques in the brain parenchyma (Cirrito et al., 2003; Hong et al., 2011). The long delay in the emergence of plaque deposits even in the presence of increased A $\beta$ 42, suggests an initial slow process where monomeric A $\beta$  forms small aggregates, followed by further A $\beta$  polymerization (Harper and Lansbury, 1997). The AD field cannot yet explain exactly how A $\beta$  pathology initiates, but further research on the generation of intracellular A $\beta$  monomers, their recycling, and their aggregation into oligomeric A $\beta$  may yield some answers.

One of the most widely used biomarkers in AD diagnostic research is the measurement of A $\beta$ 42 and A $\beta$ 40 in CSF (Figure 3; Rogeberg et al., 2015). Although A $\beta$ 40 is present at about 10–20 times higher concentration in CSF, A $\beta$ 42 is more prone to aggregate and shown to correlate better with AD neuropathology (Mehta et al., 2001; Hellstrand et al., 2010; Murphy and LeVine, 2010; Savage et al., 2014). It has been found that cognitively normal older adults that developed dementia in older ages had low CSF A $\beta$ 42 but not A $\beta$ 40 levels (Blennow et al., 2015). These findings can be explained in part by how A $\beta$  aggregates to form soluble oligomers, which can exist in multiple forms and are neurotoxic (Haass and Selkoe, 2007), and which finally conform to diffuse and dense plaques. Recent studies support the notion that accumulation of the A $\beta$  peptide arises from an imbalance in the production and clearance of A $\beta$  and that the ability to clear A $\beta$  diminishes with age (Wildsmith et al., 2013). An attractive early biomarker for AD is CSF A $\beta$ 42, given that both CSF t-tau and p-tau changes occur at a later time point in the disease process closer to clinically detectable dementia (Buchhave et al., 2012). Furthermore, measurement of the CSF A $\beta$ 42:A $\beta$ 40 ratio is superior to A $\beta$ 42 alone when distinguishing between MCI patients who progress and those that do not progress to AD dementia (Hansson et al., 2007; Lee et al., 2019). When comparing A $\beta$  fluid biomarkers and imaging biomarkers, studies have shown that CSF A $\beta$ 42 can detect amyloid pathology earlier than amyloid PET imaging (Figure 3; Palmqvist et al., 2016).

There appears to be a lack of consensus regarding CSF A $\beta$  concentrations in AD patients. For instance, researchers have found that CSF A $\beta$ 42 concentrations increase (Nakamura et al., 1994; Bouwman et al., 2007), decrease (Kanai et al., 1998; Tapiola et al., 2000; Wahlund and Blennow, 2003; Mollenhauer et al., 2005; de Leon et al., 2006; Beckett et al., 2010), or experience

**FIGURE 3 | AD molecular processes that can be detected by biomarkers.** *Amyloid plaques:* a widely used biomarker for diagnosis in AD is the concentration of CSF A $\beta$ 42 and A $\beta$ 40 (Roggeberg et al., 2015). Studies have shown that CSF A $\beta$ 42 can detect amyloid pathology earlier than amyloid PET imaging (Palmqvist et al., 2016). Some research shows that serum A $\beta$ 2 levels do not correlate with CSF levels (Liu et al., 2004), whereas others have found that plasma A $\beta$  can be measured with good sensitivity (Lee et al., 2019). Several S100 proteins (S100B, S100A1, S100A6, S100A8, S100A9, and S100A12) are found within amyloid plaques and in astrocytes and/or microglia near amyloid deposits (Boom et al., 2004; Shepherd et al., 2006; Walker et al., 2006; Ha et al., 2010; Afanador et al., 2014; Lodeiro et al., 2017). *NFTs:* increased CSF tau is a sensitive biomarker for neurodegeneration, but CSF p-tau is more specific to neurodegeneration linked to AD (Lewczuk et al., 2004; Blennow et al., 2015). P-tau is secreted via exosomal release, and reaches the CSF (Saman et al., 2012). Increased levels of CSF t-tau and p-tau can predict the progression of cognitive symptoms better than CSF A $\beta$ 42 (El Kadmiri et al., 2018), but the diagnostic utility of CSF t-tau and p-tau are improved when measured in combination with A $\beta$ 42 (Dubois et al., 2014). Increased plasma tau observed in AD patients compared to MCI patients and healthy controls (Mattsson et al., 2016; Pase et al., 2019). S100B and S100A9 are found within NFTs (Sheng et al., 1994, 1997; Shepherd et al., 2006). *Autophagy:* late stages of autophagy is disrupted in AD patients, as an accumulation of autophagic vesicles can be observed in dystrophic neurites (Komatsu et al., 2006), and are observed prior to extracellular A $\beta$  deposition (Mehrpour et al., 2010; Nixon and Yang, 2011). *Microglia:* YKL-40 is expressed by microglia. CSF TREM2 is associated with higher CSF t-tau and p-tau levels, probably reflecting a corresponding change in microglia activation in response to neurodegeneration (Suarez-Calvet et al., 2016). It has been shown that AD patients have higher levels of interleukin-6, 12, and 18, TNF- $\alpha$  and TGF- $\beta$ , in blood, and higher levels of TGF- $\beta$  in CSF, compared to healthy controls (Swardfager et al., 2010). Decreases in CSF neuronal CX3CL1 is found in AD patients (Perea et al., 2018). *Astrocytes:* YKL-40 is expressed in astrocytes near A $\beta$  plaques (Craig-Schapiro et al., 2010) and correlates positively with tau pathology (Querol-Vilaseca et al., 2017; Janelidze et al., 2018). *Axon terminals:* CSF levels of SNAP-25 (Brinkmalm et al., 2014; Sutphen et al., 2018) and synaptotagmin (Öhrfelt et al., 2016) have been found at elevated levels in patients with AD or MCI compared with control subjects. Synaptic neurodegeneration can be detected by DTI or FDG-PET (Shen et al., 2018). *Dendrites:* increased CSF neurogranin is found in MCI and AD patients as compared with healthy controls (Thorsell et al., 2010; De Vos et al., 2015). *Axon:* increased neurofilament light is observed in response to axonal damage, which occurs in AD. The core CSF biomarkers (A $\beta$ 42, t-tau, and p-tau) and CSF neurofilament light levels strongly correlated with AD (Olsson et al., 2016). Blood levels of this protein strongly correlate with its CSF levels (Gisslen et al., 2016; Kuhle et al., 2016; Rojas et al., 2016). *Mitochondria:* studies have shown that TDP-43 contributes to neuroinflammation and may have a role in mitochondrial and neuronal dysfunction (James et al., 2016). NAD<sup>+</sup> levels can be detected in CSF and plasma in early AD. *Extracellular:* miRNAs released from exosomes appear to be associated with neurodegenerative aspects in AD (Wang et al., 2008, 2012; Chen et al., 2017). Studies have reported that changes in levels of blood miRNA distinguished AD patients from healthy controls with 93% accuracy (Leidinger et al., 2013; Swarbrick et al., 2019). AD, Alzheimer's disease; CSF, cerebrospinal fluid; A $\beta$ , amyloid- $\beta$ ; PET, positron emission tomography; NFTs, neurofibrillary tangles; p-tau, phosphorylated tau; t-tau, total tau; MCI, mild cognitive impairment; TREM2, triggering receptor expressed on myeloid cells 2; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ ; TGF- $\beta$ , transforming growth factor- $\beta$ ; CX3CL1, CX3 chemokine ligand 1; SNAP-25, synaptosomal-associated protein 25; TDP-43, transactive response element (TAR) deoxyribonucleic acid (DNA)-binding protein 43; NAD<sup>+</sup>, oxidized nicotinamide adenine dinucleotide; miRNA, microRNA.

no significant change (Andreasen et al., 1998, 1999a; Hoglund et al., 2005; Andersson et al., 2008; Brys et al., 2009; Stomrud et al., 2010) during the disease. The prevailing explanation for a reduced amount of A $\beta$  in later stages of AD is that as the pathology progresses, more A $\beta$ , especially A $\beta$ 42, aggregates into

plaques in the brain, which effectively means that less A $\beta$  can diffuse from the brain to the CSF. Another explanation may be that A $\beta$  first accumulates intracellularly, and neurodegeneration releases A $\beta$  in the extracellular compartment, increasing CSF A $\beta$  levels, and subsequently accumulates onto neuronal surfaces and

in synapses as it clears away from the CSF. As neurodegeneration occurs, less A $\beta$  is produced and therefore smaller amounts will accumulate in the CSF and subsequently in the brain, where A $\beta$  will reach plateau levels. Alternatively, reduced CSF A $\beta$ 42 might follow neuronal dysfunction, which results in decreased metabolism of APP and A $\beta$ . It is important to note that this is unlikely in transgenic mice, as A $\beta$ 42 levels in the CSF decline, while its levels in the brain keep rising. Also, when above a certain level, parts of CSF A $\beta$ 42 may aggregate into a large assembly that antibodies of currently used enzyme-linked immunosorbent assay (ELISA) kits cannot capture (Pitschke et al., 1998; Liu et al., 2004). These seemingly disparate findings regarding CSF A $\beta$  concentrations may therefore reflect different timepoints of the disease progression.

With regard to studies using A $\beta$  as a fluid biomarker for AD, studies have shown that concentrations of CSF A $\beta$ 42 increased between 5 and 7 months of age, but not between 8 and 13 months of age in an APP/PS1 mouse model (Liu et al., 2004). This was despite a rapid increase in brain levels of A $\beta$ 42 (Liu et al., 2004). However, between 6 and 9 months of age in another APP/PS1 mouse model with a more aggressive AD phenotype a decline in CSF A $\beta$ 42 levels was reported (Liu et al., 2004). Based on these findings, it appears that CSF A $\beta$ 42 may initially reflect the rate of A $\beta$ 42 production (most likely in the synaptic cleft), but after reaching a critical threshold, CSF A $\beta$ 42 levels stay in equilibrium until plaque formation leads to their decrease (Liu et al., 2004). Consistent with this notion, CSF A $\beta$ 42 levels have a strong link with the deposition of amyloid plaques, whereby an inverse correlation between A $\beta$ 42 levels, plaques (Strozyk et al., 2003) and amyloid PET is observed (Toledo et al., 2015; Leuzy et al., 2016; Niemantsverdriet et al., 2017). This implies that as A $\beta$  aggregates and forms plaques in the brain, lower levels of the protein diffuse into the CSF (Lee et al., 2019).

Compared to tau as a fluid biomarker, the drop in CSF A $\beta$ 42 should precede the increase in CSF tau proteins. This notion is supported by biomarker studies in sporadic AD patients demonstrating that a decrease in CSF A $\beta$ 42 was the earliest change reported (Skoog et al., 2003; Gustafson et al., 2007), while in patients with familial AD reductions in CSF A $\beta$ 42 and elevations in tau occur around 10–15 years prior to symptom development (Bateman et al., 2012; Ringman et al., 2012). Similar to A $\beta$ , tau can also change its conformation to prion-like oligomers and there is evidence for misfolded A $\beta$  initiating tau misfolding (Pulawski et al., 2012; Nussbaum et al., 2013). Therefore, A $\beta$  appears to be an initiator of tau pathology and subsequent neurodegeneration.

## Tau as a Biomarker for AD

Tau is a microtubule-associated protein comprising six human isoforms and is located in neuronal axons (Barten et al., 2011; Khan and Bloom, 2016). A characteristic of many neurons in AD is that tau is hyperphosphorylated and translocated from axons to the somatodendritic compartment, where it becomes misfolded and aggregates. Tau aggregates develop intracellularly and may thus trap functional proteins adding to microtubule destabilization, cellular dysfunction and eventually neurodegeneration (Benilova et al., 2012). Intracellular trafficking

is dependent on the phosphorylation of tau in order to separate tau from microtubules, allowing transport, followed by dephosphorylation in order to return tau into microtubules (Avila et al., 2004). It has been proposed that A $\beta$  pathology drives the abnormal phosphorylation of tau in AD (Bakota and Brandt, 2016; Khan and Bloom, 2016). However, transgenic mice modeling A $\beta$  pathology alone do not develop NFTs endogenously (Lee and Trojanowski, 2001), while intracerebral injections of human mutated and/or aggregated tau are necessary to observe this neuropathological hallmark (Clavaguera et al., 2013; Ahmed et al., 2014; Kaufman et al., 2017; Lewczuk et al., 2017; Mudher et al., 2017; Narasimhan et al., 2017; He et al., 2018). Tau aggregates and NFTs are produced in the cytoplasm under pathological conditions, when tau changes its conformation from a highly soluble state to one with a high  $\beta$ -sheet content and is hyperphosphorylated (Yamada et al., 2015). Studies have shown that the elevation in CSF tau in AD is due to axonal loss and neuronal death, leading to the release of the intracellular protein (Blennow and Hampel, 2003; Hampel et al., 2010). However, despite significant neurodegeneration and tau pathology, CSF tau is not elevated in other pure tauopathies (Grossman et al., 2005; Bian et al., 2008). This suggests that cell death may not be the only mechanism responsible for CSF tau elevations in AD (Jack et al., 2010).

When using tau as a fluid biomarker for AD, increased CSF concentrations of the protein constitutes a sensitive marker for neurodegeneration, but an entirely unspecific one for AD (**Figure 3**). However, the increased concentration of p-tau molecules seems much more AD specific (**Figure 3**; Lewczuk et al., 2004; Blennow et al., 2015). P-tau is secreted via exosomal release, and reaches the CSF (Saman et al., 2012; **Figure 3**). CSF p-tau levels are usually stable in other dementias, whereas both CSF p-tau and t-tau levels can be used to distinguish AD patients from healthy controls, suggesting that CSF tau is an important biomarker for differential dementia diagnosis (Blennow et al., 2015). In addition, high CSF t-tau and p-tau can predict the progression of cognitive symptoms better than CSF A $\beta$ 42 (El Kadmiri et al., 2018; **Figure 3**). Researchers have found correlations between p-tau in CSF and NFTs in the brain (Clark et al., 2003; Buerger et al., 2006; Tapiola et al., 2009; de Souza et al., 2012), and CSF t-tau has been found to correlate with neurodegeneration (Lee et al., 2019). Importantly, the utility of CSF p-tau and t-tau for AD diagnosis is markedly improved when measured together with CSF A $\beta$ 42 (**Figure 3**; Dubois et al., 2014).

To examine CSF tau levels in rodents, researchers have used P301S human tau transgenic mice and found that ISF tau was at fivefold higher levels compared to endogenous tau, in line with its elevated levels of expression (Yamada et al., 2011). It is important to keep this in mind when comparing CSF tau between rodents and patients, as the CSF tau from rodents might be contaminated by ISF tau levels, and the CSF levels may not reflect the actual tau levels expressed in the brain. Studies have found that tau in brain tissue is approximately 50,000-fold more abundant than its levels in the CSF (Barten et al., 2011). In humans, patients with sporadic AD display longitudinal increases in tau when low levels of tau were detectable early in the disease course, but no differences (or

increases) have been observed in tau in patients with high levels of tau at baseline (Kanai et al., 1998; Sunderland et al., 1999).

Compared to A $\beta$ , which aggregates broadly in the brain parenchyma and the perivascular space, tau readily drains into CSF. In contrast to A $\beta$ , tau levels increase in the CSF with the progression of AD (Olsson et al., 2016). Changes in CSF A $\beta$ 42 precede changes in CSF tau, consistent with the proposition that A $\beta$  affects and drives CSF tau levels (Jack et al., 2010). However, further research is needed to explain whether A $\beta$  and tau pathology represent early initiators of neurodegeneration and cognitive decline, or merely downstream effects of other early pathophysiological events in AD.

## Neuroinflammatory Biomarkers

Inflammation is now considered another core feature of AD as it relates to the pathogenesis of the disease and also serves as a link between amyloid plaques and NFTs (Akama and Van Eldik, 2000; Akiyama et al., 2000). Inflammatory response has now been reported in post-mortem tissues of AD patients (Gomez-Nicola and Boche, 2015) and is routinely observed in preclinical models. The presence of inflammation in the brain of AD patients was initially thought to be a consequence of the accumulating neurodegeneration present at late stages of the disease. However, a substantial body of research now demonstrates that a persistent immune response in the brain not only is associated with neurodegeneration, but it also exacerbates A $\beta$  and tau pathology (Figure 1). Inflammatory markers may be able to give evidence to intracellular abnormalities early in the course of AD, prior to extracellular A $\beta$  deposition (marked by an increase in CSF A $\beta$ 40/A $\beta$ 42 and amyloid PET) as evidence points to a dysfunction in autophagic processes in AD patients (Figure 1; Menzies et al., 2015). Moreover, there have been reports of immune-related proteins and cells opposed to amyloid plaques (Figure 1; Griffin et al., 1989). In line with this, it has been suggested that inflammation may provide a link between the initial A $\beta$  pathology and subsequent development of NFTs (Kitazawa et al., 2004; Rhein et al., 2009; Garwood et al., 2011; Nisbet et al., 2015).

## Autophagic Markers

One way for intracellular accumulation of A $\beta$  peptides to occur is through a disruption in the autophagic and lysosomal clearance systems. In this way, autophagic markers could ultimately serve as the earliest biomarker to diagnose AD patients, as this process may likely initiate the aggregation of monomeric A $\beta$  into oligomeric A $\beta$  intracellularly (Figure 1). Autophagy is a complex process, in which a vesicle known as the phagophore elongates around the cytoplasmic components selected for degradation. The recognition of these components are dependent on the lipidated form of the microtubule-associated protein light chain 3 (LC3) (Milisav et al., 2015). The late stage of autophagy depends on the successful fusion of the autophagosome with the lysosome, which then degrades and recycles the autophagosome cargo. There is evidence supporting that the late stage of autophagy is disrupted in AD, as accumulation of autophagic vesicles can be observed in dystrophic neurites (components of dense plaques) (Komatsu et al., 2006), and these are observed prior

to extracellular A $\beta$  deposition in model systems and patients (Figure 3; Mehrpour et al., 2010; Nixon and Yang, 2011).

The above findings suggest that autophagy dysfunction leads to the accumulation of intracellular A $\beta$  by avoiding proper degradation and/or recycling. In line with this, researchers have found that LC3-associated endocytosis is used to clear and recycle A $\beta$  surface receptors (Heckmann et al., 2019). In model systems with LC3-associated endocytosis disrupted, an increase in extracellular A $\beta$  deposition, NFTs, neurodegeneration and behavioral deficits was observed. Another line of research found that autophagic markers were significantly increased in AD patients compared with control subjects (Cho et al., 2019). Furthermore, other studies suggest that metabolism of A $\beta$  and tau is crucially influenced by autophagy (Uddin et al., 2018). Recent evidence suggests that A $\beta$  monomers and oligomers modulate autophagy differently in neurons. Monomers have been found to stimulate autophagy, increasing autophagosome rates and elevation of LC3 protein levels, while simultaneously impairing the lysosomal pathway affecting the autophagy efflux, leading to autophagosome accumulation (Menzies et al., 2015). By contrast, A $\beta$  oligomers do not cause a significant increase in LC3 protein levels nor affect efflux of autophagic vacuoles (Menzies et al., 2015), which suggests that an increase in intracellular A $\beta$  monomers may be the result of a defective autophagic system. This fits the proposition that autophagic disruption and accumulation of A $\beta$  monomers constitute some of the earliest events in the AD cascade (Figure 1). The exact cascade by which autophagy can degrade amyloid plaques is still not known, however, microglial autophagy appears to play an important role.

## Glial Cells and Markers

Neuroinflammation involving astrocytes, microglia, and secreted compounds like reactive oxygen species, cytokines, and chemokines are key pathophysiological processes assessed when diagnosing AD (Ramesh et al., 2018a). Microglia and astrocytes are the two types of glial cells primarily affected (McGeer et al., 1987; Rogers et al., 1988; Bronzuoli et al., 2016), which in turn affect the clearance and production of A $\beta$ 42 (Hickman et al., 2008; Liu et al., 2017). Glial cells also affect the development and propagation of tau pathology (Asai et al., 2015) and thus influence disease progression and severity (Block et al., 2007; Calsolaro and Edison, 2016). Importantly, if glial cells are activated for too long, they can become pro-inflammatory (Bronzuoli et al., 2016). Chitinase-3-like protein 1 (or YKL-40) is an inflammatory marker expressed by microglia and astrocytes (Figure 3). In AD, YKL-40 is expressed in astrocytes near A $\beta$  plaques (Craig-Schapiro et al., 2010) and correlates positively with tau pathology (Figure 3; Querol-Vilaseca et al., 2017; Janelidze et al., 2018).

Another glial marker is triggering receptor expressed on myeloid cells 2 (TREM2), which is an inflammatory cell-surface receptor. Loss-of-function mutations of TREM2 are associated with an increased risk of developing AD (Suarez-Calvet et al., 2016). Researchers have found that TREM2 phagocytose A $\beta$  in early AD stages (Jay et al., 2017). A rare mutation in the TREM2 gene affects the phagocytic activity of microglia and consequently

contributes to accumulation of A $\beta$  (Kleinberger et al., 2014; Ramesh et al., 2018b). With regard to TREM2 measured in CSF, studies have shown increased levels to be associated with higher CSF t-tau and p-tau levels, probably reflecting a corresponding change in microglia activation in response to neurodegeneration (Figure 3; Suarez-Calvet et al., 2016). Relevant research findings imply that neuroinflammation is a robust biomarker even at pre-symptomatic stages (Janelidze et al., 2018). In line with this, high levels of inflammatory biomarkers are associated with increased CSF levels of t-tau (Janelidze et al., 2018). Interestingly, PET studies have revealed increased microglial activation in the precuneus (Hamelin et al., 2016; Fan et al., 2017), a region in the default mode network that displays early A $\beta$  deposits in AD (Palmqvist et al., 2017).

### Cytokines

With regard to cytokines, it has been shown that AD patients have higher levels of interleukin-6, 12, and 18, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and transforming growth factor- $\beta$  (TGF- $\beta$ ), in blood, and higher levels of TGF- $\beta$  in CSF, compared to healthy controls (Figure 3; Swardfager et al., 2010). Endothelial growth factor receptor 1 (also known as Flt-1), has been found to be upregulated in entorhinal cortical sections from human AD brains and in human microglia following treatment of A $\beta$ 42 (Ryu et al., 2009). Following neuroinflammation, oxidative stress in the intracellular environment occurs. Oxidative stress plays an important role in the early stages of AD (Oh et al., 2010) and its associated signaling cascades are being investigated and explored for biomarkers. For instance, higher reactive oxygen species levels lead to post-translational modification of proteins, toxic cell damage, fragmentation and aggregation of A $\beta$  (Brinkmalm et al., 2014). One type of reactive oxygen species are sulfatides, which have been found to be depleted in both gray and white matter of AD patients, and results in decreased hippocampal volume and cognitive decline (Ramesh et al., 2018b).

Since neuroinflammation occurs in AD brains, the levels of several S100 proteins are increased and some of the proteins play roles related to the processing of APP, regulation of A $\beta$  levels and tau phosphorylation. S100A1, S100A6, and S100B have been found to be involved in the disassembly of microtubules and tau protein release (Zimmer et al., 2005; Roltsch et al., 2010; Wruck et al., 2016; Sidoryk-Wegrzynowicz et al., 2017), while S100B and S100A9 are found within NFTs (Figure 3; Sheng et al., 1994, 1997; Shepherd et al., 2006). Traumatic brain injury (TBI) has been found to predispose people to developing AD (Johnson et al., 2010). Interestingly, TBI results in an increase in S100A1 and S100B levels in plasma and CSF in patients (de Boussard et al., 2005). Research has shown that levels of S100B originating from necrotic tissue might enhance or amplify neurodegeneration by apoptosis (Sedaghat and Notopoulos, 2008). Thus, various S100 proteins could be a link between neurodegenerative diseases induced by brain damage. Comorbidities often accompany a diagnosis of AD, thus the spectrum of pathological processes that can end in AD at different degrees of severity and symptomology needs to be kept in mind in order to accurately diagnose and treat patients. Additionally, S100 proteins may serve as an early biomarker for

a later AD diagnosis in patients with TBI or other comorbidities that increase S100 levels.

Moreover, several S100 proteins are implicated in the amyloidogenic pathway of APP cleavage. S100A9 regulates  $\gamma$ -secretase and BACE1 expression and activity (Kummer et al., 2012; Li et al., 2014), and S100B and S100A1 regulate APP levels (Zimmer et al., 2005; Anderson et al., 2009; Mori et al., 2010). S100A7, S100A8, S100A9, and S100B have been found to influence A $\beta$  levels (Qin et al., 2009; Lee et al., 2013; Lodeiro et al., 2017; Cristovao et al., 2018). Moreover, S100B and S100A6 have been found to reduce zinc levels and senile plaque load in preclinical models (Roltsch et al., 2010; Hagmeyer et al., 2017; Tian et al., 2019). S100A1, S100A9, and S100B proteins can interact and alter the aggregated A $\beta$  and is found to co-aggregate with A $\beta$  peptides (Zimmer et al., 2005; Shepherd et al., 2006; Ha et al., 2010; Mori et al., 2010; Chang et al., 2012; Afanador et al., 2014; Cristovao et al., 2018). In line with this, several S100 proteins (S100B, S100A1, S100A6, S100A8, S100A9, and S100A12) are present in amyloid plaques and in astrocytes and/or microglia near amyloid deposits (Figure 3; Boom et al., 2004; Shepherd et al., 2006; Walker et al., 2006; Ha et al., 2010; Afanador et al., 2014; Lodeiro et al., 2017).

### Chemokines

In order to maintain brain homeostasis, microglia establish continuous communication with neurons and astrocytes, through the expression and secretion of chemokines (Mennicken et al., 1999). The CX3 chemokine ligand 1 (CX3CL1; or fractalkine), is predominantly expressed in neurons (Bazan et al., 1997) and interacts with the CX3 chemokine receptor 1 (CX3CR1) exclusively present in microglia (Imai et al., 1997; Maciejewski-Lenoir et al., 1999). The CX3CL1/CX3CR1 tandem allows for direct communication between neurons and microglia (Harrison et al., 1998; Sheridan and Murphy, 2013), and it has been suggested that this axis becomes impaired in AD patients (Bolos et al., 2017). Consistent with this, neuronal CX3CL1 is found to be decreased in CSF from AD patients compared to MCI and control subjects (Figure 3; Perea et al., 2018). Furthermore, researchers have aimed to regulate neuroinflammation in tau depositing mouse lines by overexpressing CX3CL1 and found that it significantly reduced tau pathology, ameliorated neuronal loss, reduced microgliosis (Nash et al., 2013) as well as rescuing cognitive function (Finneran et al., 2019). In another line of research, it has been found that when microglia are transferred from tau depositing knock-out *Cx3cr1* mice, hyperphosphorylation of endogenous murine tau is observed (Maphis et al., 2015). Disruption of CX3CL1 signaling in amyloid depositing mouse lines has shown reduced pathology due to increased microglial phagocytosis of amyloid plaques (Lee et al., 2010).

### Synaptic Neurodegeneration Markers

There is of yet no established or reliable biomarker test for synaptic degeneration, which is considered a crucial feature for the development of AD-related cognitive decline. The ability to monitor neurodegeneration as a downstream effect of synaptic dysfunction would be an important advantage for

early AD diagnosis and in clinical trials related to drug testing. Synaptotagmin, a pre-synaptic calcium sensor vesicle protein, facilitates neurotransmitter release from the synaptic vesicle by exocytosis and also functions as an essential vesicle cargo molecule in hippocampal neurons (Leinenbach et al., 2014). Various studies have shown a decrease in synaptotagmin-1 in AD patients (Mattsson et al., 2011).

Another marker for synaptic degeneration is synaptosomal-associated protein 25 (SNAP-25), which is an essential component of the soluble N-ethylmaleimide-sensitive fusion protein attachment protein receptors (SNARE) complex that mediates synaptic communication by initiating fusion of synaptic vesicles (Olsson et al., 2016). A negative correlation has been found between SNAP-25 and cognitive decline, suggesting that this is a promising novel CSF biomarker for AD (Andreasen et al., 1999b). Overall, CSF levels of SNAP-25 (Brinkmalm et al., 2014; Sutphen et al., 2018) and synaptotagmin (Öhrfelt et al., 2016) have been assessed and found at elevated levels in patients with AD or MCI compared with control subjects (Figure 3). Another marker for synaptic neurodegeneration is neurogranin, which plays an important role in synaptic plasticity and long-term potentiation processes (Geppert et al., 1994; Sudhof and Rizo, 1996; Thorsell et al., 2010). Neurogranin has also been found at increased levels in CSF of patients with MCI and dementia due to developing AD as compared with healthy controls (Figure 3; Thorsell et al., 2010; De Vos et al., 2015). CSF neurogranin concentrations have been found at increased levels in patients that have reached the threshold for A $\beta$  PET detection (Palmqvist et al., 2019), and also CSF neurogranin and tau levels have been found to correlate strongly (Thorsell et al., 2010; De Vos et al., 2015).

## Novel Biomarkers for AD

Many biomarkers are now being investigated as complimentary to the core AD biomarkers. One such biomarker is neurofilament light, which is a marker of neuronal integrity reflecting axonal damage of the subcortical white matter (Petzold, 2005; Jahn and Fasshauer, 2012; Neselius et al., 2012; Kuhle et al., 2015; Zetterberg et al., 2016). Neurofilament light is released from axons into the extracellular space during healthy aging, which results in increased CSF level concentrations (Figure 3). The release of neurofilament light is accelerated during axonal damage, which occurs in AD (Figure 3). A recent meta-analysis showed that the core CSF biomarkers (A $\beta$ 42, t-tau, and p-tau) and CSF neurofilament light levels strongly correlated with AD (Figure 3; Olsson et al., 2016). Importantly, CSF neurofilament light levels have been shown to be higher in AD (Sjogren et al., 2001; Pijnenburg et al., 2007; Zetterberg et al., 2016; Alcolea et al., 2017; Lista et al., 2017). Blood neurofilament levels strongly correlate with CSF levels (Figure 3; Gisslen et al., 2016; Kuhle et al., 2016; Rojas et al., 2016), and blood neurofilament light concentrations have been found at increased levels in many forms of neurodegenerative disease (Gisslen et al., 2016; Kuhle et al., 2016; Rohrer et al., 2016; Rojas et al., 2016; Steinacker et al., 2016, 2017; Weydt et al., 2016; Mattsson et al., 2017a) and have proven almost as reliant as CSF analysis in monitoring treatment outcome in patients (Bacioglu et al., 2016; Disanto

et al., 2017). Another novel biomarker is the transactive response element (TAR) deoxyribonucleic acid (DNA)-binding protein 43 (TDP-43) protein, which can become pathologic if triggered by A $\beta$  peptides. Studies have shown that TDP-43 contributes to neuroinflammation and may have a role in mitochondrial and neuronal dysfunction (Figure 3; James et al., 2016). In accordance with this, TDP-43 pathology has been observed in some AD cases (Amador-Ortiz et al., 2007; Chang et al., 2015; James et al., 2016). Another novel biomarker is oxidized nicotinamide adenine dinucleotide (NAD<sup>+</sup>; involved in mitochondrial homeostasis), which has been found to decrease during healthy aging, but even more rapidly in neurodegenerative diseases (Figure 3; Lautrup et al., 2019). This could be related to the observed decrease in neuronal metabolism that occurs during healthy aging, but this is accelerated in the AD brain. NAD<sup>+</sup> levels can be detected in CSF and plasma early during the disease progression, and in combination with core biomarkers, it presents as a novel preclinical biomarker for AD (Figure 3).

Neuropathology is associated with a distinct subset of cells in specific regions in the brain and this makes the identification of relevant biomarker molecules a challenge. The transport of macromolecules from the brain to the CSF and blood, mediated by extracellular vesicles, presents a promising source of central nervous system (CNS)-specific biomarkers (Thompson et al., 2016). One such trafficking macromolecule is exosomes, which can be picked up in CSF. An increasing body of evidence suggests that exosomal proteins and microRNAs (miRNAs) may constitute novel biomarkers for clinical AD diagnosis (Van Giau and An, 2016). miRNAs released from exosomes appear to be associated with neurodegenerative aspects in AD (Figure 3; Wang et al., 2008, 2012; Chen et al., 2017). miRNAs are a class of small non-coding RNAs which regulate over 50% of protein-coding genes, and miRNA-107 has been found to be downregulated in AD brains (Van Giau and An, 2016; Fransquet and Ryan, 2018; Ramesh et al., 2018b). Accumulating evidence presents that miRNAs regulate A $\beta$  production, NFT formation, and neurodegeneration by targeting different genes (Wang et al., 2008; Van Giau and An, 2016). Research has also identified BACE1 as a target of miRNA-107, connecting the level of miRNA-107 to A $\beta$  formation and neuronal pathogenesis (Wang et al., 2008).

## CSF AND BLOOD-BASED BIOMARKERS

Although protein content is lower in CSF compared to blood, CSF holds great value for developing consistent biomarkers for AD as it reflects biochemical changes in the brain by direct interaction with the extracellular space (Hampel et al., 2012). At present, there is no approved blood biomarker for AD (Stadtman and Levine, 2003). It is important to note, however, that blood biomarkers have lower sensitivity and specificity than CSF biomarkers, and this can be attributed to the fact that the blood-brain barrier (BBB) prevents diffusion of analytes into the blood via a filtering mechanism (Lee et al., 2019). Furthermore, one complication of measuring CNS biomarkers in blood is that many of the analytes are produced in the

periphery as well as in the brain, and thus the source of detectable change may be difficult to determine (Barten et al., 2017). However, there is currently an urgent need within the field to develop blood-based biomarkers which are inexpensive and which can detect early neuropathological changes in AD (Hane et al., 2017). For instance, detection of autophagic markers in plasma could serve as an early biomarker for AD (Cho et al., 2019). Blood test sampling is routinely performed in the clinic, it is minimally invasive, cheap and suitable for recurrent measurements (Shen et al., 2018).

When comparing A $\beta$  levels in blood and CSF, some researchers have found that serum A $\beta$ 42 levels do not correlate with CSF levels (Figure 3; Liu et al., 2004). However, contrary to this, others have found that plasma A $\beta$  can be measured with good sensitivity (Figure 3; Lee et al., 2019). A $\beta$  can easily penetrate the BBB and is therefore an attractive blood biomarker candidate (Lee et al., 2019). Indeed, studies have shown that cerebral amyloid deposits may be sourced in the periphery, while other studies suggest that amyloid deposits in cerebral vessels may originate from circulating A $\beta$  peptides (Yankner and Mesulam, 1991; Chen et al., 1995; DeMattos et al., 2002; Lee et al., 2019). Plasma A $\beta$  and A $\beta$ -approximate peptide concentrations have been reported to be consistent with amyloid PET results (Kaneko et al., 2014). Moreover, levels of A $\beta$ 42 and the ratio of A $\beta$ 42:A $\beta$ 40 in plasma have been shown to correlate with CSF concentrations and with amyloid PET (Janelidze et al., 2016; Verberk et al., 2018). However, it is important to note that some researchers have found that reduction of A $\beta$  in the periphery does not reduce brain A $\beta$  levels (Georgievska et al., 2015) [but see Jin et al. (2017)].

To date, neurofilament light is the only biomarker that is translatable from plasma to CSF, and therefore holds great promise as a clinical tool to predict cognitive decline and neurodegeneration in AD (Figure 3; Zetterberg et al., 2016; Mattsson et al., 2017a; Lewczuk et al., 2018). Furthermore, it has been shown that measurements in blood and CSF levels strongly correlate and that neurofilament light increases coincided with the onset and progression of corresponding amyloid pathology in the brain (Figure 3; Bacioglu et al., 2016). Studies have shown that plasma neurofilament light can be used as a non-invasive biomarker that strongly correlates with neurodegeneration in human AD patients (Mattsson et al., 2019). Moreover, plasma t-tau levels can be used for screening and prognosis of cognitive decline in patients where CNS injury has been ruled out (Molinuevo et al., 2018). However, there are decreased amounts of tau in plasma compared to CSF (Barten et al., 2017; Mattsson et al., 2017b), but increases have been found in plasma of AD patients when compared to MCI patients and healthy controls (Figure 3; Mattsson et al., 2016; Pase et al., 2019). Studies looking at circulating RNA biomarkers for AD have reported that changes in levels of blood miRNA distinguished AD patients from healthy controls with 93% accuracy (Figure 3; Leidinger et al., 2013; Swarbrick et al., 2019). Therefore, blood miRNAs could be an addition to the biomarker toolbox for diagnosing AD patients. For a more extensive review on comparisons between CSF and blood biomarkers in AD, and developments in biochemical analyses of blood, see Ashton et al. (2020).

## METHODS FOR CSF SAMPLING

### CSF Collection in Human Patients

The most commonly used method for sampling CSF in human patients is by lumbar puncture. Clinically, lumbar punctures are routinely performed for diagnosing multiple brain disorders (e.g., meningitis, encephalitis, multiple sclerosis) and for the administration of spinal anesthesia and chemotherapy. However, there are several limitations associated with the use of lumbar punctures, such as associated pain during and after the sampling (including post-puncture headache) in patients (Blennow et al., 2015). Additionally, CSF sampling in patients who cannot cognitively consent to the procedure is ethically problematic. One also needs to keep in mind that A $\beta$  is higher in lumbar CSF (Brandner et al., 2014), and tau is higher in ventricular CSF (Tarnaris et al., 2011; Pyykkö et al., 2014; Herukka et al., 2015) when using this method for CSF collections. However, the timing of intraventricular CSF sampling will likely affect concentrations of A $\beta$  and tau, for example whether the sample is taken immediately after the insertion of a ventricular catheter. Research suggests that increased ventricular CSF tau concentrations may be caused by the sampling procedure itself, whereby neurons affected by the insertion of the needle for spinal tap increasingly release tau molecules (Brandner et al., 2014). In line with this, CSF samples taken shortly after surgery often have elevated tau and neurofilament light levels (Barten et al., 2017). CSF flow rate is slower in lumbar regions compared to cephalic regions (Sweetman and Linninger, 2011), and this may additionally cause the differences in concentrations of analytes. However, contradictory evidence suggests that p- and t-tau concentrations are 20–30% lower in intraventricular CSF, compared to lumbar CSF, and that this initial upregulation post-surgery is stable in patients irrespective of brain A $\beta$  pathology (Leinonen et al., 2019).

### CSF Collection in Animal Models

The most commonly used method for sampling CSF in rodents is collections from the cisterna magna, however, this sampling method usually constitutes a terminal procedure. Collections from the cisterna magna in preclinical models for *in vivo* sampling of CSF have proven a valuable technique for studying treatment outcomes after drug delivery to the CNS. This CSF sampling method offers the advantage of serial sampling without the cofound of anesthesia, with the added benefit of using animals as their intrinsic controls (Amen et al., 2017). Another technique involves inverting animals during CSF collection in order to drain spinal CSF into the cisterna magna (DeMattos et al., 2002). An alternative technique involves collecting CSF by puncturing the membrane by suction using a pipette (DeMattos et al., 2002; Barten et al., 2011). One major limitation of collections from the cisterna magna in preclinical models is the small volume of CSF that can be obtained. In transgenic mice, the average volume is approximately 5–15  $\mu$ l for terminal sampling (Liu and Duff, 2008). For serial sampling, a maximum of 7–8  $\mu$ l can be safely taken each time at an interval of 2–3 months (Liu and Duff, 2008).

Microdialysis is an alternative CSF sampling technique, which allows continuous *in vivo* sampling of molecules within the extracellular space (Takeda et al., 2011), which may help circumvent some of the above limitations. Sampling using this method relies on diffusion of analytes across a semi-permeable dialysis membrane (Takeda et al., 2011). This method is advantageous over other CSF sampling techniques as it enables serial sampling that follows the dynamic temporal alterations of a target molecule without necessitating the collection of biopsy samples or sacrifice (Meyding-Lamadé et al., 1996; Trickler and Miller, 2003; Liu et al., 2004; Liu and Duff, 2008). Importantly, each preclinical model can serve as their own intrinsic control in order to reduce inter-animal variability and the number of animals used in experiments. One limitation of this method, however, is detection of large molecules due to adsorption in tubing and the dialysis membrane, as well as low concentration of analytes in the target tissue (Ao and Stenken, 2006). Furthermore, histochemical techniques have revealed that severe gliosis around implanted devices such as microdialysis cannulas takes place at about 4 days after the surgery (Hamberger et al., 1985; Benveniste and Diemer, 1987; Benveniste et al., 1987). Reports suggest that a complete recovery of physiological functions occurs at the earliest at 5–7 days after the implantation surgery (Drijfhout et al., 1995).

## CSF AD BIOMARKERS AND TREATMENT

Studies suggest that the neuropathological events that occur in AD may disturb physiological functions of the BBB and thereby distribution of drugs to the brain (Pahnke et al., 2014; Vellonen et al., 2017). Drug molecules in the peripheral circulation are controlled and limited from entry into the brain by the BBB, while dysfunction of the BBB has been associated with neurodegeneration (Vellonen et al., 2017). Furthermore, AD drugs may not be transported to their site of action due to a dysfunctional BBB. This may lead to an increase of the drug in the brain leading to unwanted effects, or decreased drug circulation leading to an insufficient response (Vellonen et al., 2017). Many agents are better dosed directly into the CSF than peripherally because of limited permeability of the drug through the BBB (Barten et al., 2017). The presence of A $\beta$  plaques, brain atrophy and dilated ventricles in the AD brain may affect the distribution of drugs in brain tissue (Vellonen et al., 2017). CSF levels of autophagic markers, A $\beta$  and tau may help select an appropriate AD treatment for the timepoint of diagnosis. The CSF pharmacokinetics of a treatment after administration may show how well the drug entered the CNS. Therefore, levels of CSF autophagic markers or A $\beta$  could be a pharmacodynamic marker of inhibited A $\beta$  production (Dockens et al., 2012; Albright et al., 2013; Coric et al., 2015), and, in a longer term, CSF tau decreases could be a downstream functional marker of reduced neurodegeneration (Riekse et al., 2006).

## Assessing Autophagy in CSF Samples

Inductors of autophagy could be used in order to halt or stop the development and progression of A $\beta$  pathology in model systems and patients with AD. Trehalose, an inductor of autophagy,

was found to significantly improve memory and learning tasks in APP/PS1 mice (Rami, 2009). Importantly, A $\beta$  deposits were found to be significantly reduced in the hippocampus of these mice (Rami, 2009). Furthermore, the induction of autophagy by rapamycin in another model system was found to improve cognitive performance through the degradation of extracellular A $\beta$  depositions (Rami, 2009), and has been found by others to inhibit tau pathology (Caccamo et al., 2010). In AD, changes in early endocytosis and autophagy can be detected in CSF (Armstrong et al., 2014). Moreover, some work within the AD field has focused on lysosomal proteins, as they can be found in and around amyloid plaques and is present in CSF (Cataldo and Nixon, 1990; Schwagerl et al., 1995). It is now widely believed that the deposition of A $\beta$  is an early initiator of neurodegeneration in AD, thus finding methods that can reduce A $\beta$  or enhance its clearance could be a strong therapeutic target. In this sense, autophagy appears to be the first line of defense against accumulation of A $\beta$ .

## Assessing A $\beta$ Pathology in CSF Samples

Cerebrospinal fluid A $\beta$ 40 and A $\beta$ 42 may be useful (in addition to other biomarkers) in assessing efficacy of drugs such as BACE1 inhibitors, which selectively decrease toxic forms of A $\beta$  (Kennedy et al., 2016). For instance, when CSF levels of A $\beta$ 42 are still rising during early stages of amyloid pathology, decreased levels of CSF A $\beta$ 42 measured after treatment would show a successful outcome, but at a later stage in amyloid pathology the same finding may indicate accelerated plaque formation (Liu et al., 2004). Anti-amyloid agents are most likely more effective during early AD since deposition of the protein begins many years before diagnosis (Musiek and Holtzman, 2015). Promoting the elimination of A $\beta$  by enzymatic degradation or by clearance enhancement may halt both the aggregation and the accumulation of the peptide (Menendez-Gonzalez et al., 2018). The choroid plexus is known to produce A $\beta$  (Krzyzanowska and Carro, 2012), thus the effect of A $\beta$  synthesis inhibitors on CSF A $\beta$  is bound to reflect changes both sourced in the brain and in the choroid plexus. In addition, evidence suggests that the choroid plexus can remove substances, such as A $\beta$ , from the CSF (Matsumoto et al., 2015).

## BACE1 Inhibitors

A potent BACE1 inhibitor known as Verubecestat has been shown to reduce plasma, CSF and brain levels of A $\beta$ 40, A $\beta$ 42, and soluble APP $\beta$  (a direct product of BACE1 enzymatic activity) after short- and long-term administration in rats and monkeys (Kennedy et al., 2016). Recently, a study in healthy elderly AD subjects who received treatment with a BACE1 inhibitor showed no alterations in CSF BACE1 levels following treatment, but revealed a strong link between levels of CSF BACE1 and downstream markers such as CSF A $\beta$ 42 (Timmers et al., 2017). Genetic deletion of BACE1 eliminated A $\beta$  production and resolved the amyloid plaques and cognitive deficits observed in transgenic mice over-expressing human APP with familial AD mutations (Dominguez et al., 2005; McConlogue et al., 2007; Ohno et al., 2007). Researchers have demonstrated that long-term BACE1 inhibition diminishes CSF tau levels both in early

depositing APP transgenic mice and APP transgenic mice with moderate A $\beta$  pathology (Schelle et al., 2017). Overall, BACE1 inhibition appears to not only reduce A $\beta$  generation, but also downstream AD neuropathology (Schelle et al., 2017).

### $\gamma$ -Secretase Inhibitors

$\gamma$ -secretase inhibitors have also proven promising as a therapeutic approach; APP/PS1 mice treated with this compound displayed that a modest decrease (~30%) of A $\beta$  in ISF was enough to halt amyloid plaque development (Yan et al., 2009). Also, NGP 555 (a  $\gamma$ -secretase inhibitor) has been shown to shift amyloid peptide production to the smaller, non-aggregating forms of amyloid (Olsson et al., 2014; Kounnas et al., 2017). Inhibition of  $\gamma$ -secretase has initially been unsuccessful as a therapeutic target (Cummings, 2010), but more recent compounds have been shown to avoid notch-related toxicity and side effects (Basi et al., 2010; Imbimbo et al., 2010). One failure of slowing A $\beta$  production in patients may be that non-homogenous groups of patients have been included in the trials, and that the treatment has been administered too late in the disease course or has been too short (Bjerke and Engelborghs, 2018). In line with this, some clinical trials have reported changes in CSF A $\beta$ 42, but no improvement in clinical endpoints (Ritter and Cummings, 2015).

## COMPARATIVE BIOMARKING

Studies aiming to translate findings between AD system models and patients found that tau derived from AD brains injected into susceptible mouse models induced prion-like tau aggregation (Skachokova et al., 2019). CSF from AD or MCI patients injected into the hippocampus of young P301S tau transgenic mice increased tau phosphorylation and NFT formation 4 months following injection. Post-seeding, the injections accentuated tau pathology in the contralateral hippocampus of the mice, indicative of spreading (Skachokova et al., 2019). Other researchers found that peritoneal dialysis reduced plasma A $\beta$  levels in both chronic kidney disease patients and APP/PS1 mice. ISF A $\beta$  levels in APP/PS1 mice immediately decreased after reducing blood A $\beta$  by peritoneal dialysis. The treatment also attenuated other AD-type pathologies, including inflammation, tau hyperphosphorylation, neurodegeneration, synaptic dysfunction, and rescued the behavioral deficits of the mice. Importantly, the A $\beta$  phagocytic function of microglia was enhanced in APP/PS1 mice after peritoneal dialysis (Jin et al., 2017). Current strategies for clearing A $\beta$  focus on introducing agents into the brain (Jin et al., 2017), but this likely causes adverse effects such as neuroinflammation and tissue scarring (Iijima-Ando et al., 2008; Liu et al., 2012), in addition to increased endogenous tau levels.

### The ABC Scoring System

Well-characterized mouse models hold great translational value given that identifying patients at preclinical AD stages has proven difficult (Bacioglu et al., 2016). However, there are important differences between species, which should be kept in mind while interpreting results (Barten et al., 2017). The ideal

**TABLE 2 |** The ABC scoring system developed by NIA-AA.

Assessment	NIA-AA scoring
A $\beta$ plaques	A0 (not)
	A1 (low)
	A2 (intermediate)
	A3 (high)
NFTs, including pretangles and threads	B0 (not)
	B1 (low)
	B2 (intermediate)
	B3 (high)
Neuritic and diffuse plaque density	C0 (not)
	C1 (sparse)
	C2 (moderate)
	C3 (frequent)

*The scoring system can be used to help assess and validate the neuropathological features of AD in mouse lines that are potential preclinical models for AD research. Reproduced with permission from Keene et al. (2016). NIA-AA, Alzheimer's Association; A $\beta$ , amyloid- $\beta$ ; NFT, neurofibrillary tangle.*

translational model for AD would require A $\beta$  and tau deposition in a pathological manner and disease-relevant accumulation of amyloid plaques and tangles similar to that seen in AD patients (Keene et al., 2016). The ABC scoring system (Table 2) can be used to determine the level of AD neuropathological change in both system models and patients. The ABC score is generated by a summary of measures of amyloid plaque distribution A0 to A3 (Thal stages), NFT distribution B0 to B3 (Braak stages), and cortical neuritic plaque density C0 to C3 [Consortium to Establish a Registry for Alzheimer's Disease (CERAD) score] (Keene et al., 2016). The ideal translational model system of human AD would display amyloid plaques and NFTs in a spatial and temporal manner correlating with "no" or "low" AD pathology at early ages, progressing to "intermediate" and "high" AD pathology at older ages or in the presence of gene mutations related to neuropathological development (Keene et al., 2016).

In terms of the specifics of the ABC scoring system (Table 2), scoring of diffuse A $\beta$  plaques is based on assessment in the cerebral cortex, hippocampus, striatum, midbrain, brainstem, and cerebellum (Box 1) according to staging established by Thal et al. (2002) resulting in a Thal phase 0–5, which is translated into the NIA-AA score of A0–A3. Meanwhile, scores for NFTs are determined in the *trans*-entorhinal cortex, corpora ammonis, fronto-parietal cortex, and primary visual cortex (Box 1) to generate a Braak stage (Braak and Braak, 1991), which is translated into the NIA-AA score of B0–B3. Since most existing mouse models do not generate NFTs, the NIH have developed a modified B score for p-tau pathology, including distribution of pre-tangles and threads. In addition, most existing mouse models do not form neuritic plaques (contains fibrillar A $\beta$ ), so a C score for CERAD (Sperling et al., 2011) neuritic plaque density (none, sparse, moderate, or frequent) and a modified C score for diffuse plaque (does not contain fibrillar A $\beta$ ) density are generated from frontal and parietal cortex. Considering that behavioral data from mice have replication issues and are challenging to translate to patients, memory testing *per se* should not constitute a validation criterion or a drug testing endpoint (Keene et al., 2016).

## CSF Collection Methods

When translating CSF biomarkers between system models and patients, an advantage with subcutaneous access systems is that drugs can be dosed and also samples can be obtained from unanesthetized animals, as is typical with humans, and without the confound of anesthesia on CSF production or flow. It has been shown that anesthesia can cause disturbances in neurotransmitter density and cell metabolism, and therefore most times, it is desirable to perform experiments on non-anesthetized animals (Kehr, 1999). It is important to note that in most rodent studies, CSF is collected from the cisterna magna above the spinal column, whereas in humans most CSF is collected from the lumbar spinal vertebrae, and therefore drainage from this latter area in preclinical models has a translational advantage (Barten et al., 2017).

Due to the difficulties in collecting CSF samples from preclinical models the quality of the sample may be comprised, and therefore should be tested. The quality of the sample is most often affected by blood and brain-derived protein contamination (Barten et al., 2017). It is critical to minimize blood-contamination when analytes of interest are found in much higher concentration in the blood compared to the CSF, such as the 1:50,000-fold gradient of tau. Another major contamination source of CSF is proteins released in the brain during the collection procedure; this has a higher impact on tau levels compared to A $\beta$  (Barten et al., 2005).

Furthermore, biomarker development for clinical utility is currently being hampered as comparisons of measurements and techniques between laboratories tend to be unreliable. Factors that may induce variability include storage in different tube types, different aliquot volumes, and the number of freeze-thaw cycles performed, which significantly influences CSF biomarker concentrations (Clough, 2005; Bjerke and Engelborghs, 2018). For instance, CSF A $\beta$ 42 measures have been found to be greatly influenced by pre-analytical factors such as the type of collection tube used and the number of freeze-thaw cycles of the sample (Perret-Liaudet et al., 2012b; Toombs et al., 2013; Leitão et al., 2015). Various studies have determined the importance of tube types when collecting CSF samples, highlighting that it is crucial to use polypropylene vials (Perret-Liaudet et al., 2012a), and that the tubes are filled to enhance the volume to surface ratio (Perret-Liaudet et al., 2012a). Ultimately there is poor standardization of biobanking protocols and assay consistency, a fact that hampers novel biomarker discoveries and replication of important findings (Teunissen et al., 2018).

One of the reasons why non-human primates are being preferred over canine or rodent species in CSF studies is that they share an upright orientation of the spinal column akin to humans (Spector et al., 2015). Moreover, the difference in brain size (and thereby CSF volume) between mice and humans is over 3000 times, whereas macaque brains are 10- to 20-fold smaller than human brains. Therefore, the distance from the CSF compartments to deeper regions of the brain significantly varies across species and likely influences the exchange analytes (Spector et al., 2015). Nevertheless, most differences across species are otherwise minor, including the volume ratio of CSF to the brain, ranging from 9 to 18% across species

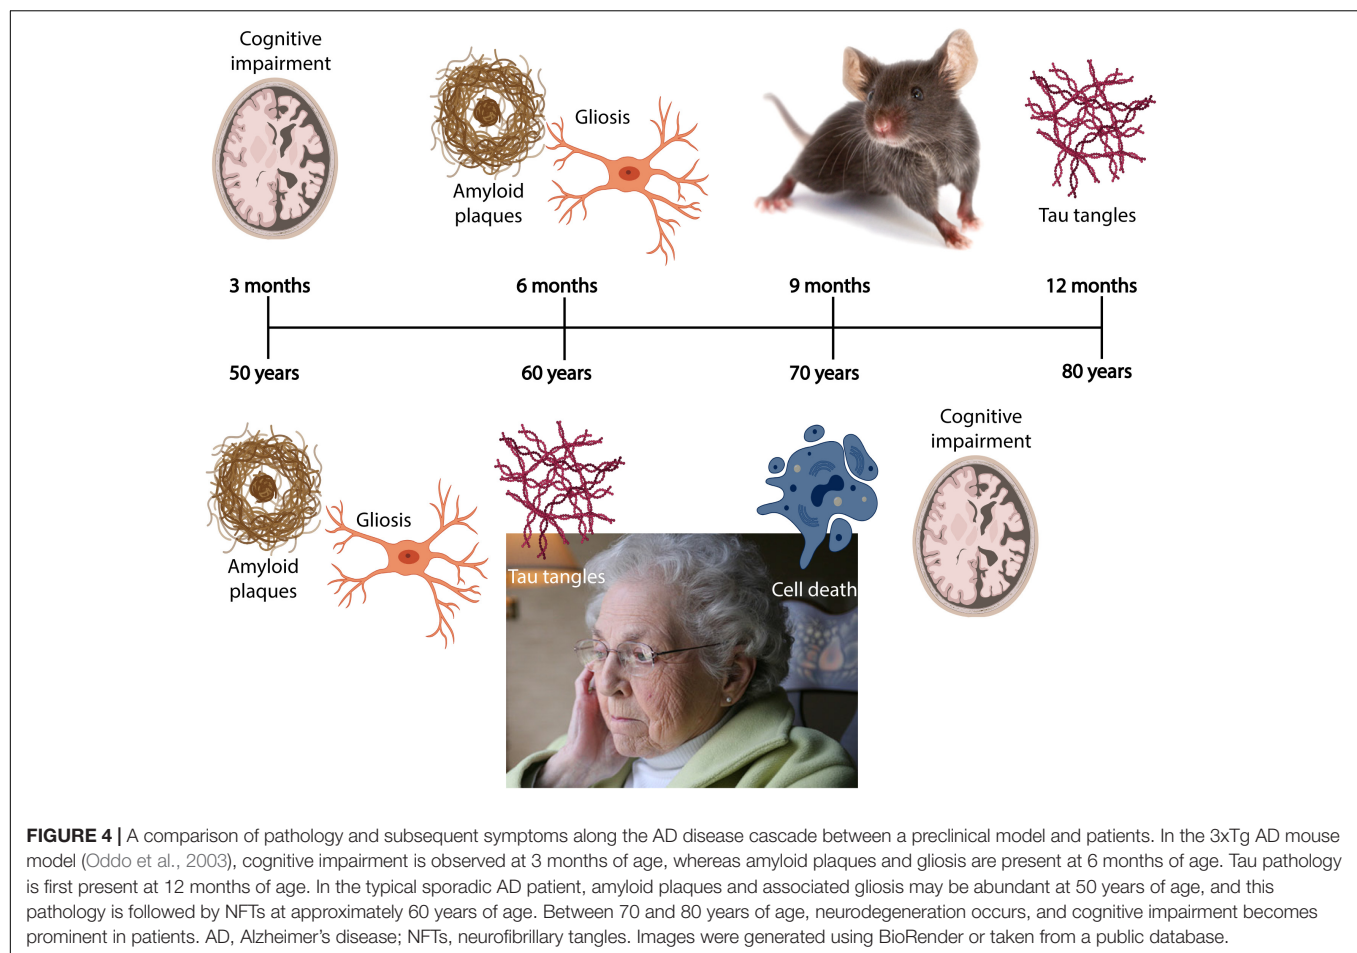

(Barten et al., 2017). CSF turnover per day is also similar between humans and macaques, but is approximately 2-fold higher for rats and 3-fold higher for mice (Barten et al., 2017). The higher turnover rate for rodents can be explained by movement of CSF initiated by the ventricles and arterial pressure as a result of a fast heartbeat, which creates an increase in back- and forth movement of the CSF (Feinberg and Mark, 1987; Sweetman and Linninger, 2011).

## The Physiology of CSF

The exchange of CSF analytes (including therapeutics) may be highly different between patients and rodents as the latter have a much faster heart rate. However, this factor has not been studied. Non-human primates are most likely better preclinical *in vivo* models for biomarker translation because body weight-based allometric scaling is comparable (Karelina et al., 2017). Moreover, ventricular CSF from AD patients has been found to contain a rare high-molecular-weight tau species that was found to exert high seeding activity (Takeda et al., 2016). This needs to be kept in mind when comparing CSF samples gathered from different regions. Moreover, the sleep-wake cycle regulates ISF and CSF levels of A $\beta$  in AD (Holth et al., 2019), and it has been shown that chronic sleep deprivation increases A $\beta$  plaques. Mouse ISF tau was found to increase ~90% during normal wakefulness versus sleep and ~100% during sleep deprivation. The relevant study found that sleep deprivation significantly increased CSF A $\beta$  by 30% (Lucey et al., 2018). This means that the time of day is bound to influence A $\beta$  levels in CSF, which suggests that the timing of sampling needs to be chosen with care and kept consistent between clinical sampling and experiments for correct comparisons.

## The Efficacy of Drugs

One major drawback of comparative biomarking is the translatability of AD drugs from animal models to human clinical trials. Compared to preclinical models, AD pathology in patients develops over decades rather than over months. Longitudinal studies in AD system models may determine the initiation and progression of biomarkers that allow for evaluation of disease-modifying drugs. For example, research shows that BACE1 inhibitors can decrease both plasma and CSF A $\beta$ 40 and A $\beta$ 42 concentrations in mice, guinea pigs (Tagawa et al., 1991), and non-human primates (Sankaranarayanan et al., 2009; Gravenfors et al., 2012; Jeppsson et al., 2012; Wu et al., 2012). A separate study found that a  $\gamma$ -secretase inhibitor reduced CSF A $\beta$  production in rhesus monkeys without a subsequent rise in A $\beta$  production (Cook et al., 2010). Candidates for therapeutics could be further addressed by extending these findings to translational transgenic AD models and may ultimately offer insights into mechanisms of the disease. Furthermore, increased plasma levels of interleukin-10 has been shown following A $\beta$  immunotherapy in Tg2576 mice (Town et al., 2002; Kim et al., 2007). In a separate study, researchers found that peripheral structures play important roles in clearing A $\beta$  sourced from the brain, suggesting that removing A $\beta$  from the blood may also be effective as an AD therapy (Jin et al., 2017).

$\gamma$ -secretase modulators have proven especially useful as therapeutic candidates because they do not alter the total amount of A $\beta$  peptides produced by  $\gamma$ -secretase activity, instead, they spare the products of other  $\gamma$ -secretase processing, such as notch (Toyn et al., 2016). Importantly, these compounds do not accelerate the production of the potentially toxic product BACE1-C-terminal fragment (C99) (Toyn et al., 2016). In all species, research suggests that  $\gamma$ -secretase modulator treatment decrease A $\beta$ 42 and A $\beta$ 40 levels while increasing A $\beta$ 38 and A $\beta$ 37 by a corresponding amount. Therefore, the mechanism of action of  $\gamma$ -secretase modulators may translate well across species, validating its therapeutic strategy for utility in AD (Toyn et al., 2016).

Other translational research across species has shown increased levels of plasma interleukin-10 following A $\beta$  immunotherapy in Tg2576 mice (Town et al., 2002; Kim et al., 2007). Thereby, translation of inflammatory mechanisms and their peripheral markers may benefit from investigation of changes in microglial markers. However, when interpreting and comparing immune markers from mice caution is warranted, as recent evidence suggests that these markers do not translate well to human inflammatory diseases (Seok et al., 2013). Moreover, increased levels of isoprostanes have been shown in Tg2576 mice prior to plaque formation (Pratico et al., 2001), suggesting

isoprostane levels may be useful as a predictive biomarker. Neurofilament light in bodily fluid constitutes a biomarker of neurodegeneration reflecting its translational value in system models and in clinical settings (Bacioglu et al., 2016).

## Comparative AD Neuropathology

The earliest (current) detectable A $\beta$  deposition in humans is the formation of diffuse plaques, whereas in the brain of Tg2576 mice diffuse plaques are not observed until 12 months of age, which is 4 months after biochemically detectable alterations of A $\beta$  (Kawarabayashi et al., 2001). The most common observation in AD patients is minor amounts of A $\beta$ 40 deposited in the brain, whereas in 33% of patients great amounts of this A $\beta$  variant are detected. Intriguingly, this latter group of patients also display substantial amyloid angiopathy (amyloid build up on the walls of the arteries in the brain) (Gravina et al., 1995). Similarly, the Tg2576 mouse model displays marked angiopathy and the deposition of a large amount of A $\beta$ 40 (Gravina et al., 1995). Generally CSF A $\beta$ 40 levels are much higher in patients compared to mice, while brain concentrations are similar (Karelina et al., 2017). In terms of plasma concentrations of A $\beta$ 40, this is highly similar between patients and mice, and therefore the greater A $\beta$ 40 concentrations observed in human CSF may likely reflect a higher brain production of the peptide (Karelina et al., 2017).

In terms of the similarity between system models and patients, and specifically transgenic mice and human patients, mice and humans share virtually the same set of genes. Almost every gene found in mice or humans has been observed in a closely related form in the other. To look directly at differences along the AD disease cascade, we compare pathological events between the 3xTg AD mouse model and sporadic AD patients (**Figure 4**). The 3xTg AD mouse model develops amyloid and tau pathology, including amyloid plaques and NFTs (Oddo et al., 2003). At 3 months of age these mice have developed cognitive impairment (Oddo et al., 2003), whereas at approximately 50 years of age an AD patient has developed amyloid plaques and gliosis (Braak and Del Trecidi, 2015). At 6 months of age, the mice develop amyloid plaques and gliosis (Oddo et al., 2003), while patients develop tau tangles at approximately 60 years of age (Braak and Del Trecidi, 2015). At 70 years of age, patients usually suffer from neurodegeneration because of the presence of tau tangles and exhibit cognitive impairment (Braak and Del Trecidi, 2015). First at 12 months of age will the mice develop tau tangles (Oddo et al., 2003).

There are two important differences observed along the AD disease cascade between the species: first, mice exhibit cognitive impairment prior to tau tangles, whereas cognitive impairment is most likely a result from neurodegeneration caused by NFTs in human patients. Second, one does not observe neuronal death in this mouse model, while neuronal death is thought to be the sole causative pathology for symptom development in AD patients. In line with this, by comparing CSF, plasma and *in vivo* amyloid imaging, cross-sectional data obtained at baseline in individuals from AD families enrolled in the Dominantly Inherited Alzheimer Network (DIAN) show lower concentrations of CSF A $\beta$ 42 when amyloid plaques accumulate, and elevated concentrations of CSF t-tau and p-tau in mutation carriers 10–20 years prior to symptom onset and detection of cognitive deficits (Fagan et al., 2014). This highlights the need for longitudinal CSF sampling in animals modeling AD, in order to compare biochemical, imaging and behavioral tests against each other, and eventually to patients. However, given the difficulty of identifying patients at preclinical AD stages, it is important to remember that well-characterized preclinical disease models hold great translational value (Mattsson et al., 2017a).

## CONCLUSION AND FUTURE DIRECTIONS

Clearly, there is a pressing need for better quality data from model systems investigating biomarkers that can be directly translated to human biomarkers. The core biomarkers (A $\beta$ 42, t-tau, and p-tau) have been found to translate well across species, whereas biomarkers of inflammation translate to a lesser extent between mouse models and patients. Researchers should use autophagic and synaptic degeneration markers when analyzing samples from preclinical models because these markers appear promising in predicting development of AD. Changes in levels of autophagic markers and neurofilament light correlate

strongly with the core biomarkers of AD, and other novel biomarkers should be tested in combination in preclinical models to validate findings observed in patients. Currently, non-invasive structural and functional imaging can detect AD onset and longitudinally monitor disease progression in AD patients. By the combination of early predictive CSF biomarkers, imaging modalities can be strengthened in their ability to characterize patients along the disease cascade. Additional non-invasive methods for detecting AD biomarkers need to be established, such as blood sampling, which could be used in combination with CSF sampling. CSF sampling is invasive but reflects changes in protein levels in the brain to a greater extent compared to blood-based markers. Another advantage of CSF sampling compared to blood testing is that A $\beta$  is found in the periphery, so it is difficult to differentiate between brain- and periphery-based A $\beta$  levels. Additionally, there are greater levels of tau in ISF compared to CSF, so this needs to be controlled for when analyzing CSF samples. Neurofilament light is transferable between CSF and plasma in humans, but this needs to be verified in system models.

Furthermore, large inter- and intra-laboratory variations in biomarker sampling may have great consequences in terms of comparisons of results, while within individual laboratories such variations may affect planning and interpretations of longitudinal studies (Blennow et al., 2015). One also needs to consider differences in the CSF sampling methods used, given that protein levels differ between ventricular and lumbar CSF. Studies have shown that changes in the levels of core biomarkers as measured in CSF may be useful for assessing the efficacy of drugs. When translating findings across species, it is important to use the same scoring or grouping system when assessing changes in biomarkers and observed neuropathology. Ultimately, an early diagnosis by utilizing biomarkers detectable at this stage of disease will be the cornerstone for early identification of patients that are regressing away from the prodromal stage of AD (Teunissen et al., 2018). There is a need for continued progress within the AD biomarker field so that markers can be translated across animal models and clinical populations to serve as a translational bridge between model systems and clinical populations (Sabbagh et al., 2013). We still cannot translate all pathological hallmarks seen in AD patients to preclinical models, and we therefore need to be aware of pertinent differences when comparing AD research across species and bringing findings into the clinic.

<sup>1</sup> Clinical Research Center, The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China, <sup>2</sup> Department of Neurology, The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China, <sup>3</sup> Department of Neurology, Huxian Hospital of Traditional Chinese Medicine, Xi'an, China

**Objectives:** Recent studies regarding the relationships between plasma amyloid- $\beta$  (A $\beta$ ) levels and cognitive performance had inconsistent results. In this study, we aimed to characterize the relationship between cognitive decline and plasma A $\beta$  levels in a large-sample cognitively normal population.

**Methods:** This population-based, prospective cohort study included 1,240 participants with normal cognition. The Mini-Mental State Examination (MMSE) was used to assess cognitive function at baseline and 2 years later. Restricted cubic splines, multivariate logistic regression, and multivariate linear regression models were used to evaluate the type of relationship between cognitive decline during the 2-year follow-up period and plasma A $\beta$  levels (A $\beta$ <sub>40</sub>, A $\beta$ <sub>42</sub>, and A $\beta$ <sub>42/40</sub>).

**Results:** Participants with moderate A $\beta$ <sub>40</sub> levels had the highest risk of cognitive decline during a 2-year follow-up relative to individuals with low A $\beta$ <sub>40</sub> [odds ratio (OR): 0.60, 95% confidence interval (CI): 0.45–0.81,  $p < 0.001$ ] or high A $\beta$ <sub>40</sub> (OR: 0.65, 95% CI: 0.49–0.87,  $p = 0.004$ ) levels. The association between A $\beta$ <sub>40</sub> and cognitive decline did not depend on sex, education level, or APOE  $\epsilon$ 4 status. There was an interaction found between age ( $\leq 65$  and  $> 65$  years) and A $\beta$ <sub>40</sub> ( $p$  for interaction = 0.021). In individuals older than 65 years, there was a positive linear relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline (OR: 1.02, 95% CI: 1.00–1.04,  $p = 0.027$ ). For participants  $\leq 65$  years old, the lower A $\beta$ <sub>40</sub> and higher A $\beta$ <sub>40</sub> groups had a lower risk of cognitive decline than the medium A $\beta$ <sub>40</sub> group (OR: 0.69, 95% CI: 0.50–0.94,  $p = 0.02$ ; OR: 0.63, 95% CI: 0.45–0.86,  $p = 0.004$ ). None of relationship between plasma A $\beta$ <sub>42</sub>, A $\beta$ <sub>42/40</sub> and cognitive decline was found during a 2-year follow-up.

**Conclusion:** The relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline was not linear, but an inverted-U shape in a cognitively normal population. The underlying mechanism requires further investigation.

**Keywords:** Alzheimer's disease, plasma amyloid- $\beta$ , cognitive decline, cognitively normal population, age

## INTRODUCTION

Amyloid- $\beta$  (A $\beta$ ) pathology has been confirmed as a pathological change in the early phase of Alzheimer's disease (AD) (Sperling et al., 2011; Yaffe, 2011; Dubois et al., 2016; Jack et al., 2018; Nakamura et al., 2018; Jansen et al., 2018). Abnormal A $\beta$  deposition in the brain increases the risk of cognitive decline and the development of dementia (Villemagne et al., 2011; van Harten et al., 2013; Jaunmuktane et al., 2015; Toledo et al., 2015; Donohue et al., 2017; Roberts et al., 2018; Greenberg et al., 2020). Accelerating our understanding of the relationship between amyloid pathology and cognitive functioning can contribute to the efficient screening of preclinical AD at an early stage, and considerably delay the progression of the disease (Jansen et al., 2018).

Amyloid pathology, visualized on positron emission tomography (PET) scans or measured in cerebrospinal fluid (CSF), has been extensively studied and has proven clinical applications for AD (Sperling et al., 2013; Vos et al., 2013; Toledo et al., 2015; Dubois et al., 2016; Olsson et al., 2016; Donohue et al., 2017). However, because these techniques are invasive or expensive, more economical and easily-acquired plasma A $\beta$  measurements are needed. Recent studies have revealed that plasma A $\beta$  are related to brain A $\beta$  burden and incident dementia (Graff-Radford et al., 2007; Yaffe, 2011; Gabelle et al., 2013; Hanon et al., 2018; Hilal et al., 2018; Nakamura et al., 2018; Verberk et al., 2018; Chen et al., 2019; de Wolf et al., 2020), however, the relationships between plasma A $\beta$  levels and cognitive performance were inconsistent. Previous studies reported that lower plasma A $\beta_{42/40}$  or A $\beta_{42}$  increased the risk of cognitive decline and the progression of dementia (Yaffe, 2011; Gabelle et al., 2013; Hilal et al., 2018; Verberk et al., 2018; de Wolf et al., 2020). Other studies have suggested that a positive relationship between plasma A $\beta_{42}$ , A $\beta_{42/40}$  and cognitive impairment (Hanon et al., 2018; Wang et al., 2018; Chen et al., 2019).

In order to rapidly identify patients with cognitive decline earlier, and therefore delay the occurrence of AD, the present study aimed to determine the change in cognitive status, its relationship with plasma A $\beta$ , and the type of association, during a 2-year follow-up in a cognitively normal population. This study also investigated whether this association was altered by sex, age, education level, or Apolipoprotein E (APOE) genotype, and estimated the relationship between plasma A $\beta$  and cognitive disorder and cardio-cerebrovascular diseases during a 2-year follow-up.

## MATERIALS AND METHODS

### Study Population

Participants were enrolled from a village in the suburbs of Xi'an city, located in northwestern China, between October, 2014 and November, 2015. This study was a community population cohort study in which each interviewee received a face-to-face questionnaire. Participants were asked about detailed history by neurologists, and received a nervous system

examination, a systemic physical examination, blood biochemical examination aimed at determining whether there were any related neurological diseases. All patients with cerebral disease had received the CT or MRI scans. For patients who had a diagnosis of mild cognitive impairment (MCI) or dementia due to AD, we provided free MRI scan to confirm the diagnosis of AD in a local designated hospital. Inclusion criteria was that participants were (1) older than 40 years and (2) a current resident of the village and had lived there for more than 3 years. Exclusion criteria was that (1) the Mini-Mental State Examination (MMSE) was not completed; (2) there was evidence of MCI or dementia, or (3) other neurological conditions that may influence cognitive function (such as epilepsy, central nervous system infections, essential tremor, Parkinsonism, anxiety, depression, thyroid hypofunction, intracranial trauma, or surgery); (4) plasma A $\beta$  was not measured; and (5) other baseline information was missing. This study was approved by the First Affiliated Hospital of Xi'an Jiaotong University. Written informed consent was obtained from all participants.

### Cognitive Evaluation

The MMSE was conducted as global cognitive screening at enrollment. The MMSE, other neurological, physical and imaging examinations were assessed at baseline and repeated 2 years later. Cutoff values were  $\leq 17$  for subjects with illiteracy,  $\leq 20$  for primary school educated subjects, and  $\leq 24$  for those educated at the junior high school level or above (Bohm et al., 2015). After initial screening, study participants with MMSE score  $\leq$  these cutoff values underwent the 2nd phase cognitive examinations, including the Fuld Object Memory Evaluation test, Rapid Verbal Retrieval test, Trail-Making test, Digit Span test, and Block Design test. Finally, combining all the available imaging and clinical information, the diagnosis and subtype of dementia and MCI were determined according to international diagnostic criteria for dementia (American Psychiatric Association [APA], 2000) and Petersen MCI criteria (Petersen, 2011) by a panel of senior clinicians. The diagnosis of AD was based on NINCDS-ADRDA criteria (McKhann et al., 2011).

### Laboratory Measurement

All plasma samples were acquired between 7 and 11 a.m. Plasma A $\beta_{40}$  and A $\beta_{42}$  tests were measured using enzyme-linked immunosorbent assay kits (ELISA, Yuanye Co. Shanghai, China) (Wei et al., 2017; Jiang et al., 2018). Concentrations of A $\beta_{40}$  and A $\beta_{42}$  were conducted in duplicate and determined from standard curves using a Rayto RT-6000 analyzer (Rayto Co., Shenzhen, China) at OD 450 nm. Apolipoprotein E (APOE) was genotyped by polymerase chain reaction (PCR), followed by sequencing, as previously described (Wenham et al., 1991).

### Outcome Definition

The primary outcome was cognitive decline, which was defined as the difference of MMSE between the first visit and the second visit  $> 0$ . Cognitive disorder was defined as MMSE score  $\leq 17$  for illiterate,  $\leq 20$  for primary school educated, and  $\leq 24$  for junior high school educated or above (Katzman et al., 1988). New cardiovascular and cerebrovascular diseases were defined as

incident cardiovascular and cerebrovascular diseases during the 2-year follow-up.

## Other Covariates

Lack of physical exercise was defined as exercising fewer than three times a week, fewer than 30 min a time. Smoking was defined as a current smoker. Diabetes mellitus was defined as a self-reported medical diagnosis, diabetic medication use, a fasting glucose of  $\geq 7.0$  mmol/l, a random plasma glucose concentration  $\geq 11.1$  mmol/l, or glycated hemoglobin  $\geq 6.5\%$ . Hypertension was defined as a self-reported medical diagnosis, antihypertensive medication use, a systolic blood pressure of  $\geq 140$  mmHg, or a diastolic blood pressure of  $\geq 90$  mmHg.

## Statistical Analysis

Continuous variables are presented as mean  $\pm$  SD, and categorical variables are presented as proportions. We determined the association between baseline information and cognitive decline using Pearson's  $\chi^2$  or Fisher's exact test for categorical variables, and Student's *t*-test or Mann-Whitney *U*-test for continuous variables. Differences of basic characteristics between different A $\beta$  groups were compared using Pearson's  $\chi^2$  or Fisher's exact test for categorical variables, and ANOVA test or Kruskal-Wallis H test for continuous variables.

Restricted cubic splines with a logistic regression model were applied to test the relationship between cognitive decline and A $\beta$  levels, and to evaluate the type of correlation of cognitive decline with A $\beta$  levels. Four knots defined at the 5th, 35th, 65th, and 95th percentiles of A $\beta$  levels were prespecified (Harrell, 2001). The reference point was the mean value of A $\beta$  levels. A $\beta$  categories were based on the type of relationship between cognitive decline, and A $\beta$  levels suggested in restricted cubic splines. A series of pre-planned categories of A $\beta$  levels were tested, defined by tertiles and interquartiles. The differences in MMSE scores between baseline and 2 years later were compared with the paired *t*-test.

To assess the association between A $\beta$  levels (categorical and continuous) and various outcomes, unadjusted, age- and sex-adjusted, and multivariable-adjusted logistic regression models were used. A multivariable linear regression model was used to evaluate the relationship between A $\beta$  and 2-year MMSE score change. In multivariable models, adjustments were made for age, sex, diabetes, hypertension, smoking, lack of physical activity, APOE  $\epsilon 4$  status, and education. In subgroup analyses, we examined the relationship between A $\beta_{40}$  and cognitive decline by sex, age ( $\leq 65$  and  $> 65$  years), education ( $\geq$  high school and  $<$  high school), and APOE  $\epsilon 4$  status in multivariable-adjusted logistic regression models. SPSS ver. 24.0 and R ver. 3.5.3 were used for statistical analysis. A  $p < 0.05$  was considered significant.

## RESULTS

### Characteristics of the Study Population at Baseline

The study population screening process is shown in **Figure 1**. There were 2,173 individuals examined from October, 2014 to

November, 2015. A total of 138 participants did not complete the MMSE, 58 had MCI or dementia, 112 had neurologically-related diseases, 470 did not undergo plasma A $\beta$  tests, 131 had missing baseline information, and 24 did not complete the follow-up MMSE. Finally, 1,240 participants were included in our study.

Baseline characteristics of the study population are listed in **Table 1**. Among 1240 participants, 456 experienced cognitive decline. The mean age of the study participants was  $55.2 \pm 9.7$  years and 469 (37.8%) were men. In the group without cognitive decline, the percentage of higher education level was higher (63.3%) than that in the group with cognitive decline (55.3%,  $p = 0.005$ ). MMSE score was higher ( $27 \pm 3.2$ ) in the group with cognitive decline than that in the population without cognitive decline ( $25.5 \pm 3.7$ ,  $p < 0.001$ ). There were no other significant differences between two groups.

### Association Between Continuous A $\beta_{40}$ , A $\beta_{42}$ , A $\beta_{42/40}$ Levels and Cognitive Decline

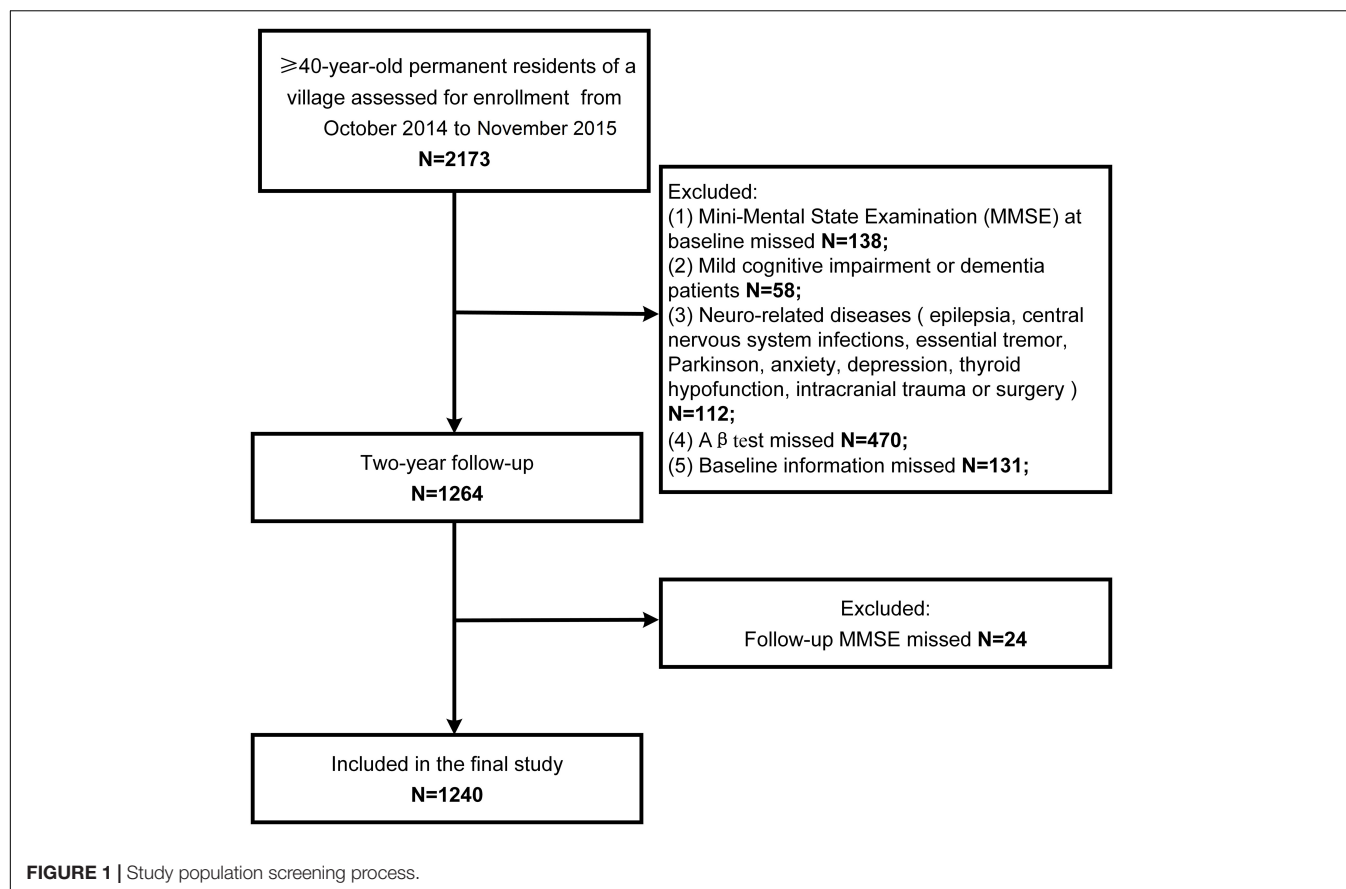

The associations between continuous A $\beta_{40}$ , A $\beta_{42}$ , A $\beta_{42/40}$  levels and cognitive decline were listed in **Table 2**. After multivariable adjustment, none of three biomarkers reached statistical significance (all  $p > 0.05$ ).

The associations between A $\beta$  levels and cognitive decline using restricted cubic splines are shown in **Figure 2**. A $\beta_{40}$  showed a non-linear relationship ( $p$  overall = 0.040,  $p$  non-linear = 0.017) with cognitive decline. A $\beta_{42}$  and A $\beta_{42/40}$  didn't show any relationship with cognitive decline ( $p$  overall  $> 0.05$ ;  $p$  non-linear  $> 0.05$ ).

### Non-linear Relationship Between Plasma A $\beta_{40}$ Level and Cognitive Decline

Because of the non-linear relationship between plasma A $\beta_{40}$  and cognitive decline, and the inverted U shape found in the restricted cubic spline, we transformed continuous A $\beta_{40}$  into two kinds of categorical variables: three tertiles defined by the 33rd percentiles and 66th percentiles, and 3-class classified variables defined by the 25th and 75th percentiles. In multivariate logistic regression analyses evaluating the relationship between cognitive decline and categorical A $\beta_{40}$ , 3-classified A $\beta_{40}$  had a better goodness of fit ( $\chi^2 = 32.20$ ,  $p < 0.001$ ) than A $\beta_{40}$  defined by the 33rd and 66th percentiles ( $\chi^2 = 15.44$ ,  $p = 0.117$ ). Therefore, 3-classified A $\beta_{40}$ , defined by the 25th and 75th percentiles, was used in the present study.

Two-year changes in MMSE score in the three A $\beta_{40}$  groups are shown in **Figure 3**. Paired comparisons of MMSE scores between baseline and 2 years later in the medium and high A $\beta_{40}$  groups were significant ( $p < 0.001$ , **Figure 3A**). When plasma was  $45 \text{ pg/mL} \leq \text{A}\beta_{40} < 58.4 \text{ pg/mL}$ , the change in MMSE scores between the 2 visits was more evident than in the other 2 groups (**Figure 3B**). The changes in MMSE scores in the low, medium, and high A $\beta_{40}$  groups were  $0.09 \pm 1.53$ ,  $0.65 \pm 1.89$ , and  $0.39 \pm 1.78$  pg/mL respectively. Baseline characteristics of the study population, stratified by low ( $< 45 \text{ pg/mL}$ ), medium ( $45 \text{ pg/mL} \leq \text{A}\beta_{40} < 58.4 \text{ pg/mL}$ ), and high A $\beta_{40}$  ( $\geq 58.4 \text{ pg/mL}$ ) are listed in **Supplementary Table S1**.

**TABLE 1 |** Baseline characteristics according to cognitive decline.

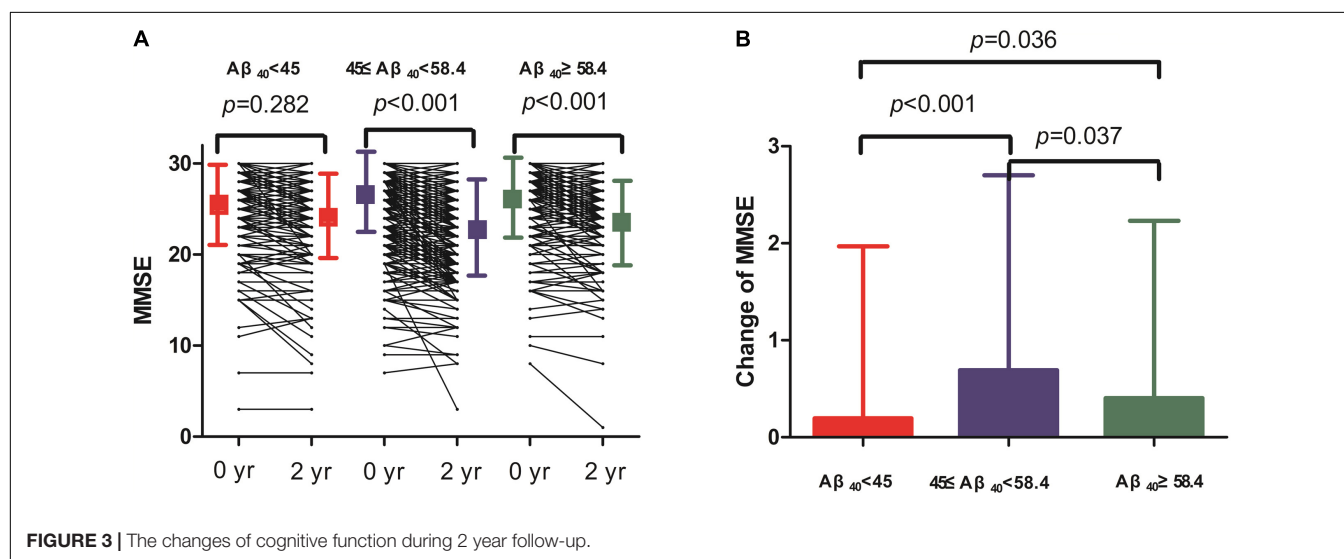

Variable	Cognitive decline <i>n</i> = 456	Without cognitive decline <i>n</i> = 784	<i>p</i>
Age (y)	56 ± 10	54.8 ± 9.4	0.048
Male, <i>n</i> (%)	186 (40.8)	283 (36.1)	0.100
Education ≥ high school, <i>n</i> (%)	252 (55.3)	496 (63.3)	0.005
Diabetes, <i>n</i> (%)	39 (8.6)	62 (7.9)	0.689

**FIGURE 2** | Plot of dose-response relationship between plasma A $\beta$  levels and cognitive decline during two-year follow-up.**FIGURE 3** | The changes of cognitive function during 2 year follow-up.

The relationship between plasma A $\beta$ <sub>40</sub> and various outcomes during follow-up using multivariable logistic regression models are listed in **Table 3**. In unadjusted analyses, compared with participants with A $\beta$ <sub>40</sub> between 45 and 58.4 pg/mL, participants in the low A $\beta$ <sub>40</sub> group and high A $\beta$ <sub>40</sub> group had lower risks of cognitive decline (OR: 0.61, 95% CI: 0.46–0.82,  $p < 0.001$ ;

OR: 0.67, 95% CI: 0.50–0.89,  $p = 0.006$ ). After adjustments for age and sex, the results were the same as before. In the fully adjusted model, participants in the low A $\beta$ <sub>40</sub> (< 45 pg/mL) and high A $\beta$ <sub>40</sub> groups ( $\geq 58.4$  pg/mL) still had a lower risk of cognitive decline, compared with the medium A $\beta$ <sub>40</sub> group (OR: 0.60, 95% CI: 0.45–0.81,  $p < 0.001$ ; OR: 0.65, 95% CI: 0.49–0.87,

$p = 0.004$ ). In addition, participants in the low A $\beta_{40}$  group had a lower risk of a new cognitive disorder (OR: 0.29, 95% CI: 0.12–0.70,  $p = 0.006$ ) than participants in the medium A $\beta_{40}$  group, while participants with high A $\beta_{40}$  levels did not show this association. There were no significant associations found in other outcomes. The relationships of categorical A $\beta_{40}$  defined by the 33th percentiles and 66th percentiles, and cognitive decline are listed in **Supplementary Table S2**.

The relationship between plasma A $\beta_{40}$  and 2-year change in MMSE score using a multivariate linear regression model is shown in **Figure 4**. An inverted U-shaped association between A $\beta_{40}$  and MMSE score change was still apparent. Compared with participants with medium A $\beta_{40}$ , those with low A $\beta_{40}$  and high A $\beta_{40}$  had a lower risk of MMSE score change ( $\beta$ :  $-0.57$ , 95% CI:  $-0.81$  to  $-0.33$ ,  $p < 0.001$ ;  $\beta$ :  $-0.29$ , 95% CI:  $-0.53$  to  $-0.05$ ,  $p = 0.020$ ).

### Subgroup Analyses of the Relationship Between Plasma A $\beta_{40}$ and Cognitive Decline

Subgroup analyses of the relationship between plasma A $\beta_{40}$  and cognitive decline are listed in **Table 4**. The association between A $\beta_{40}$  and cognitive decline did not depend on sex, education level, or APOE  $\epsilon$ 4 status. There was an interaction found between age ( $\leq 65$  and  $> 65$  years) and A $\beta_{40}$  ( $p$  for interaction = 0.021). For participants  $\leq 65$  years old, the lower A $\beta_{40}$  and higher A $\beta_{40}$  groups had a lower risk of cognitive decline than the medium A $\beta_{40}$  group (OR: 0.69, 95% CI: 0.50–0.94,  $p = 0.02$ ; OR: 0.63, 95%

CI: 0.45–0.86,  $p = 0.004$ ). In participants aged  $> 65$  years, lower A $\beta_{40}$  levels correlated with cognitive decline (OR: 0.29, 95% CI: 0.14–0.63,  $p = 0.002$ ) compared with the medium A $\beta_{40}$  group. Continuous A $\beta_{40}$  level was associated with the increased risk of cognitive decline (OR: 1.02, 95% CI: 1.00–1.04,  $p = 0.027$ ).

## DISCUSSION

In this large, prospective, population-based cohort study, we found an inverted U-shaped relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline during a 2-year follow-up in individuals with normal cognition. People with medium plasma A $\beta$ <sub>40</sub> concentrations (45–58.4 pg/mL) had the highest risk of cognitive decline than persons with plasma A $\beta$ <sub>40</sub> < 45 pg/mL and ≥ 58.4 pg/mL.

Previous studies have shown evidence of an association between plasma A $\beta$  levels and the progression of AD, although

most studies focused on plasma A $\beta$ <sub>42</sub> and plasma A $\beta$ <sub>42/40</sub> ratio (Schupf et al.; Graff-Radford et al., 2007; Yaffe, 2011; Gabelle et al., 2013; de Rojas et al., 2018; Hanon et al., 2018; Hilal et al., 2018; Verberk et al., 2018; Chen et al., 2019). Hanon et al. (2018) did not find a significant linear association between A $\beta$ <sub>40</sub> and MMSE score in their prospective cohort study, which included 1,040 participants. Several prospective cohort studies found that plasma A $\beta$ <sub>42</sub> or A $\beta$ <sub>42/40</sub> ratio was associated with an increased risk of developing AD, while no associations of this kind were found for plasma A $\beta$ <sub>40</sub> (Graff-Radford et al., 2007; Schupf et al., 2008; Yaffe, 2011; Gabelle et al., 2013;

de Rojas et al., 2018; Hilal et al., 2018; Verberk et al., 2018). Chen et al. reported a linear relationship between plasma A $\beta$ <sub>42</sub> and MMSE score, regardless of plasma A $\beta$ <sub>40</sub> (Chen et al., 2019). This is the first study to report a non-linear relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline. The reason may be attributed to different study population and different follow-up time. Most of previous studies observed marked cognitive decline (clinical progression to MCI) or the incidence of dementia for a long follow-up time in old and high-risk dementia populations (Yaffe, 2011; Gabelle et al., 2013; Verberk et al., 2018; de Wolf et al., 2020). In our study, we just observed 2-year MMSE change in a cognitively normal population with middle and old age. Two prior studies ever reported that higher plasma A $\beta$ <sub>40</sub> level was correlated with a decreased hippocampal volume (Kaffashian et al., 2015; Hanon et al., 2018). There was also evidence to reveal that A $\beta$  levels were linked with brain atrophy only at an initial stage before cognitive impairment. The relationship between plasma A $\beta$  levels and brain structural variation or cognitive outcomes during earlier stage of AD progression or normal cognitive aging may be different with the association at later stages (Hanon et al., 2018). Therefore, the association between plasma A $\beta$ <sub>40</sub> and cognitive decline may be earlier detected than the relationship between plasma A $\beta$ <sub>42</sub> and cognition progression due to a shorter observation period (2-year follow-up) and younger population in our study. It is why we only find the correlation of cognitive decline with plasma A $\beta$ <sub>40</sub>, not plasma A $\beta$ <sub>42</sub>.

The precise mechanisms underlying the relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline remain unclear. There may be both of neurodegenerative and cerebrovascular pathologies promoting cognitive impairment in the study participants (Greenberg et al., 2020). A $\beta$ <sub>40</sub> was reported to be associated with the development of vascular dementia as well as AD (Hansson et al., 2012). Compared with moderate plasma A $\beta$ <sub>40</sub> group, higher plasma A $\beta$ <sub>40</sub> level may indicate more A $\beta$  efflux from the brain to the peripheral blood and fewer deposition in brain. Therefore, the cognitive decline in the high plasma A $\beta$ <sub>40</sub> group may be slower. Besides, although the concentration of A $\beta$ <sub>40</sub> measured in peripheral blood was not high in the moderate A $\beta$ <sub>40</sub> group, the deposit of A $\beta$ <sub>40</sub> in the wall of vessels may be relatively high, which was involved with the development of vascular dementia. Compared with moderate A $\beta$ <sub>40</sub> group, low concentration of plasma A $\beta$ <sub>40</sub> may suggest increased degradation of A $\beta$ <sub>40</sub> by peripheral tissues, such as liver and kidney and decreased production of A $\beta$ <sub>40</sub> from brain and peripheral tissues (Kaffashian et al., 2015). It could reflect favorable condition of blood vessels, liver and kidney, which was significant to maintain normal cognitive function.

The characteristics of A $\beta$ <sub>40</sub> is different with A $\beta$ <sub>42</sub>. A $\beta$ <sub>40</sub> is more soluble than A $\beta$ <sub>42</sub>, which can diffuse along perivascular drainage pathways to deposit in the walls of vessels, while A $\beta$ <sub>42</sub> tends to be retained in the brain parenchyma and initiate insoluble plaque nucleation (Greenberg et al., 2020). In addition, A $\beta$ <sub>40</sub> is produced or degraded by peripheral tissues as well as A $\beta$ <sub>40</sub> produced and deleted in the brain (Kaffashian et al., 2015). Plasma A $\beta$ <sub>40</sub> may be not a direct surrogate marker for cerebral A $\beta$ <sub>40</sub>, which can't

reflect A $\beta$ <sub>40</sub> and A $\beta$ <sub>42</sub> metabolism in the brain (Sonnen et al., 2008). Accordingly, the effect of A $\beta$ <sub>40</sub> on the physiologic process of dementia may be more complicated than A $\beta$ <sub>42</sub>. Because this study is a community-based cohort study, which failed to measure the liver and kidney function comprehensively, nor did it assess the deposition of A $\beta$  in the brain parenchyma and vascular wall. The mechanisms of plasma A $\beta$ <sub>40</sub> affecting cognitive performance still needs further studies.

Of note, we found that the inverted U-shaped relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline was more marked for young people (40–65 years old), while there seems to be a positive linear relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline in individuals older than 65 years. This result agrees with other studies that suggested that amyloid-cognition association varied by age (Rowe et al., 2010; Rentz et al., 2011; Sperling et al., 2013; Petersen et al., 2016; Jansen et al., 2018). Jansen et al. (2018) found that the relationship between higher amyloid deposition in the brain and low memory scores was more evident in individuals older than 70 years old. Coincidentally, another recent study found no association between continuous PET-A $\beta$  levels and memory scores in younger people (50–69 years old) (Mielke et al., 2016). In older population (> 65 years old), our results supported the previous studies (Hansson et al., 2012; Kaffashian et al., 2015; Hanon et al., 2018). For younger individuals (40–65 years old), our studies suggested that conventional evaluation methods (continuous or dichotomized A $\beta$ <sub>40</sub>) were not suitable for assessing the relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline.

There are still limitations that need to be considered. First, only the total MMSE score was evaluated for every participant in this study; sub-items of MMSE and other cognitive scores should be included to confirm cognitive decline. Second, ELISA is not the most sensitive technique for assessing plasma A $\beta$  levels. Recent studies have employed single-molecule array or hybrid mass spectrometry techniques which may be more accurate approaches than ELISA (Nakamura et al., 2018; Vergallo et al., 2019). Nevertheless, ELISA is suitable for epidemiological studies with large sample size because of simple operation and cheapness. Third, the correlation of plasma A $\beta$ <sub>40</sub> with CSF A $\beta$ <sub>40</sub> and brain A $\beta$ <sub>40</sub>, and the mechanism of transportation and clearance of A $\beta$ <sub>40</sub>, were not studied. It would be useful to explore the dynamic transportation mechanism of A $\beta$ <sub>40</sub> between the brain and peripheral blood in future studies, in order to verify the present results.

## CONCLUSION

This population-based, prospective cohort study showed that the relationship between plasma A $\beta$ <sub>40</sub> and cognitive decline is not linear, but an inverted-U shape, in a cognitively normal population. Medium concentration of plasma A $\beta$ <sub>40</sub> is associated with a greater risk of cognitive decline, compared with low and high levels of plasma A $\beta$ <sub>40</sub>, primarily in younger persons ( $\leq 65$  years old). The underlying mechanism needs to be further elucidated.

Neuromodulation techniques such as deep brain stimulation (DBS) are a promising treatment for memory-related disorders including anxiety, addiction, and dementia. However, the outcomes of such treatments appear to be somewhat paradoxical, in that these techniques can both disrupt and enhance memory even when applied to the same brain target. In this article, we hypothesize that disruption and enhancement of memory through neuromodulation can be explained by the dropout of engram nodes. We used a convolutional neural network (CNN) to classify handwritten digits and letters and applied dropout at different stages to simulate DBS effects on engrams. We showed that dropout applied during training improved the accuracy of prediction, whereas dropout applied during testing dramatically decreased the accuracy of prediction, which mimics enhancement and disruption of memory, respectively. We further showed that transfer learning of neural networks with dropout had increased the accuracy and rate of learning. Dropout during training provided a more robust “skeleton” network and, together with transfer learning, mimicked the effects of chronic DBS on memory. Overall, we showed that the dropout of engram nodes is a possible mechanism by which neuromodulation techniques such as DBS can both disrupt and enhance memory, providing a unique perspective on this paradox.

**Keywords:** neuromodulation, deep brain stimulation, memory, neural network, dropout

## INTRODUCTION

Memory systems are crucial for survival and, to a large extent, define who we are. However, memory systems can fall into disease when expressed pervasively (e.g., anxiety or addiction) or degenerate (e.g., dementia)—both of which are major health challenges worldwide (World Health Organization, 2012, 2017). Neuromodulation techniques such as deep brain stimulation (DBS) have shown promising results as treatments for memory-related disorders (Tan et al., 2019b, 2020b), yet the mechanisms behind these effects are still largely unknown. Furthermore, the effects of treatments such as DBS appear to be paradoxical, in that they can both disrupt (Hamani et al., 2010; Tan et al., 2019a) and enhance memories (Hamani et al., 2011; Tan et al., 2020c)

even when applied to the same brain target (detailed review in Tan et al., 2020b). We have previously suggested that DBS is able to disrupt memory by “removing” nodes in an engram (Tan et al., 2019b). Engrams are a theoretical means by which memory is physically stored in the brain and can be thought of as a subset of neurons in a given memory brain region (e.g., hippocampus) that are recruited in the initial memory encoding phase (Ramirez et al., 2013). In this manuscript, we take the view that engrams are plastic synapses (associative/connectionist model), and hence, engram nodes are synapses between engram neurons (Langille and Gallistel, 2020). Despite increased knowledge of engrams and new techniques to study them, the theory that DBS disrupts memory by “removing” engram nodes (synapses associated with the engram) remains untested partly due to the lack of technology to monitor large engram networks in real time. Besides, this theory does not explain (at least directly) how memory enhancement is achieved.

The development of machine learning techniques offers a unique computational approach to simulate hypothetical models of learning and memory, and the effects of manipulation on memory, which we have previously used to highlight potential mechanisms of memory disruption by DBS (Tan et al., 2019b). To model the learning process, we trained a convolutional neural network (CNN) to classify handwritten digits and letters.

CNNs are a type of artificial neural network that is commonly applied to image recognition tasks. The concept of CNNs was developed from early observations of the visual cortex by Hubel and Wiesel (1959, 1962), in which groups of neurons fired distinctively in response to different light patterns (e.g., straight lines, circles). In a typical CNN, features are extracted by the network using a convolutional layer followed by classification. For image tasks, this convolutional layer is comprised of a series of convolution filters that are associated with particular patterns of pixels, which mimic receptive fields in the retina. These trainable filters are also referred to as weights of the network, similar to synapse/synaptic strength in biological systems. In image classification, the CNN decomposes the input image into patterns of pixels known as features. First, an input image is partitioned into non-overlapping regions with each region mapped to a specific neuron. Second, the neurons are convolved by multiple filters to generate a feature map in the convolution layer. The resultant feature maps can be further decomposed by inputting these maps into successive convolution layers. After a specified number of decompositions, the resultant features are used to classify the input image using the fully connected layer.

In this article, we hypothesize that the paradoxical ability of DBS to both disrupt and enhance memory can be explained through dropout (a process of randomly shutting down or dropping neurons) in engram nodes by using CNN to simulate learning and memory.

Due to limited systematic studies looking at DBS and memory, we based our modeling on the results from our previous studies that showed high-frequency stimulation of the ventromedial prefrontal cortex (vmPFC) could both enhance (Tan et al., 2020c) and disrupt (Tan et al., 2019a) memory. Based

on these findings, we focused on the hippocampal engram and implicit associative memories in the proposed simulation.

## MATERIALS AND METHODS

### Dataset

To model the learning process, we trained a CNN to classify handwritten digits and letters from the EMNIST dataset. The EMNIST dataset is a public database of over 800,000 handwritten digits and letters across 62 different classes (Cohen et al., 2017). In our study, we used the EMNIST balanced dataset, which is derived by merging similar classes of letters. This dataset contains 131,600- $28 \times 28$  pixel images of 47 balanced classes (10 digits and 37 uppercase and lowercase letters).

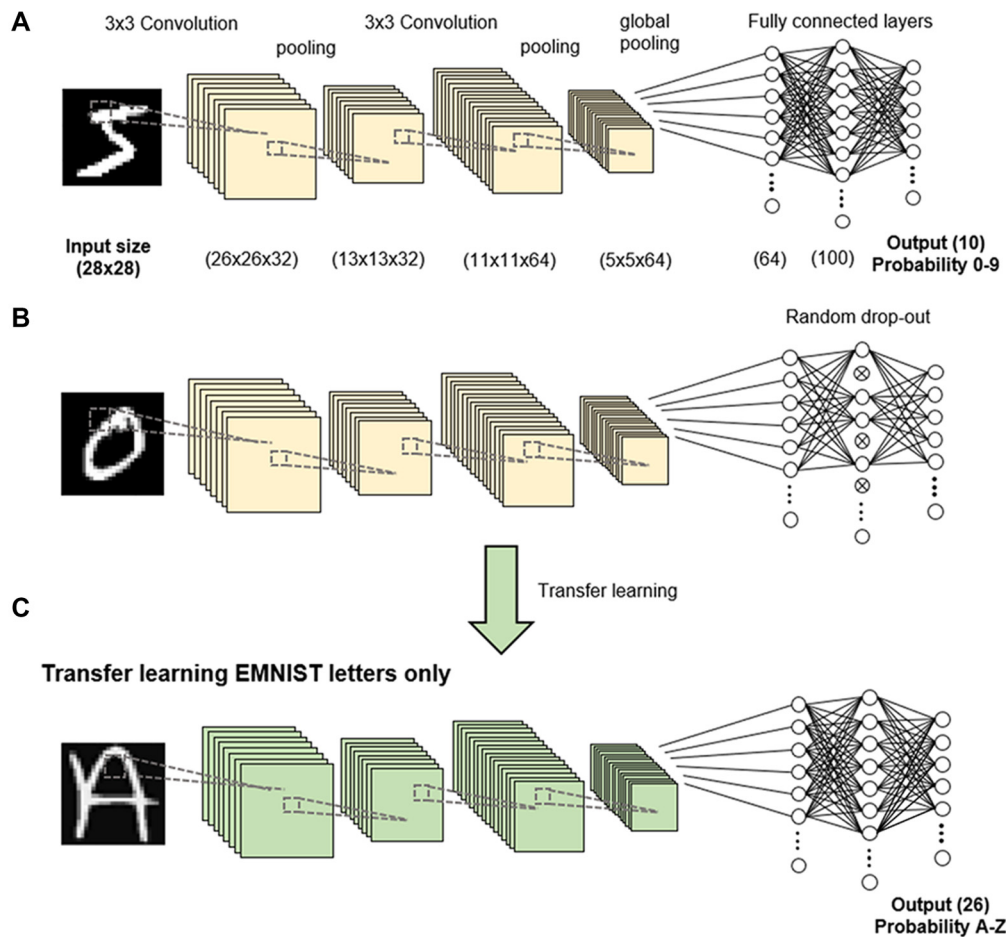

### Network Architecture

The CNN consists of an input layer of size  $28 \times 28 \times 1$  followed by two convolution layers of 32 and 64 filters, leading to a feature map of size  $5 \times 5 \times 64$ . No padding was used for the convolutions, and a filter of size  $3 \times 3$  was used in both layers. At the end of each convolution layer, we applied max pooling with a  $2 \times 2$  window. Max pooling is a standard process for reducing the dimensions of feature maps by sampling the maximum value for a given window size, which forces the network to enhance and focus on important features (Yamaguchi et al., 1990). Global max pooling was applied to the feature map to extract  $64 \times 1$  latent features. For feature classification, the features were passed through to a fully connected layer of 100 neurons. A rectified linear unit (ReLU) was applied as an activation function in all the layers, which is a ramp function where all negative value neurons are zeroed to ensure unidirectionality. The parameters in all the networks were optimized using binary cross-entropy or loss function. All networks were trained for 500 epochs in batches of 10 images. An epoch is defined as one complete run-through of all the training data. For the analysis, the average loss of training data and average classification accuracy of the testing data were evaluated at the end of each epoch.

### Experiments

We conducted three sets of experiments in this study. In Experiment 1, we trained a network to classify 10 different digits (0–9) from the EMNIST balanced dataset. We applied dropout (a process of randomly shutting down or dropping neurons) either during the training stages or just prior to testing at each epoch. We used a dropout rate of 50%, such that half the neurons were dropped at each step (Figures 1A,B). Dropout was only done on fully connected latter layers of the network. As the aim of the study was not to train a network to classify the digits accurately but to analyze the learning process, the network was trained on 1,000 randomly sampled digits as the training dataset, and the network was evaluated on another 1,000 randomly sampled digits as the testing dataset. All networks were trained with the same training dataset and tested with the same testing dataset.

In Experiment 2, we similarly trained a network identical to that of Experiment 1 but applied variable dropout rates (20%, 40%, 60%, and 80%) during the training stages.

**FIGURE 1 |** Methodology. A convolutional neural network (CNN) was trained to classify handwritten digits in the EMNIST dataset (A). Dropout was applied to 50% of nodes in the fully connected layer (B). Transfer learning was performed to retrain the network to recognize uppercase letters (C).

In Experiment 3, we transferred the network to learn 26 uppercase letters (A to Z) in a process known as transfer learning, in which the networks and weights of the control (non-dropout) group and dropout group were applied to the new task (Figure 1C). We retrained the network to recognize uppercase letters by stripping the last output layer and replacing it with the 26 classes corresponding to each letter class. We evaluated the performance of the transfer learning using the trained network with and without dropout compared to the performance of a network directly trained on letters without transfer learning (Figure 1C). Due to the increased complexity of more letter classes, we used 5,000 randomly sampled letters as the training dataset and 1,000 randomly sampled letters as the testing dataset.

## RESULTS

### Experiment 1

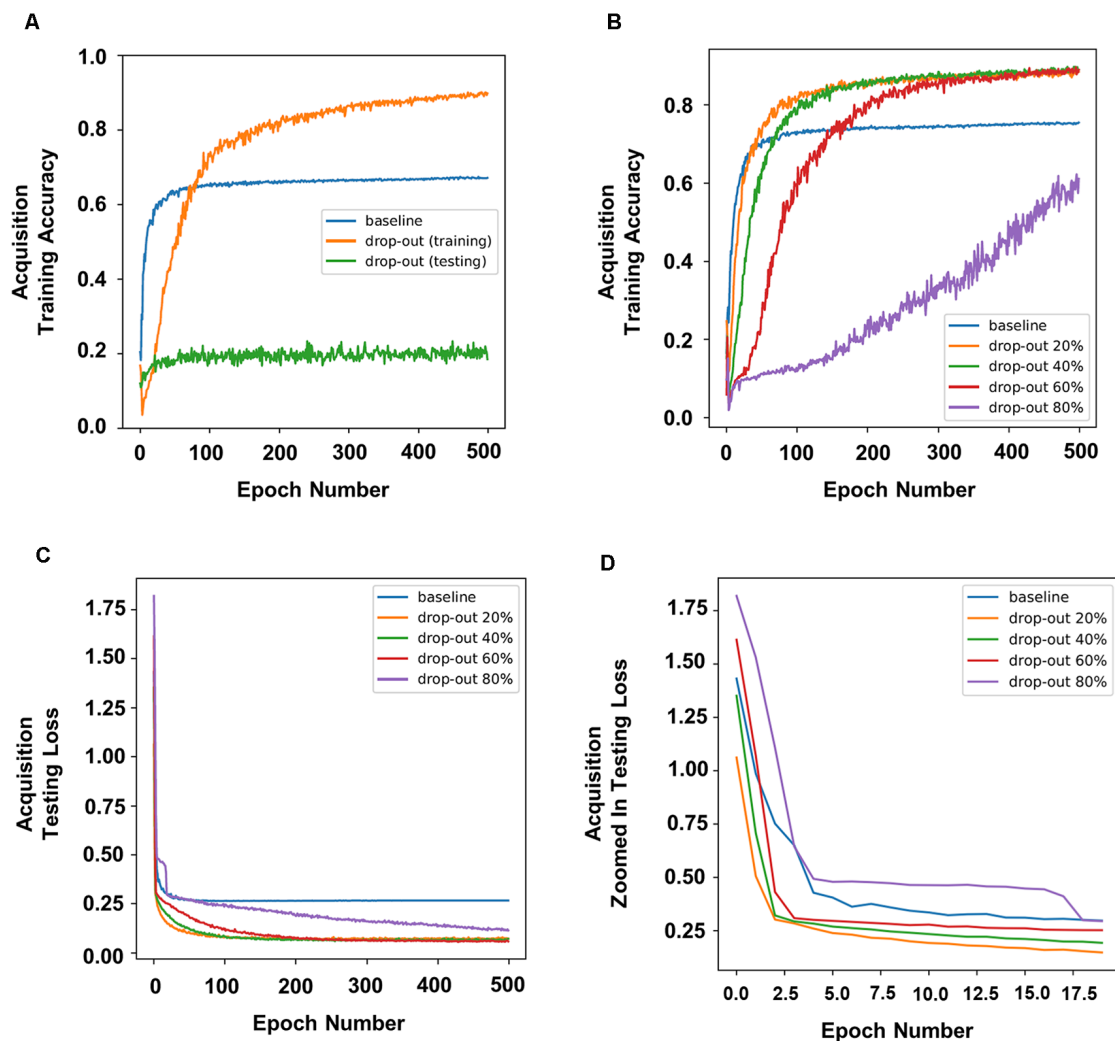

To simulate the effects of DBS on memory, we applied dropout during the training or testing stages. The accuracy of prediction

was used as an indication of how “well” the neural network had learned the task, which serves as a proxy for memory. Therefore, a higher accuracy of prediction should indicate higher memory function. In our experiment, dropout applied during training improved the accuracy of prediction, whereas dropout applied during testing dramatically decreased the accuracy of prediction (Figure 2A).

### Experiment 2

To simulate the different parameters of DBS and to further understand how different rates of dropout would affect DBS during the training stages, we applied different percentages of dropout. In our experiments, a dropout of 20%, 40%, or 60% resulted in a higher training accuracy, whereas a dropout of 80% resulted in a lower training accuracy (Figure 2B). Interestingly, 20% or 40% dropout resulted in lower training loss (defined as the average errors made across the testing) than the baseline initially, and 60% dropout resulted in higher training loss than the baseline by the second epoch, whereas 80% dropout showed the highest training loss throughout (Figures 2C,D).

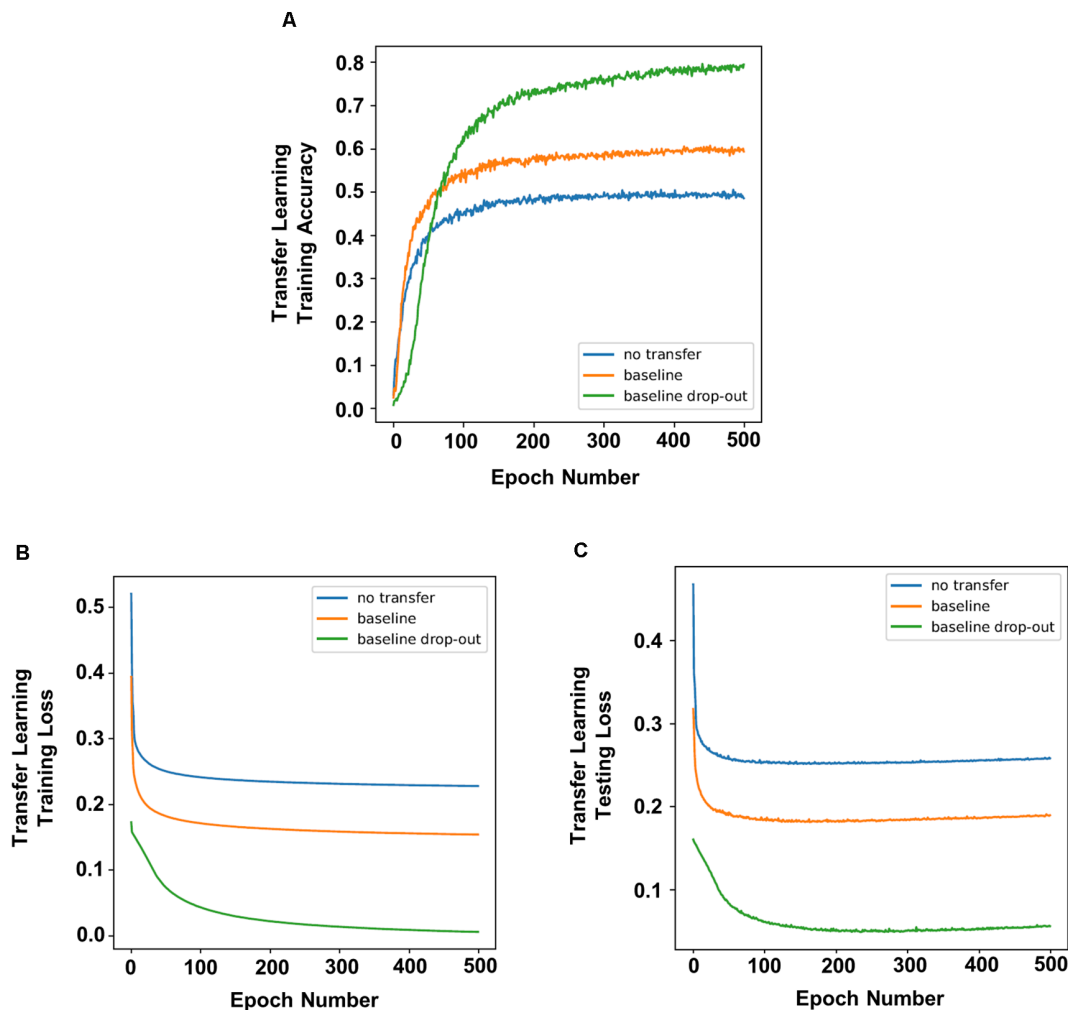

**FIGURE 2 |** Dropout in neural nodes disrupted or enhanced learning in the neural networks depending on when it was applied. Dropout applied during training improved prediction accuracy, whereas dropout applied during testing dramatically decreased prediction accuracy (A). (B) Prediction accuracy of different rates of dropout during training. (C) The training loss and (D) a zoomed in version of the first 20 epochs in panel (C).

### Experiment 3

To simulate a novel memory task post chronic DBS, we applied the process of transfer learning on the trained network, in which the networks and weights of the control (non-dropout) group and dropout groups were applied to a new task. Overall, transfer learning of a network showed increased accuracy compared to a network without transfer learning (Figure 3A), indicating higher memory function. In addition, there were decreased testing and training losses (Figures 3B,C; defined as the average errors made across the testing or training, respectively). Decreased loss indicates better performance or better fitting of the training/testing data, which serves as a proxy for increased rate of learning. Transfer learning in neural networks with dropout resulted in better accuracy (Figure 1) and lower training and testing loss (Figures 3B,C) compared to transfer learning in networks with no dropout.

### DISCUSSION

We have previously argued that timing plays an important role in the outcome of DBS on memory (Tan et al., 2020b). DBS applied post or during behavior testing tended to disrupt memory, whereas DBS applied prior to behavior testing tended to enhance memory. However, the mechanisms behind these outcomes are still relatively unknown. Indeed, we found that dropout applied during training improved the accuracy of prediction, which was similar to the enhancement of memory seen when DBS was applied prior to behavior testing in our previous animal studies (Liu et al., 2015). On the contrary, we found that dropout applied post training dramatically decreased the accuracy of prediction, which was similar to the disruption of memory seen when DBS was applied during consolidation of memory in our previous animal studies (Tan et al., 2019a; Figure 2A).

**FIGURE 3 |** Transfer learning of networks that underwent dropout showed higher prediction accuracy and faster learning. Compared to non-dropout networks, transfer learning of neural networks with dropout had increased accuracy (A) with lower training loss (B) and testing loss (C).

We used CNNs (as opposed to standard fully connected networks) in this study as they are commonly applied in image recognition tasks. Although CNNs are modeled on the visual cortex, dropout was only applied on fully connected latter layers in the network to represent dropouts applied in the hippocampus rather than in the visual cortex. This mimicked our previous experiments on the effects of prefrontal cortex stimulation on the hippocampus (Tan et al., 2019a, 2020c).

In order to simulate different DBS parameters in a generalized manner, we applied different percentage dropouts during the training stage. We showed that lower dropout rates (20%) effectively increased both accuracy and training loss, whereas a higher dropout rate (80%) drastically decreased the ability of the neural network to learn the task effectively. First, this indicates that DBS is more likely to result in lower dropout rates. Second, it simulates variations in DBS parameters in a generalized way, showing that even at low dropout rates (20%), the effects are still robust, and is only ineffective at high dropout rates.

One difference between Experiment 1 and our previous animal experiments was that chronic DBS was not applied during the training stage, but rather in the home-cage prior to behavior experiments. To more accurately represent the enhancement of memory through chronic DBS prior to a memory task (Liu et al., 2015), we applied transfer learning in previously trained networks with or without dropout. We showed that transfer learning did indeed increase the accuracy of prediction and decrease training and testing loss (representing an increased learning rate), indicating that transfer learning was successful in this model. More importantly, we showed that transfer learning applied to neural networks with dropout increased the accuracy of prediction, indicating higher memory function compared to neural networks without dropout. We further showed that transfer learning applied to neural networks with dropout had lower training and testing loss, indicating not only improved memory function but also increased rate of learning. Overall, we showed that applying dropout during training provides a

more robust “skeleton” network, and applying transfer learning in this network increases accuracy and decreases training and testing loss. This model showed similar memory enhancement results to that in our previous study on chronic mPFC DBS (Liu et al., 2015), which suggests a potential mechanism for this process.

An early hypothesis of the mechanism of DBS was that it creates a temporary neural activity lesion (McIntyre et al., 2004). We further showed that prelimbic cortex DBS was associated with the disruption of memory and a drop in the neural activity marker c-fos in the ventral hippocampus (Tan et al., 2019a). Dropout of neural nodes, while congruent with the disruption of memory, has not played a major role in the mechanistic understanding of memory enhancement seen in DBS, although it should be noted that other mechanisms such as neurogenesis and wave syncing have been suggested (Tan et al., 2020b). In this article, we propose that DBS causes dropout in neural nodes that “forces” the activation of new pathways and creates more robust networks, similar to how dropout enhanced the neural networks. Mechanistically in the brain, this could be hypothesized to relate to increased synaptic plasticity or synaptogenesis—activating new pathways could be seen as the formation of new synapses, and the change in weights by the “backward steps” of dropout could be related to synaptic plasticity. Indeed, DBS has been shown to be related to both plasticity and synaptogenesis (Visanji et al., 2015; Pohodich et al., 2018). It is, however, difficult to properly hypothesize how DBS achieves this mechanistically due to the complexities of the changes induced by DBS and the fact we still do not know how it works. To the best of our knowledge, this article is the first to suggest a cohesive mechanism in which disruption of neural activity through DBS can lead to both disruption and enhancement of memory. Although no behavioral experiments were performed in conjunction with our modeling, we based the models on our previous animal behavioral experiments that showed that DBS prior to the behavioral task resulted in memory enhancement (Tan et al., 2020c) and DBS during consolidation of memory resulted in memory disruption (Tan et al., 2019a), which were similarly demonstrated in this present article. However, we acknowledge the simplistic and preliminary nature of our methodology and results. Although more complex models of associative memory and learning have been previously presented (Yusoff and Grüning, 2012; Osawa and Kohno, 2015), the lack of understanding on how neuromodulation actually affects neuronal firing in memory, especially in a remote downstream target like the hippocampus (in the case of vmPFC neuromodulation), makes it difficult to use these models. A simpler model, like that one presented here, is therefore more generalizable and better serves as a hypothetical and conceptual tool for more sophisticated research.

Although DBS has been suggested as a treatment for memory-related disorders including Alzheimer’s disease (AD) and anxiety disorders, its mechanism is still largely unknown. In this article, we suggest hypothetical mechanisms for the effects of DBS on memory. We showed that dropout of engram nodes could disrupt memory processes, which might be useful in translating DBS as a treatment for anxiety disorders like PTSD (Gouveia et al., 2020). We also showed that dropout of engram nodes could improve memory function and suggested that this happens through increased synaptic function. Given that impaired synaptic plasticity and synaptogenesis have been associated with AD (Levi et al., 2003; Shankar et al., 2008) and DBS has shown promise as a treatment for AD (Liu et al., 2015), dropout of engram nodes could be a potential mechanism of DBS neuromodulation.

In conclusion, using a machine learning model based on previous animal experiments, we showed that dropout of nodes could be a potential mechanism in which neuromodulation techniques like DBS can both disrupt and enhance memory. While preliminary in nature, this article serves as a basis for further experimentation on engrams to understand the effects of neuromodulation on memory.

## DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. This data can be found here: <https://www.nist.gov/itl/products-and-services/emnist-dataset>.

## AUTHOR CONTRIBUTIONS

ST, RD, and SC conceived and designed the experiments. JP, LWL, and VV contributed significantly to the experimental design. RD conducted the experiments. ST, RD, and LWL contextualized the data. ST drafted the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

The scientific work was funded by grants from the Hong Kong Research Grants Council (RGC-ECS 27104616) and the University of Hong Kong Seed Funding for Basic Research awarded to LWL.

## ACKNOWLEDGMENTS

This manuscript has been released as a pre-print at BioRxiv (Tan et al., 2020a).

Parkinson disease (PD) is the second most common neurodegenerative disorder, characterized by loss of nigrostriatal dopaminergic neurons. Impairment of the neurovascular unit (NVU) has been hypothesized to play a critical role in early PD pathophysiology, and to precede neurodegenerative mechanisms. [C-11]-PE2I (*N*-(3-iodoprop-2E-enyl)-2b-carbomethoxy-3b-(4-methyl-phenyl)nortropane) (PE2I) is a PET radiotracer targeting neuronal dopamine transporters (DaT) with high specificity, allowing for highly accurate and specific DaT quantification. We investigated NVU integrity using arterial spin labeling (ASL) MRI in a prospective cohort of 26 patients with PD, and correlated our findings with analysis of striatal DaT density using PE2I PET in a subcohort of 17 patients. Analysis was performed in FreeSurfer to obtain rCBF and mean standardized regional PET avidity. Pearson correlations and Mann-Whitney tests were performed. Significantly lower mean normalized striatal PE2I SUV values were seen in multiple regions in patients with greater disease duration ( $p < 0.05$ ). PET uptake in the putamen correlated with disease duration independent of patient age. Stratifying patients based on Montreal Cognitive Assessment (MoCA) scores (stratified into  $\geq 27$  vs.  $< 27$ ), there was statistically significantly lower PE2I PET avidity in the higher MoCA score group in both more and less affected sides of the caudate, putamen and pallidum ( $p < 0.05$ ). A moderate negative correlation between MDS-UPDRS part 3 (motor) "off" and rCBF values was also seen in the L and R cerebellum WM ( $r = -0.43$  and  $-0.47$ ,  $p < 0.05$ ). A statistically significant negative correlation was found between dominant hand pegboard test results and rCBF in the less affected pallidum ( $r = -0.41$ ;  $p = 0.046$ ). A statistically significant negative correlation of ASL MRI with [11C]-PE2I PET was also found ( $r = -0.53$  to  $-0.58$ ;  $p$ -value 0.017–0.033) between left cerebral WM rCBF and more and less affected striatal PET regions. Our ROI-based analyses suggest that longer disease duration is associated with lower rCBF and lower PE2I mean SUV, implying greater NVU dysfunction and dopaminergic neuronal loss, respectively. Combined ASL MRI and PE2I PET imaging could inform future prospective clinical trials providing an improved mechanistic understanding of the disease, laying the foundation for the development of early disease biomarkers and potential therapeutic targets.

## INTRODUCTION

Parkinson disease (PD) is the second most common neurodegenerative disorder and the most common movement disorder. Traditionally, PD is still diagnosed on the basis of motor symptoms and signs of resting tremor, bradykinesia and rigidity. There are many well-validated and highly studied clinical batteries and rating scales available to quantitate motor features, such as the Movement Disorders Society Unified Parkinson's Disease Rating Scale (MDS-UPDRS) – Part III “Motor Symptoms off” (Martinez-Martin et al., 2015), or the 9-hole pegboard testing to assess motor dexterity (Proud et al., 2019). However, these classic motor symptoms of PD often present later in the course of the disease, becoming apparent when almost 50–80% of dopaminergic neurons has been lost (Simon et al., 2020). Thus, there is a strong need to identify early disease biomarkers that may allow earlier diagnosis. Furthermore, non-motor features of PD may be as, or more, important. For example mild cognitive impairment (MCI) and dementia are well-recognized as important contributing factors to disease morbidity (Reid et al., 2011). The Montreal Cognitive Assessment (MoCA) score offers a comprehensive assessment of executive cognitive function and is increasingly used as a screening tool in PD (Chou et al., 2014). Criteria for diagnosis of cognitive impairment in PD have been established delineating the importance of early diagnosis of cognitive decline before progression to dementia (Litvan et al., 2012). However, there remains a critical need for biomarkers capable of detecting and tracking changes in PD in the anatomical and network correlates of such important non-motor features.

It is widely accepted that the pathophysiology of PD is related to selective neurodegeneration and loss of dopaminergic neurons projecting from the substantia nigra to the striatum. Earlier pathophysiologic mechanisms that may precede nigrostriatal neuronal loss are the subject of current research. Neuroinflammation with resulting alpha-synuclein accumulation is a key pathophysiological event in PD, and is closely associated with impaired blood-brain-barrier (BBB) permeability (Codolo et al., 2013; Sarkar et al., 2014). Dysfunction of the neurovascular unit (NVU), which is composed of endothelial cells, pericytes, and parenchymal cells (Pelizzari et al., 2019b), correlates with increased BBB permeability and microvascular dysfunction, and has been hypothesized to play a critical role in PD pathophysiology. Cerebral microvascular dysfunction appears to contribute to dopaminergic neuronal loss in PD (Barcia et al., 2004).

Arterial spin labeling (ASL) is a non-contrast MRI technique which allows assessment of cerebral perfusion and is based on the principle of magnetically labeling protons in arterial blood prior to their entry into the tissue of interest (Haller et al., 2016). This provides an advantage over dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI), the latter necessitating the intravenous administration of gadolinium-based contrast agent (GBCA), which is associated with inherent risks (Gulani et al., 2017). ASL allows assessment of relative cerebral blood flow (rCBF) and can quantify NVU dysfunction.

To investigate neuronal dopamine transporter density in PD, [11C] *N*-(3-iodoprop-2E-enyl)-2b-carbomethoxy-3b-(4-methyl-phenyl)nortropane (PE2I) has been increasingly used. PE2I is a PET radiotracer which selectively binds neuronal dopamine transporters, allowing non-invasive *in vivo* quantitation of neuronal dopamine transporter density. The purpose of our study was to investigate dopaminergic neuronal loss and NVU dysfunction in a prospective clinical cohort of patients with PD, using [11C]-PE2I PET and ASL MRI, respectively, as well as to correlate advanced imaging findings with clinical and demographic characteristics, specifically metrics assessing motor symptoms (MDS-UPDRS scores, 9-hole pegboard testing) and cognitive impairment (MoCA).

## MATERIALS AND METHODS

### Study Population

Twenty six subjects were prospectively enrolled in this institutional review board-approved study. Informed consent was obtained at enrollment from all the participants. Inclusion criteria were PD clinical diagnosis of 3 to 12 years of duration from onset of symptoms, 30 to 70 years-old at time of enrollment, well-established response to one or more dopaminergic agents and/or amantadine, absence of disabling dyskinesias, and PD Hoehn & Yahr stage 2–3, and absence of a clinical diagnosis of dementia. Exclusion criteria were symptoms or signs suggestive of a Parkinson's plus diagnosis, receiving dopamine receptor blocking agents such as neuroleptics, treatment with acetylcholinesterase inhibitors, a history of brain surgery, history of cancer or other significant medical disease such as autoimmune disorders or others within the past 5 years, any major psychiatric condition and any history of other serious neurological disorders such as a clinically significant stroke, brain tumor, hydrocephalus, epilepsy, other neurodegenerative disorders, encephalitis or repeated head traumas. All enrolled patients were evaluated by a movement disorder specialist at the time of enrollment, with clinical assessment including evaluation of motor, sensory, cognitive and overall disease scores. Clinical chart review was performed by trained research personnel with documentation of duration of disease, symptoms, and medications. MRI and PET/CT studies were performed shortly after enrollment in the study, as discussed below.

### MRI Acquisition

All subjects underwent ASL MRI. All MRI data was acquired on a 3.0 Tesla Siemens Prisma MRI scanner using a 32-channel head resonator. The 3D T<sub>1</sub>-Weighted scan was acquired with 1.0 mm x 1.0 mm x 1.0 mm isotropic resolution using a sagittal MPRAGE sequence with a TR/TE/TI of 1800 ms/2.25 ms/900 ms respectively. The ASL sequence was a 3D pseudocontinuous sequence (J. J. Wang, USC) (Wang et al., 2005). ASL acquisition parameters included a 2000 ms labeling time, a 800 ms post-labeling delay and a 2.5 mm x 2.5 mm x 2.5 mm resolution with 60 slices.

## PET/CT Acquisition

A subcohort of 17 patients underwent [11C]-PE2I PET/CT (performed on the same day as the MRI examination). [11C]-PE2I PET/CT data was acquired on a 64 slice Siemens Biograph mCT scanner. The [11C]-PE2I static images were summed from 30 to 60 min after injection. [11C]-PE2I targets neuronal dopamine transporters (Jakobson et al., 2018). The [11C] PE2I dose administered was  $384.1 \text{ MBq} \pm 51.8 \text{ MBq}$  ( $10.38 \pm 1.40 \text{ mCi}$ ). Resolution was  $1.0 \text{ mm} \times 1.0 \text{ mm} \times 2.0 \text{ mm}$ , with a 40 cm field of view. The PET images were acquired immediately after the radiotracer injection.

## MRI Processing

The ASL rCBF data was processed using the MATLAB based ASLtbx (Wang et al., 2008). rCBF images were registered to the 3D T<sub>1</sub>-Weighted data by aligning the proton density (PD) image acquired with the same sequence using the FLIRT package within FSL (FMRIB's Linear Image Registration Tool; Oxford, United Kingdom) (Jenkinson and Smith, 2001; Jenkinson et al., 2002). The 3D T<sub>1</sub>-Weighted MRI data was analyzed utilizing the FreeSurfer 6.0 image analysis suite<sup>1</sup> (Fischl et al., 2002; Desikan et al., 2006). Analyzed regions comprised the bilateral striatum (caudate, globus pallidus, putamen) for ASL and [11C]-PE2I PET data. Stratification was performed based on more versus less severely clinically affected side as documented in the standardized clinical neurological examination. Since basal ganglia control contralateral motor function, the opposite side of the one considered more affected clinically was used as the more affected region for imaging purposes. Additionally, the bilateral supratentorial white matter, and bilateral cerebellum was evaluated for ASL analysis for the 26 patients with available ASL data. Axial T<sub>1</sub> weighted MRI and an rCBF map from a representative patient is presented in **Figures 1A,D**.

## PET/CT Processing and Co-registration With MRI

The [11C]-PE2I PET data were aligned to the 3D T<sub>1</sub>-Weighted MRI using the FLIRT package in FSL as previously described. Analysis was performed with FreeSurfer 6.0 derived quantitative cortical and subcortical segmentation of structures. [11C]-PE2I PET values were measured for each subregion defined within FreeSurfer. SUV values for the same regions used in our ASL analysis were determined for a subcohort of 17 patients. An SUV for the occipital lobe was generated by combining values from the cuneus, lateral occipital, lingual and pericalcarine regions based on previously published methodology (Desikan et al., 2006). Each target SUV was normalized to this combined occipital SUV. PET findings from a representative patient are presented in **Figure 1**.

## Subgroup Stratification and Statistical Analysis

Statistical analysis was performed utilizing Graph-Pad Prism version 8. Patients were stratified into the following subgroups based on clinical characteristics. Stratification by duration of

disease was based upon a cut-off of 5 years (less than 5 years versus greater than 5 years). Stratification by MoCA and MDS-UPDRS scores was based on previously published data suggesting a cut-off MoCA score of 26 between cognitively normal and cognitively abnormal individuals (Chou et al., 2014), and a cut-off MDS-UPDRS score of 32 for differentiating between mild and moderate disease (Martinez-Martin et al., 2015). We stratified our cohort into subgroups based on clinically meaningful criteria. The final number of patients for each analyzed subgroup is presented in **Figure 2**. Of note, final numbers for each subgroup depended on available data and thus differed among subgroups, since all 26 patients underwent ASL MRI and a subset of 17 patients underwent PE2I PET. Furthermore, some of the clinical information was not available or clinical tests were not performed for some of the patients. Mann-Whitney *U*-tests were performed to evaluate for differences between subgroups. Correction for multiple comparisons was accomplished using the Benjamini-Hochberg procedure with a false discovery rate (FDR) of 0.1. To investigate the relationship between ASL MRI and [11C]-PE2I -PET data as well as the relationship between clinical scores and imaging data, Spearman correlation analysis was performed. Additionally, a multiple linear regression analysis was performed comparing regional [11C]-PE2I PET uptake normalized to the occipital region with both subject age and disease duration as covariates.

## RESULTS

### Clinical and Demographic Characteristics of the Study Population

Subjects in our cohort had a mean age of 59.5 (range: 44–70,  $SD = \pm 5.9$ ) years with mean duration of disease of 6.6 (range: 1–13,  $SD = \pm 3.5$ ) years. The mean MDS-UPDRS part 3 (motor) "off" score was 28.7 (range: 12–54,  $SD = \pm 11.5$ ) and the mean MoCA score was 25.9 (range: 21–30,  $SD = \pm 2.2$ ). With regard to clinical symptoms, 13 (50%) patients had more pronounced symptoms on the left side and 13 (50%) patients had more pronounced symptoms on the right side. 85% (22/26) patients were undergoing treatment with levodopa-containing medications, the majority in combination with other medications, with mean LEDD was 749 mg ( $SD = \pm 483$ ). Demographic and clinical characteristics of the subjects enrolled in this study are presented in **Table 1**.

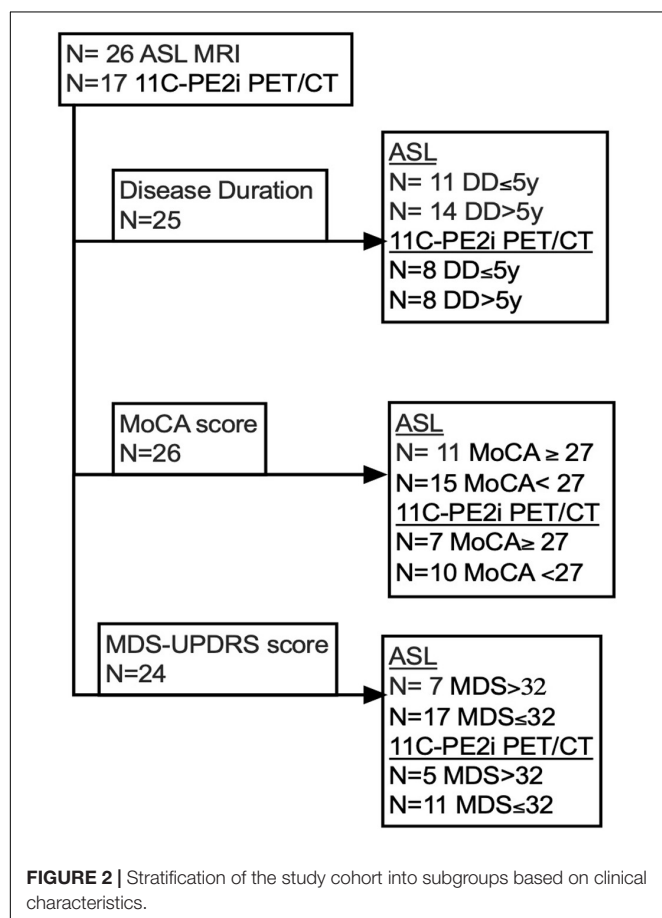

### Disease Duration

Stratification of the cohort based on disease duration resulted in  $N = 11$  patients with disease duration of  $\leq 5$  years (all underwent ASL MRI and a subset of  $N = 8$  underwent [11C]-PE2I PET); and  $N = 14$  patients with disease duration of  $> 5$  years (all underwent ASL MRI and a subset of  $N = 8$  additionally underwent [11C]-PE2I PET). Several regions displayed lower rCBF values with longer disease duration but did not reach significance. A statistically significantly lower PE2I avidity in the group with longer disease duration was shown for multiple regions in **Figure 3**. The differences between the two groups were more pronounced for [11C]-PE2I SUV in the basal ganglia

**FIGURE 1 |** Fifty five year old male with PD diagnosed 5 years ago with moderate disease based on MDS-UPDRS part 3 (motor) "off" score and associated mild cognitive impairment. **(A)** Axial T1-weighted MRI demonstrating no structural abnormalities. **(B)** Axial [11C]-PE2I PET image and **(C)** fused axial [11C]-PE2I PET/MR image demonstrating increased PE2I avidity in the bilateral caudate nuclei. **(D)** rCBF map obtained in the same patient at the same level.

**FIGURE 2 |** Stratification of the study cohort into subgroups based on clinical characteristics.

compared to reference regions (cerebellum cortex and WM, WM). Following Benjamini–Hochberg correction for multiple comparisons, our findings remained significant for all analyzed regions with the exception of left and right cerebellar cortex. rCBF and [11C]-PE2I SUV values for the different regions stratified by disease duration are presented in **Table 2**.

## Montreal Cognitive Assessment

The cutoff to stratify a subject as having MCI/dementia was 27 based on previously published data and therefore 15 patients were

**TABLE 1 |** Clinical and demographic characteristics of the study population.

Number of subjects	26 (F/M: 7/19)
Age (years)	59.5 (range: 44–70 <i>SD</i> = ± 5.9)
Duration of disease (years)	6.8 (range: 1–13 <i>SD</i> = ± 3.5)
Side of symptom predilection	13 (50%) right; 13 (50%) left
MDS-UPDRS part 3 (motor) "off" score	28.7 (range: 12–54 ± 11.5)
MoCA score	25.9 (range: 21–30 ± 2.2)
<b>Antiparkinsonian medications</b>

considered as having MCI (MoCA scores < 27). Stratification of the cohort resulted in *N* = 15 patients with MoCA scores < 27 (all underwent ASL MRI and a subset of *N* = 10 additionally underwent [11C]-PE2I PET) and *N* = 11 patients with MoCA scores ≥ 27 (all underwent ASL MRI and a subset of *N* = 7 underwent [11C]-PE2I PET). Several regions displayed higher rCBF values in patients with greater MoCA but did not reach significance (**Table 3**). Furthermore, in the subgroup of patients that had PET data available (*N* = 17) comparing PE2I avidity between the two subgroups, lower [11C]-PE2I avidity in the higher MoCA score group was found with statistically significantly lower [11C]-PE2I SUV values normalized to the occipital lobe in the caudate, pallidum, and putamen (*p* = 0.005–*p* = 0.025) (**Table 3**). Following Benjamini–Hochberg correction for multiple comparisons, our findings remained significant for all analyzed striatal regions.

When normalized to occipital lobe, there was a moderate negative statistically significant correlation between MoCA scores and normalized SUV in the pallidum on the more affected side (*p* = 0.03) (**Table 4**).

## MDS VO Part 3

Using Pearson correlation there was a moderate negative correlation between MDS-UPDRS part 3 (motor) "off" and rCBF

values in the L and R cerebellum WM ( $r = -0.43$  and  $-0.47$ ,  $p = 0.035$  and  $p = 0.021$ ), which may suggest that milder motor symptoms of PD correlate with higher cerebellar rCBF. Patients were additionally stratified based on MDS-UPDRS part 3 (motor) "off" score into groups of mild disease-MDS-UPDRS part 3 (motor) "off"  $\leq 32$  and moderate disease-MDS-UPDRS part 3 (motor) "off"  $> 32$  (Martinez-Martin et al., 2015). Differences between the two groups were not statistically significant. No patients with an MDS-UPDRS part 3 (motor) "off" 58 (severe disease) were present in our cohort. There was no significant correlation between MDS-UPDRS part 3 (motor) "off" score and [11C]-PE2I SUV values normalized to the occipital lobe.

### Dominant Hand Pegboard Testing

For this analysis, we used all the patients that had available ASL data and Dominant hand Pegboard testing ( $N = 24$ ). A statistically significant, moderate negative correlation was found between Dominant hand Pegboard Test results and rCBF in the less affected pallidum ( $r = -0.41$ ;  $p = 0.046$ ). Dominant hand Pegboard testing did not demonstrate any significant correlations with [11C]-PE2I SUV values in any of the analyzed brain regions. Non-dominant hand Pegboard testing did not demonstrate any significant correlations with rCBF values in any of the analyzed brain regions.

### Combined Imaging

We additionally correlated supratentorial rCBF with striatal [11C]-PE2I PET SUV. For this analysis, we included the 17 patients that had both ASL and [11C]-PE2I PET data. A statistically significant moderate negative correlation was present between left cerebral WM rCBF and more and less

affected striatal [11C]-PE2I avidity: more affected caudate ( $r = -0.54$ ,  $p = 0.026$ ), more affected putamen ( $r = -0.53$ ,  $p = 0.031$ ), more affected pallidum ( $r = -0.58$ ,  $p = 0.017$ ) and less affected pallidum ( $r = -0.052$ ,  $p = 0.033$ ). A moderate negative correlation for the left cerebral WM and the less affected caudate ( $r = -0.48$ ) and less affected putamen ( $r = -0.43$ ) did not reach statistical significance ( $p = 0.054$  and  $0.085$ , respectively). Analogous analyses for the right cerebral WM demonstrated a similar trend however did not reach statistical significance for either the more or the less affected striatum ( $r = -0.40$  to  $-0.31$ ;  $p = 0.109$  to  $0.221$ ).

### Effect of Age

A multiple linear regression was performed comparing regional [C-11]-PE2I PET uptake normalized to the occipital region with both subject age and disease duration as covariates. Significant correlation of PET uptake in the putamen with disease duration was found to be  $p = 0.004$  and  $p = 0.022$  on the more and less affected sides respectively. No significant correlation of PET uptake with subject age was observed (Figure 4).

## DISCUSSION

In this study, we combined ASL MRI-based assessment of the NVU with [11C]-PE2I PET-based assessment of striatal dopamine transporter density to assess pathophysiologic mechanisms in a prospective clinical cohort of patients with PD. This approach allowed us to place evaluation of NVU integrity and thereby BBB disruption into a more established clinical context.

At baseline, the BBB has tightly sealed cell-cell contacts involving the capillary endothelial cells and astrocyte endfoot processes, resulting in low transcellular and paracellular permeability. Loss of BBB integrity is associated with decreased relative cerebral blood flow (rCBF) (Montagne et al., 2016), microvascular dysfunction and hemodynamic impairment (Sweeney et al., 2016). BBB permeability is thereby linked to integrity of the NVU (Pelizzari et al., 2019b).

Neuroinflammation with resulting alpha-synuclein accumulation is a hallmark event in PD, and is closely associated with impaired blood-brain-barrier (BBB) permeability and microvascular dysfunction (Zhang et al., 2005; Sarkar et al., 2014; Sweeney et al., 2018), in particular given that certain BBB-targeting metalloproteinases (MMP) can be activated by inflammatory cytokines and chemokines (Germano et al., 2000; Jin et al., 2012). BBB dysfunction in PD has been suggested as a pathophysiologic mechanism based on compelling histopathologic findings including capillary extravasation of cells and proteins, thinning of the capillary endothelial cell layer, and extravascular IgG deposition (Gray and Woulfe, 2015; Pienaar et al., 2015).

Cerebral microvascular dysfunction appears to contribute to dopaminergic neuronal loss in PD (Barcia et al., 2004). Previous work using mouse models of acute, sub-acute and chronic PD demonstrated that area and density of endothelial cells were reduced in regions related to PD pathophysiology such

as the substantia nigra and the striatum in all three models, further supporting the importance of microvascular damage in the pathogenesis of PD (Sarkar et al., 2014). The findings of microvascular dysfunction in the substantia nigra have also been suggested by a study comparing number of capillaries, length and diameter of human brain tissue in PD and normal controls (Guan et al., 2013).

NVU dysfunction, associated with a decrease in relative cerebral blood flow (rCBF), has been proposed as an early pathophysiologic mechanism in PD [19], and several ASL-based studies have revealed altered cerebral perfusion patterns in patients with PD compared to normal subjects. [20] ASL-derived differences in rCBF in PD are presently a subject of active investigation, with one study documenting no significant differences in rCBF for any of the evaluated regions (Pelizzari et al., 2019a) while other studies demonstrated decreased striatal

rCBF in patients with PD (Wei et al., 2016), concordant with our findings of decreased rCBF in patients with longer disease duration, noting that our study did not include normal subjects for direct comparison. Differences in rCBF distribution have been attributed to BBB dysfunction in PD as well as other neurodegenerative diseases and evaluation of BBB integrity in PD remains the subject of active research. For example, an ASL-MRI-based approach to BBB assessment integrates a diffusion preparation module with pseudo-continuous ASL (pCASL) and a 3D gradient readout (Shao et al., 2019). Appropriate diffusion weighting allows for separation of the tissue and capillary fractions of the ASL signal and in turn allows quantification of capillary permeability of water (kW) between the tissue and intravascular compartments (Shao et al., 2019). Of note, there are currently no diffusion-weighted ASL-based or dynamic-contrast-enhanced (DCE) MRI-based studies in patients with PD.

Pearson correlation coefficient *r* is shown for each striatal sub-region, along with associated *p*-values.

For evaluation of neuronal dopamine transporter density in PD, to date most imaging studies have used 123I-Iodoflupane (DatSCAN) SPECT, which is in wide clinical use in the work-up of parkinsonian syndrome. [11C]-PE2I PET provides a more accurate and specific quantification of neuronal dopamine transporters in PD compared to DatSCAN SPECT. [11C]-PE2I is a cocaine analog which binds neuronal dopamine transporters with high specificity. While [11C]-PE2I is structurally related to DatSCAN, [11C]-PE2I has the advantage of higher selectivity as it binds neuronal dopamine transporters only, whereas DatSCAN additionally targets serotonin and norepinephrine transporters (Jakobson et al., 2018). [18F] *N*-(3-fluoropropyl)-2 $\beta$ -carboxymethoxy-3 $\beta$ -(4-iodophenyl)nortropane (FP-CIT) has recently been demonstrated to have utility in dopamine transporter imaging in PD and related syndromes, with comparable image quality to [11C]-PE2I (Hong et al., 2018).

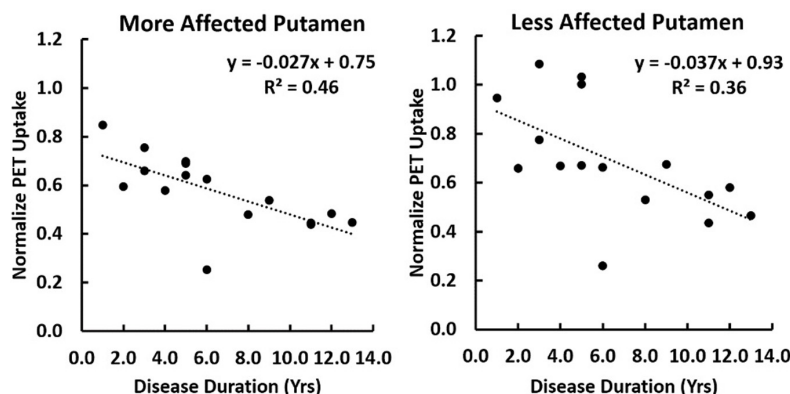

Another approach to visualization of dopamine depletion is [F-18]-Fluoro-DOPA (FDOPA) PET. FDOPA is limited in quantifying neuronal dopamine transporters as it illustrates the activity of aromatic amino acid decarboxylase which represents an intraneuronal reaction and is not specific for dopamine. Published data from a direct comparison of F-DOPA and [11C]-PE2I demonstrated greater sensitivity of [11C]-PE2I for the detection of differences in motor symptom severity and progression over time in PD (Li et al., 2018). Studies comparing [11C]-PE2I PET to combined DatSCAN SPECT and 18F-FDG PET further demonstrated superiority of [11C]-PE2I PET (Appel et al., 2015).

To our knowledge, this is the first study investigating the concurrent use of ASL imaging and [11C]-PE2I PET. We found statistically significantly lower striatal PE2I avidity in the sub-cohort of patients with longer disease duration, as well as a trend for lower rCBF values in the same cohort.

The significant negative correlations we identified between MoCA scores and [11C]-PE2I SUV values in the basal ganglia reflect current understanding that cognitive impairment in PD is not, for the most part, directly tied to dopaminergic neuronal loss, as patients with lower MoCA score had higher [11C]-PE2I SUV. Of note, cognitive impairment has been suggested to precede the development of “classic” motor symptoms in PD (Fereshtehnejad et al., 2019), and while our study only incorporates one imaging time point, this may reflect a pathophysiologic basis for our findings and needs to be studied further in future longitudinal studies.

Previously published data have shown that rCBF values in basal ganglia are inversely correlated to motor dysfunction (Wei et al., 2016). Stratification based on MDS-UPDRS score into groups of mild disease-MDS  $\leq 32$  and moderate disease-MDS-UPDRS  $> 32$  did not reveal a clear trend for rCBF values, although Pearson correlation analysis did demonstrate a weak negative correlation between MDS-UPDRS and cerebellar rCBF values.

Our study has several limitations, most notably small sample size overall as well as small sample size of the various subgroups.

**FIGURE 4 |** A correlation of [C-11]-PE2I PET uptake normalized to the occipital lobe is shown with disease duration for the putamen lateralized into the more or less affected side. A multiple regression was performed with both subject age as disease duration as covariates. Significant correlation of PET uptake in the putamen with disease duration was found to be  $p = 0.004$  and  $p = 0.022$  on the more and less affected sides respectively. No significant correlation with subject age was observed.

Another limitation is lack of direct comparison to non-diseased subjects. Furthermore, our study is cross-sectional and lacks longitudinal follow-up data. However, we demonstrate feasibility of concurrent non-invasive imaging of cerebral perfusion and dopaminergic neuronal loss, and place our findings in the clinical context of motor and cognitive decline in PD.

## CONCLUSION

Our ROI-based analyses suggest that longer disease duration is associated with lower rCBF and lower striatal [11C]-PE2I avidity, implying greater NVU dysfunction and greater dopaminergic neuronal loss, respectively. Correlative studies of ASL and [11C]-PE2I PET data further suggest that dopaminergic neuronal loss may be independent from cognitive impairment in PD.

Combined perfusion MRI and dopamine transporter targeted PET imaging may inform future prospective clinical trials, thereby providing an improved mechanistic understanding of PD and related neurodegenerative diseases, and laying the foundation for the development of early disease biomarkers and potential therapeutic targets.

Baicalein, a major bioactive flavone of *Scutellaria baicalensis* Georgi, has neuroprotective properties in several animal models of Parkinson's disease (PD). Here, we conducted a systematic review and meta-analysis to assess the available preclinical evidence and possible mechanisms of baicalein for animal models of PD. Ultimately, 20 studies were identified by searching 7 databases from inception to December 2019. Review Manager 5.3 was applied for data analysis. Meta-analyses showed baicalein can significantly improve neurobehavioral function in animal models with PD, including spontaneous motor activity test ( $n = 5$ ), pole test ( $n = 2$ ), rotarod test ( $n = 9$ ), apomorphine-induced rotations test ( $n = 4$ ), grid test ( $n = 2$ ), and tremor test ( $n = 2$ ). Compared with controls, the results of the meta-analysis showed baicalein exerted a significant effect in increasing the frequency of spontaneous activity, prolongating the total time for climbing down the pole, decreasing the number of rotations, prolongating the descent latency, reducing the amplitude, and the frequency in animal models with PD. The possible mechanisms of baicalein for PD are regulating neurotransmitters, adjusting enzyme activity, antioxidation, anti-inflammatory, inhibiting protein aggregation, restoring mitochondrial dysfunction, inhibiting apoptosis, and autophagy. In conclusion, these findings preliminarily demonstrated that baicalein exerts potential neuroprotective effects through multiple signaling pathways in animal models of PD.

## INTRODUCTION

PD is a common and severe degeneration of the central nervous system, which is mainly manifested as bradykinesia, rigidity, and static tremor (Schindlbeck and Eidelberg, 2018), usually accompanying by non-motor symptoms such as depression, sleep disturbances, cognitive decline, etcetera (Schapira et al., 2017). The figures showed that the incidence rate of PD has increased from 3.5 to 42.8% in the past few years (Kovács et al., 2019), affecting about 1% of the population over the age of 60 (Martin et al., 2011). Worse yet, about 1.174 million people died of Parkinson's disease worldwide from 2005 to 2015 (Wang et al., 2016). Although the typical clinical and pathological

features of PD have been clear, its etiology and pathogenesis are not fully clarified yet. Over the years, researchers have been exploring the pathogenesis and treatment of PD. Overwhelming evidences demonstrated that levodopa can significantly improve motor function in patients with PD (LeWitt and Fahn, 2016). But it's just about improving the symptoms of PD and cannot stop the progress of the disease (Naskar et al., 2013). Therefore, the search for new effective drugs is a hot topic in PD research. Excitedly, natural medicines characterized with high activity and low side-effect are a valuable resource for us to find compounds against PD.

Baicalein (**Figure 1**) is a major bioactive flavone, mainly extracted from the root of *Scutellaria baicalensis* Georgi. Modern pharmacological researches have proved that baicalin has a wide range of biological activities, including antioxidant, anticancer, antiviral, anti-inflammatory, antidiabetic, antithrombotic, hepatoprotective (Sowndhararajan et al., 2017). In addition, recent studies have shown that baicalin has shown strong neuroprotective effects in models of various neurological diseases. *In vivo*, baicalein exerted neuroprotective action through reducing behavioral damage and the depletion of dopaminergic neurons in rotenone-induced PD model (Zhang et al., 2017a). Moreover, other studies have shown that treatment with baicalein significantly attenuated the dopamine (DA) content in striatum induced by 1-methyl-4-phenylpyridinium (MPP<sup>+</sup>) (Hung et al., 2016) and increased the numbers of tyrosine hydroxylase (TH) neurons in PD rat model induced by 6-hydroxydopamine (6-OHDA) (Mu et al., 2009). All these data indicated that baicalin can be used as an effective drug to prevent or treat neurodegenerative diseases such as PD.

The preliminary research basis of animal experiment can provide clearly direction for clinical practice, greatly improving the understanding of clinicians and researchers on the disease mechanism and the progress of intervention measures (Sena et al., 2014). In recent years, many animal studies of baicalein have been reported. However, the efficacy and mechanisms of baicalein for PD have not been systematically appraised and summarized. Thus, in the present study, we performed a systematic review and meta-analysis to assess recent literature on the effects of baicalein therapy on animals with PD and provide current preclinical evidence and potential mechanisms on animal models.

## MATERIALS AND METHODS

### Data Sources and Search Strategy

The meta-analysis was conducted according to the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) guidelines (Moher et al., 2015). Seven English and Chinese databases, including China National Knowledge Infrastructure (CNKI), Wanfang Database, Science Direct, PubMed, Web of science, Medline, and EMBASE, were independently searched by two reviewers (XL Li and Y Wang), from their inceptions to December 2019. The following keywords and terms were as follows: "parkinsonian disorders" OR "Parkinson disease" and "Baicalein" OR "Huangqinsu" OR "Baikeli." All studies were limited to animals.

### Inclusion and Exclusion Criteria

Studies conforming to the following inclusion criteria were selected for this review: (1) participants: experimental animals including mice and rats. (2) intervention: baicalein only; (3) outcomes: The effect of baicalein on the animal model of Parkinson's disease, including neurobehavioural. Meanwhile, studies which met the following criteria were excluded: (a) combined use of other drugs; (b) non-animal based studies; (c) case report, comments, clinical experiences, or trials and review article; (d) similar and repeated studies.

### Data Extraction

Two authors (XL Li and Y Wang) extracted data independently from the qualified articles. The following information of each study was recorded: (1) the first author's name, year of publication; (2) animals' characteristics, including species, number, sex, and body weight; (3) methods for PD model establishment and anesthetic used in the model; (4) intervention characteristics, including the dosage and route of administration; (5) main outcome measures and its intergroup differences.

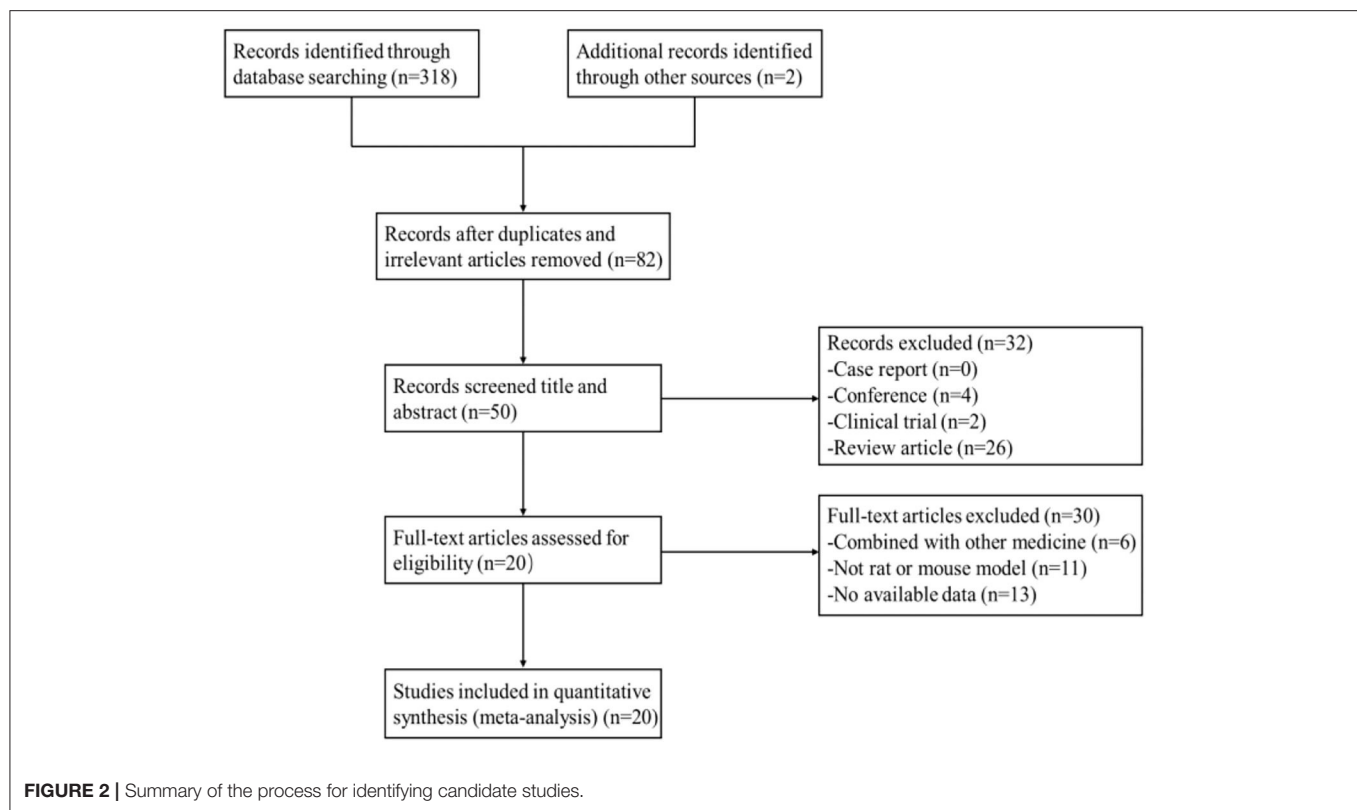

The peak time point was included if the outcomes were tested at different times. The data of the highest dose were extracted when various doses of baicalein were used in study. If the primary data were missing or demonstrated graphically, we tried to contact authors for raw data. And the numerical values in the graph were measured by the digital ruler software when no response was received from the authors.

### Risk of Bias in Individual Studies

The risk of bias in each included study was assessed independently by two investigators (XL Li and Y Wang) using the Systematic Review Centre for Laboratory animal Experimentation (SYRCLE)'s risk of bias tool for animal studies, which was used to evaluate bias in six domains: selection bias (sequence generation, baseline characteristics, and allocation concealment), performance bias (random housing and blinding), detection bias (random outcome assessment and blinding), attrition bias, reporting bias, and other biases (Hooijmans et al., 2014).

### Statistical Analysis

RevMan V.5.3 software was applied for Meta-analyses. Outcome measures were all treated as continuous data and expressed

as standardized mean difference (SMD) with 95% confidence interval (CI). Heterogeneity among individual studies was assessed using the I-square ( $I^2$ ) statistics test. If  $I^2 > 50\%$ , a random effect model was adopted. Instead, a fixed effect model was used. Publication bias was assessed by funnel plots and Egger's test. Probability value  $P < 0.05$  was considered statistically significant.

## RESULTS

### Study Selection

After primary search from seven databases, a total of 320 potentially publications were identified. After removal of repetitive and irrelevant articles, 82 records were remained. By screening titles and abstracts, 32 studies were excluded because they were conferences, clinical trials, or review articles. Then secondary screening was performed by reading the remaining full-text articles, and 30 studies were excluded for at least one of the following reasons: (1) no available data; (2) not rat or mouse model; (3) combined with other medicine. Eventually, 20 eligible studies were selected. A flow diagram of the study selection process is shown in **Figure 2**.

### Characteristics of Included Studies

Twenty rats or mice experiments between 2008 and 2019 were included. Sixteen studies were published in English, and four studies were published in Chinese which containing one online PhD theses. For animal species, Sprague-Dawley (SD) rats were

used in 9 studies, C57B/6J mice were used in 8 studies, ICR mice were used in 2 studies, and the remaining 1 study used Kunming (KM) mice. All animals were male in the included studies. The body weight of SD rats ranged from 180 to 350 g, while the body weight of mice ranged from 18 to 30 g. Anesthetic was reported in 11 studies, including sodium pentobarbital ( $n = 4$ ), chloralose ( $n = 1$ ), equithesin ( $n = 1$ ), ethyl ether ( $n = 1$ ), halothan ( $n = 1$ ), and chloral hydrate ( $n = 4$ ). PD models were established by using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) ( $n = 6$ ), 6-OHDA ( $n = 6$ ), rotenone ( $n = 5$ ), MPP<sup>+</sup> ( $n = 1$ ), acrolein ( $n = 1$ ), oxotremorine ( $n = 1$ ). There were ways of administration of baicalein, including intragastric administration ( $n = 9$ ), intraperitoneal administration ( $n = 5$ ), subcutaneous administration ( $n = 1$ ). The changes of praxeology as primary outcome for assessing baicalein were carried out by the spontaneous motor activity test ( $n = 5$ ), pole test ( $n = 2$ ), apomorphine-induced rotation test ( $n = 4$ ), rotarod test ( $n = 9$ ), grid test ( $n = 2$ ), and tremor test ( $n = 6$ ). About the changes of neurotransmitters, DA was reported in 12 studies, 5-Hydroxyindole-3-acetic acid (5-HIAA) in 2 studies, 5-HT in 2 studies, (3,4-dihydroxyphenylacetic acid) DOPAC in 8 studies, E in 2 studies, gamma-aminobutyric acid (GABA) in 2 studies and glutamate (GLU) in 2 studies. In addition, TH was reported in 13 studies, Cathepsin B in 2 studies, ED-1 in 2 studies, glial fibrillary acidic protein (GFAP) in 4 studies, a-Caspase 1 in 2 studies, superoxide dismutase (SOD) in 2 studies, malondialdehyde (MDA) 5 in studies, glutathione peroxidase (GSH-Px) in 3 studies. The

detailed characteristics of the included studies are summarized in Table 1.

Study Quality

The overall quality of the included studies was relatively low (Figure 3). All but one study was not reported randomization. All studies included were unclear in baseline characteristics, allocation concealment, blinding of participants, and detection bias. while, these studies were all provided information regarding selective reporting and other bias. Six studies adequately reported

random housing and 16 studies adequately reported incomplete outcome data.

Effectiveness Behavior Function

In spontaneous motor activity test, meta-analysis of 5 studies (Cheng et al., 2008; Li, 2011; Mu et al., 2011; He et al., 2015; Zhang et al., 2017b) showed significant effect of baicalein for increasing the frequency of spontaneous activity in PD animals compared with control group [ $n = 54$ ,  $SMD = 2.22$ , 95% CI (1.72–2.73),  $P < 0.00001$ ; heterogeneity:  $\chi^2 = 4.55$ ,  $df = 4$  ( $P = 0.34$ );  $I^2 =$

12%; **Figure 4A**]. In pole test, meta-analysis of 2 studies (Cheng et al., 2008; Gao et al., 2015) showed significant effect of baicalein for prolongating the total time for climbing down the pole in PD animals compared with control group [ $n = 21$ , SMD =  $-1.77$ , 95% CI ( $-2.52$  to  $-1.03$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 1.61$ ,  $df = 1$  ( $P = 0.20$ );  $I^2 = 38\%$ ; **Figure 4B**]. In rotarod test, meta-analysis of 9 studies (Im et al., 2005; Li, 2011; Mu et al., 2011; Lee et al., 2014; Xue et al., 2014; Gao et al., 2015; Hu et al., 2016; Kuang et al., 2017; Zhang et al., 2017b) showed significant effect of baicalein for extending the time spent on the rod in PD animals compared with control group [ $n = 96$ , SMD =  $4.04$ , 95% CI ( $3.50$ – $4.58$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 12.38$ ,  $df = 8$  ( $P = 0.14$ );  $I^2 = 35\%$ ; **Figure 4C**]. In apomorphine-induced rotations test, meta-analysis of 4 studies (Im et al., 2006; Mu et al., 2009; Li, 2011; He et al., 2015) showed significant effect of baicalein for decreasing in the number of apomorphine-induced rotations in PD animals compared with control group [ $n = 42$ , SMD =  $-1.96$ , 95% CI ( $-2.55$  to  $-1.37$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 21.68$ ,  $df = 3$  ( $P < 0.00001$ );  $I^2 = 86\%$ ]. Through sensitivity analysis, we removed one study (Im et al., 2006) which utilized ICR mice with PD, while the other studies used models established with SD rats. Meta-analysis of 3 studies (Mu et al., 2009; Li, 2011; He et al., 2015) showed significant effect of baicalein for decreasing in the number of apomorphine-induced rotations in PD animals compared with control group [ $n = 34$ , SMD =  $-1.85$ , 95% CI ( $-2.45$  to  $-1.26$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 2.87$ ,  $df = 2$  ( $P = 0.24$ );  $I^2 = 30\%$ ; **Figure 4D**]. In grid test, meta-analysis of 2 studies (Hu et al., 2016; Kuang et al., 2017) showed significant effect of baicalein for prolongating the descent latency in PD animals compared with control group [ $n = 22$ , SMD =  $3.09$ , 95% CI ( $2.16$ – $4.02$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 0.63$ ,  $df = 1$  ( $P = 0.43$ );  $I^2 = 0\%$ ; **Figure 4E**]. In tremor test, meta-analysis of 2 studies (Mu et al., 2009; Yu et al., 2012) showed significant effect of baicalein for reducing the amplitude in PD animals compared with control group [ $n = 24$ , SMD =  $-7.81$ , 95% CI ( $-9.62$  to  $-6.00$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 0.65$ ,  $df = 1$  ( $P = 0.42$ );  $I^2 = 0\%$ ; **Figure 4F**]. Meta-analysis of 4 studies (Mu et al., 2009; Li, 2011; Yu et al., 2012; He et al., 2015) showed significant effect of baicalein for reducing the frequency in PD animals compared with control group [ $n = 40$ , SMD =  $-5.96$ , 95% CI ( $-7.11$  to  $-4.82$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 5.22$ ,  $df = 3$  ( $P = 0.16$ );  $I^2 = 43\%$ ; **Figure 4G**]. These results suggested that baicalein ameliorated behavioral deficits in PD animals.

## Neuroprotective Mechanism

### *The adjustment of neurotransmitters disequilibrium*

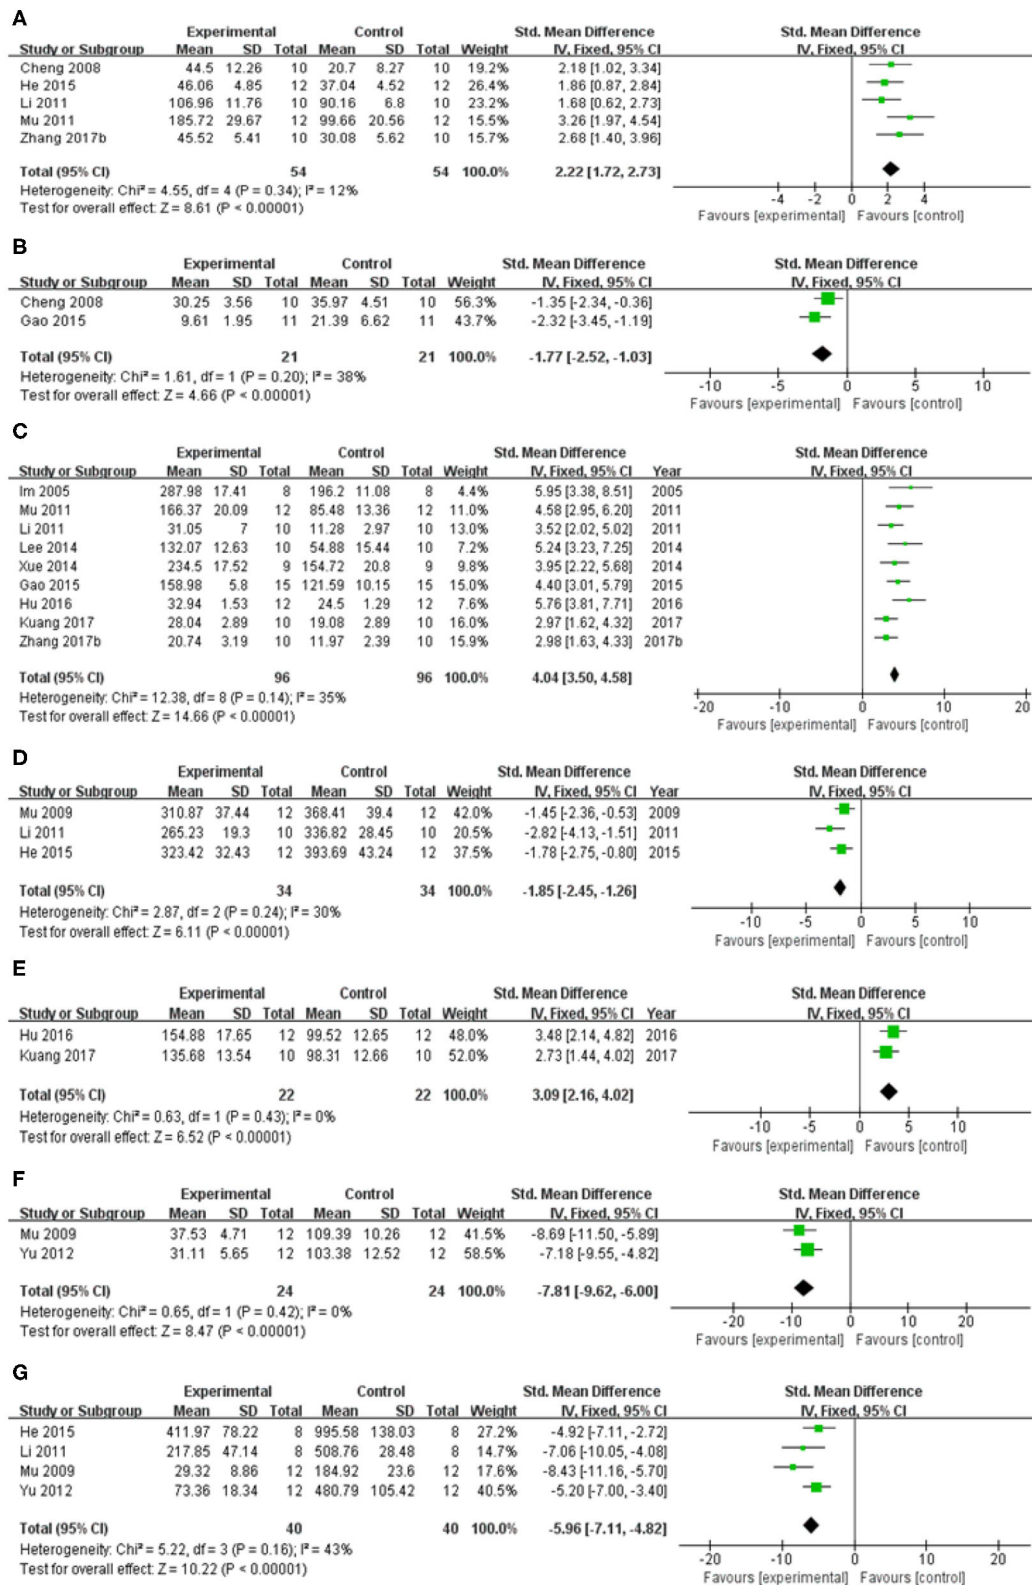

Compared with control group, meta-analysis of 12 studies (Im et al., 2005, 2006; Cheng et al., 2008; Li, 2011; Mu et al., 2011; Yu et al., 2012; He et al., 2015; Hu et al., 2016; Hung et al., 2016; Kuang et al., 2017; Yang et al., 2018; Zhao et al., 2018) showed baicalein has significant effects on increasing DA [ $n = 75$ , SMD =  $3.31$ , 95% CI ( $2.71$ – $3.90$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 22.59$ ,  $df = 11$  ( $P = 0.02$ );  $I^2 = 51\%$ ]. One study (Li, 2011) was removed through sensitivity analysis because baicalin was not administered until 5 weeks after modeling. The remain 11 studies (Im et al., 2005, 2006; Cheng et al., 2008; Mu et al., 2011; Yu et al., 2012; He et al., 2015; Hu et al., 2016; Hung et al., 2016; Kuang

et al., 2017; Yang et al., 2018; Zhao et al., 2018) showed significant effects on increasing DA in analysis [ $n = 69$ , SMD =  $3.66$ , 95% CI ( $3.01$ – $4.32$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 16.30$ ,  $df = 10$  ( $P = 0.09$ );  $I^2 = 39\%$ ; **Figure 5A**]. Eight studies (Cheng et al., 2008; Li, 2011; Mu et al., 2011; He et al., 2015) for increasing DOPAC [ $n = 49$ , SMD =  $1.89$ , 95% CI ( $1.34$ – $2.44$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 16.26$ ,  $df = 7$  ( $P = 0.02$ );  $I^2 = 57\%$ ]. Through sensitivity analysis, we removed one study (Yang et al., 2018) because the PD model was established with oxyphenylalanine which was less commonly available. The remain seven studies (Im et al., 2005, 2006; Cheng et al., 2008; Li, 2011; Mu et al., 2011; He et al., 2015; Hu et al., 2016) showed significant effects on increasing DOPAC in analysis [ $n = 41$ , SMD =  $1.70$ , 95% CI ( $1.13$ – $2.26$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 6.84$ ,  $df = 6$  ( $P = 0.34$ );  $I^2 = 12\%$ ; **Figure 5B**]. Meta-analysis of 2 studies (Cheng et al., 2008; Li, 2011) increasing the level of 5-HT [ $n = 12$ , SMD =  $2.12$ , 95% CI ( $1.02$ – $3.23$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 1.19$ ,  $df = 1$  ( $P = 0.28$ );  $I^2 = 16\%$ ; **Figure 5C**]. Meta-analysis of 2 studies (Cheng et al., 2008; Li, 2011) increasing the level of 5-HIAA [ $n = 12$ , SMD =  $1.45$ , 95% CI ( $0.49$ – $2.42$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 1.39$ ,  $df = 1$  ( $P = 0.24$ );  $I^2 = 28\%$ ; **Figure 5D**]. Meta-analysis of 2 studies (Li, 2011; Yang et al., 2018) showed insignificant effect of baicalein for increasing the level of E in PD animals compared with control group [ $n = 14$ , SMD =  $0.47$ , 95% CI ( $0.29$ – $1.23$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 0.53$ ,  $df = 1$  ( $P = 0.47$ );  $I^2 = 0\%$ ; **Figure 5E**]. Meta-analysis of 2 studies (Li, 2011; Yu et al., 2012) increasing the level of GABA [ $n = 12$ , SMD =  $5.57$ , 95% CI ( $3.44$ – $7.70$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 1.42$ ,  $df = 1$  ( $P = 0.23$ );  $I^2 = 29\%$ ; **Figure 5F**]. Meta-analysis of 2 studies (Li, 2011; Yu et al., 2012) increasing the level of GLU [ $n = 12$ , SMD =  $-2.47$ , 95% CI ( $-3.67$  to  $-1.27$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 1.68$ ,  $df = 1$  ( $P = 0.19$ );  $I^2 = 41\%$ ; **Figure 5G**].

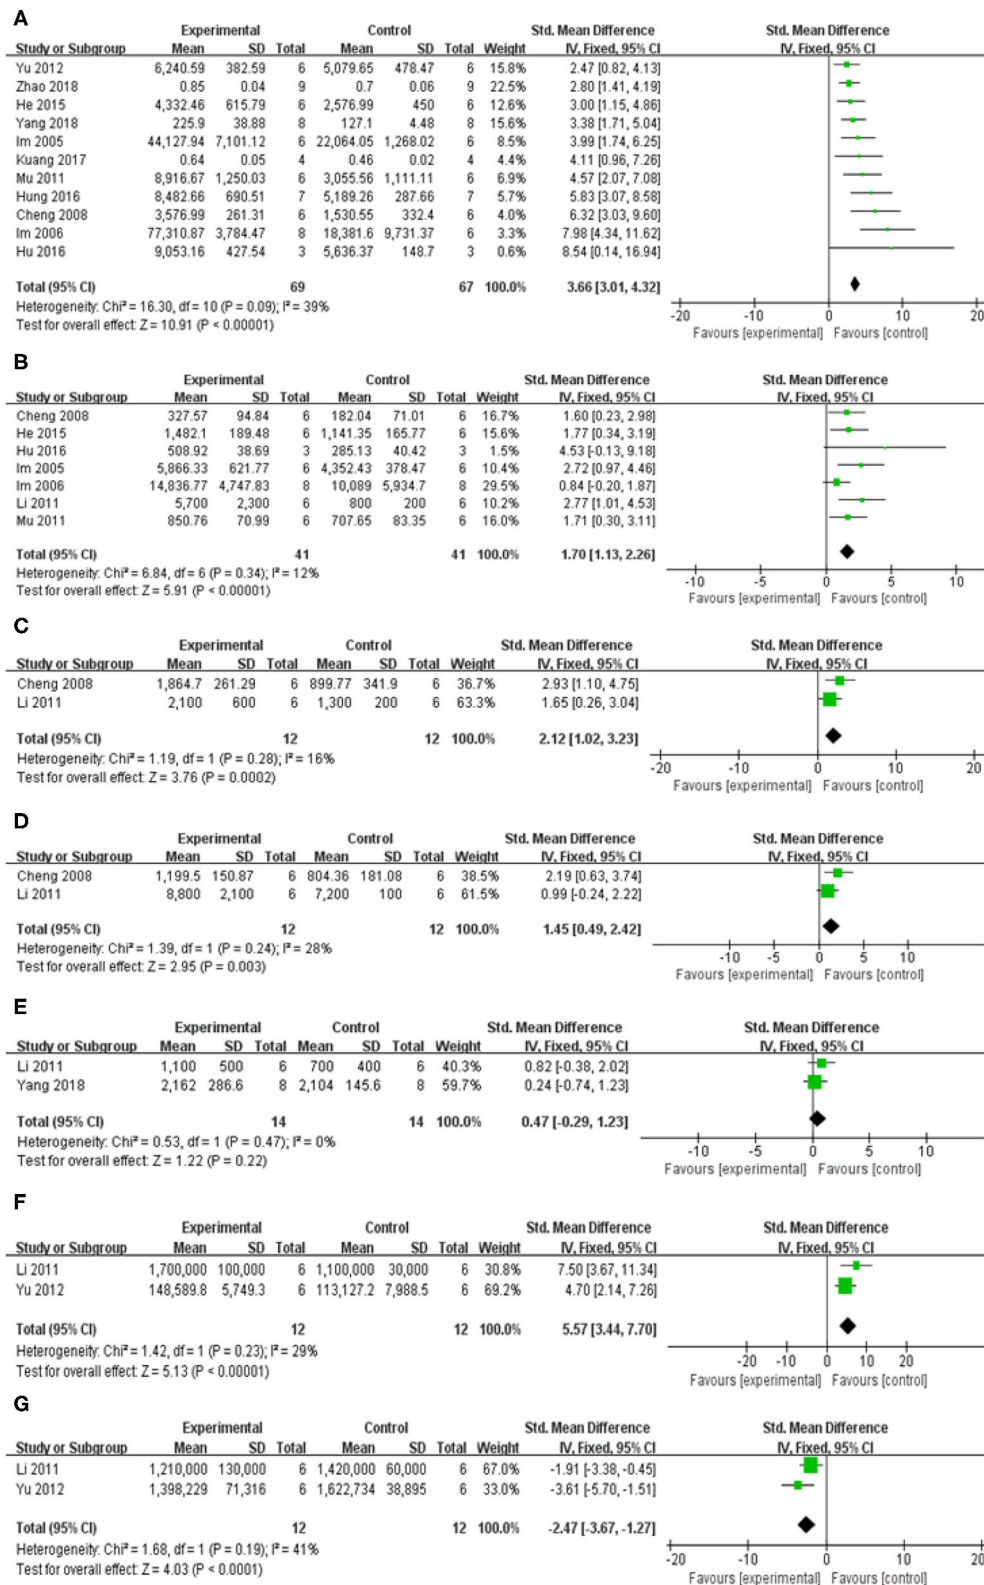

### *The inhibition of oxidative stress*

Compared with control group, meta-analysis of two studies (Cheng et al., 2008; Mu et al., 2011) showed baicalein has significant effects on increasing SOD [ $n = 12$ , SMD =  $3.85$ , 95% CI ( $2.28$ – $5.42$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 0.79$ ,  $df = 1$  ( $P = 0.38$ );  $I^2 = 0\%$ ; **Figure 6A**]. Meta-analysis of five studies (Im et al., 2005, 2006; Cheng et al., 2008; Mu et al., 2011; Yang et al., 2018) showed baicalein has significant effects on decreasing MDA [ $n = 38$ , SMD =  $-3.62$ , 95% CI ( $-4.55$  to  $-2.68$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 28.91$ ,  $df = 4$  ( $P < 0.00001$ );  $I^2 = 86\%$ ]. Through sensitivity analysis, we removed one study (Yang et al., 2018) because of the same reason mentioned above. The remain four studies (Im et al., 2005, 2006; Cheng et al., 2008; Mu et al., 2011) showed significant effects on decreasing MDA in analysis [ $n = 30$ , SMD =  $-6.61$ , 95% CI ( $-8.11$  to  $-5.11$ ),  $P < 0.00001$ ; heterogeneity:  $\chi = 4.01$ ,  $df = 3$  ( $P = 0.26$ );  $I^2 = 25\%$ ; **Figure 6B**]. Meta-analysis of three studies (Cheng et al., 2008; Mu et al., 2011; Yang et al., 2018) showed baicalein has significant effects on increasing GSH-Px [ $n = 20$ , SMD =  $0.54$ , 95% CI ( $-0.34$  to  $1.42$ ); heterogeneity:  $\chi = 25.75$ ,  $df = 2$  ( $P < 0.00001$ );  $I^2 = 92\%$ ]. We used sensitivity analyses omitting one study at a time. And one study (Yang et al., 2018) was removed because of the same reason mentioned above. The remain two studies (Cheng et al., 2008; Mu et al., 2011) showed significant

effects on increasing GSH-Px in analysis [ $n = 12$ ,  $SMD = 3.99$ , 95% CI (2.38–5.61),  $P < 0.00001$ ; heterogeneity:  $\chi = 0.76$ ,  $df = 1$  ( $P = 0.38$ );  $I^2 = 0\%$ ; **Figure 6C**].

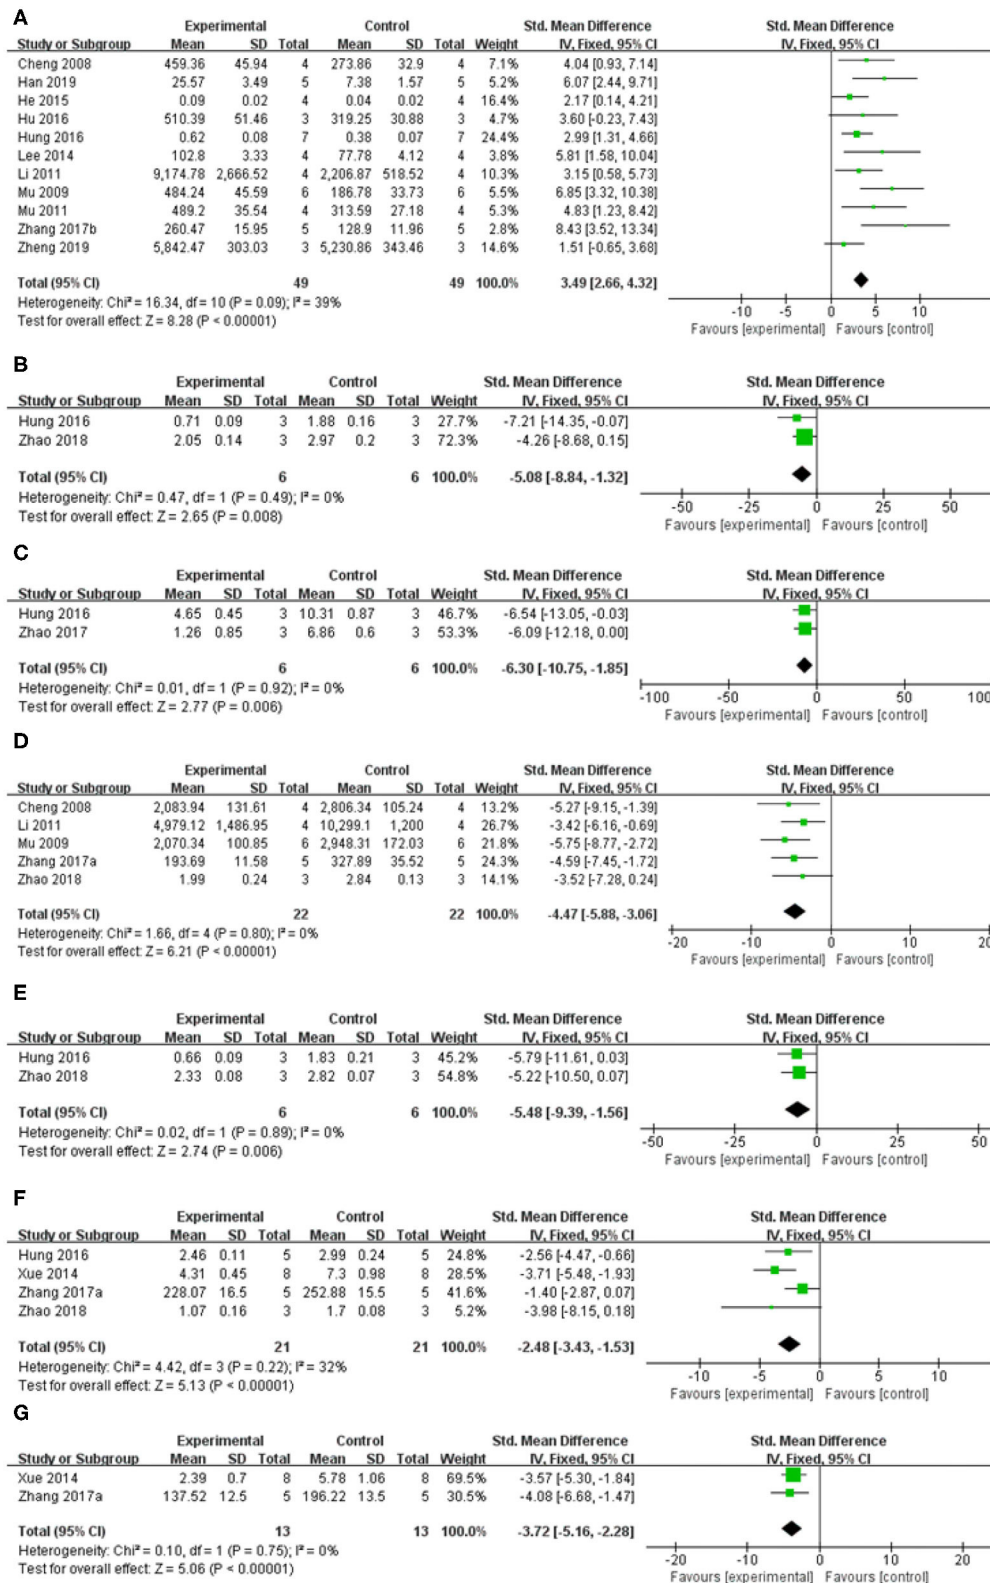

### Regulation of enzyme activity

Meta-analysis of 13 studies (Im et al., 2005, 2006; Cheng et al., 2008; Mu et al., 2009; Mu et al., 2011; Li, 2011; Lee et al., 2014; He et al., 2015; Hu et al., 2016; Hung et al., 2016; Zhang et al., 2017b; Han et al., 2019; Zheng et al., 2019) showed baicalein had significant effect on increasing the level of TH compared with the control group [ $n = 63$ ,  $SMD: 3.80$ , 95% CI (2.98–4.62),  $P < 0.00001$ ; heterogeneity:  $\chi = 41.40$ ,  $df = 12$  ( $P < 0.00001$ );  $I^2 = 71\%$ ]. Owing to the obvious heterogeneity, we conducted a sensitivity analyses and removed two study (Im et al., 2005, 2006) that Parkinson's model of ICR mice was induced with 6-OHDA. Meta-analysis of the remaining 11 studies (Cheng et al., 2008; Mu et al., 2009; Mu et al., 2011; Li, 2011; Lee et al., 2014; He et al., 2015; Hu et al., 2016; Hung et al., 2016; Zhang et al., 2017b; Han et al., 2019; Zheng et al., 2019) showed baicalein had significant effect on increasing the level of TH compared with the control group [ $n = 49$ ,  $SMD: 3.49$ , 95% CI (2.66–4.32),  $P < 0.00001$ ; heterogeneity:  $\chi = 16.34$ ,  $df = 10$  ( $P = 0.09$ ),  $I^2 = 39\%$ ; **Figure 7A**]. One study (Yu et al., 2012) demonstrated that baicalein increased the GS activity ( $P < 0.05$ ), while reduced the

GABA-T activity ( $P < 0.05$ ) compared with the control group. One study (Yang et al., 2018) increased the AchE activity ( $P < 0.05$ ).

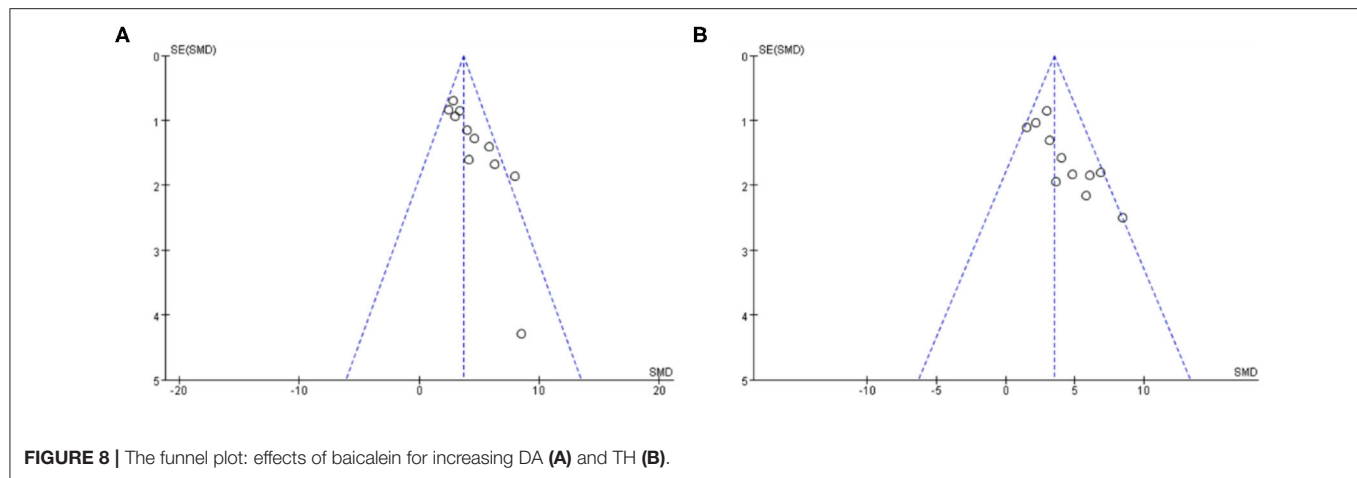

### The inhibition of neuroinflammation

Meta-analysis of 4 studies (Xue et al., 2014; Hung et al., 2016; Zhang et al., 2017a; Zhao et al., 2018) indicated baicalein was significant for decreasing the level of Interleukin-1 $\beta$  (IL-1 $\beta$ ) compared with control group [ $n = 21$ ,  $SMD = -2.48$ , 95% CI (-3.43 to -1.53),  $P < 0.00001$ ; heterogeneity:  $\chi = 4.42$ ,  $df = 3$  ( $P = 0.22$ );  $I^2 = 32\%$ ; **Figure 7F**]. Meta-analysis of 2 studies (Xue et al., 2014; Zhang et al., 2017a) decreasing expression of tumor necrosis factor (TNF- $\alpha$ ) [ $n = 13$ ,  $SMD = -3.72$ , 95% CI (-5.16 to -2.28),  $P < 0.00001$ ; heterogeneity:  $\chi = 0.10$ ,  $df = 1$  ( $p = 0.75$ );  $I^2 = 0\%$ ; **Figure 7G**]. Meta-analysis of 2 studies (Hung et al., 2016; Zhao et al., 2018) showed baicalein was significant for decreasing the level of Cathepsin B [ $n = 6$ ,  $SMD = -5.08$ , 95% CI (-8.84 to -1.32),  $P = 0.008$ ; heterogeneity:  $\chi = 0.47$ ,  $df = 1$  ( $P = 0.49$ );  $I^2 = 0\%$ ; **Figure 7B**], and ED-1 [ $n = 6$ ,  $SMD = -6.30$ , 95% CI [-10.75 to -1.85],  $P = 0.006$ ; heterogeneity:  $\chi = 0.01$ ,  $df = 1$  ( $P = 0.92$ );  $I^2 = 0\%$ ; **Figure 7C**] compared with control group. Meta-analysis of 5 studies (Cheng et al., 2008; Mu et al., 2009; Li, 2011; Zhang et al., 2017a; Zhao et al., 2018) showed baicalein was significant for decreasing the level of GFAP compared with

**FIGURE 7 |** Forest plot: effects of baicalein for the change of (A) TH, (B) Cathepsin B, (C) ED-1, (D) GFAP, (E) a-Caspase-1, (F) IL-1 $\beta$ , and (G) TNF- $\alpha$  compared with control group.

**FIGURE 8 |** The funnel plot: effects of baicalein for increasing DA (A) and TH (B).

control group [ $n = 22$ ,  $SMD = -4.47$ , 95% CI ( $-5.88$  to  $-3.06$ ),  $P < 0.00001$ ; heterogeneity:  $\chi^2 = 1.66$ ,  $df = 4$  ( $p = 0.80$ );  $I^2 = 0\%$ ; **Figure 7D**]. Two studies (Zhang et al., 2017a; Zheng et al., 2019) for decreasing expression of IL-6. 1 study (Zhang et al., 2017a) for decreasing expression of p-IkB/IkB, p-p65/p65, p-p38/p38, and p-Erk1/2/Erk1/2 ( $P < 0.05$ ), while increasing expression of p-JNK/JNK ( $P < 0.05$ ).

#### *The inhibition of neuronal apoptosis*

Meta-analysis of 2 studies (Hung et al., 2016; Zhao et al., 2018) indicated baicalein was significant for decreasing the expression of a-Caspase 1 compared with control group [ $n = 6$ ,  $SMD = -5.48$ , 95% CI ( $-9.39$  to  $-1.56$ ),  $P = 0.006$ ; heterogeneity:  $\chi^2 = 0.02$ ,  $df = 1$  ( $P = 0.89$ );  $I^2 = 0\%$ ; **Figure 7E**]. One study (Hung et al., 2016) for decreasing protein expression of a-Caspase 9 ( $P < 0.05$ ) and a-Caspase 12 ( $P < 0.05$ ). One study (Zhao et al., 2018) for decreasing protein expression of a-Caspase 3 ( $P < 0.05$ ), RIPK-1 ( $P < 0.05$ ), and RIPK-3 ( $P < 0.05$ ). One study (Zheng et al., 2019) for decreasing expression of Bax mRNA ( $P < 0.05$ ).

#### *The restoration of mitochondrial dysfunction*

One study (Zhang et al., 2017b) for increasing the protein levels of PGC-1 $\alpha$  ( $P < 0.05$ ), NRF-1 ( $P < 0.05$ ), TRAM ( $P < 0.05$ ), and the activity of mitochondrial complex I ( $P < 0.05$ ) and ATP levels ( $P < 0.01$ ) in the ventral midbrain in rotenone-induced PD rats.

#### *The inhibition of abnormal protein aggregation*

One study (Hu et al., 2016) showed that baicalein decreased  $\alpha$ -Synuclein ( $\alpha$ -syn) levels in the ileum and thoracic spinal cord in the rotenone induced PD mouse model.

#### *The prevention of MPP<sup>+</sup>-induced autophagy*

One study (Hung et al., 2016) showed that baicalein inhibited MPP<sup>+</sup>-induced elevation in light chain 3-II (LC3-II) level in the rat nigrostriatal dopaminergic system.

### **Publication Bias**

Funnel plots were reviewed for two outcomes about DA and TH (**Figure 8**). The funnel graph revealed an asymmetry distribution of included studies. The Egger's regression ( $p < 0.05$ ) also

confirmed the publication bias due to a small number of studies reporting negative Baicalein treatment effects. Although the Trim and Fill methods were used to correct publication bias, the results did not change.

## **DISCUSSION**

### **Summary of Results**

To our knowledge, this is the first preclinical evidences to determine the effects of baicalein for experimental PD in mice and rats. The findings available from the present study showed that baicalein could improve behavior function in experimental PD, mainly through the mechanisms of adjusting neurotransmitters, regulating enzyme activities, suppressing oxidative stress, ameliorating mitochondrial dysfunction, restraining neuroinflammation, inhibiting abnormal protein aggregation, and neuronal apoptosis.

### **Limitations**

This meta-analysis had several limitations. First, all the databases we searched were in English or Chinese, leading to certain deviations. Second, negative findings are less likely to be published, which may overestimate the true efficacy of baicalein to a certain degree. Third, the methodological quality of included studies was considered moderate, which was an inherent drawback in the primary study. In particular, all the studies failed to mention the allocation concealment, blinding of outcome assessment, etc. Fourth, the high heterogeneity among studies was possibly associated with different conditions including different models of PD induction, different administration route, and different doses of neurotoxins and baicalein. Thus, the results in this study should be partially treated with caution.

### **Implications for Practice**

Currently, the medical animal experiments have become an important means of biomedical research which link basic research and clinical trials. Due to the limitations of medical ethics, some trauma researches, toxicological characteristics, and pharmacodynamics studies are not suitable for human clinical

trials. Therefore, animal models capable of replicating important functional, structural, and molecular pathological features of human disease to the maximum extent are essential for clinical translation (Saulnier-Blache et al., 2018).

The present study demonstrated that baicalein had neuroprotective effects in PD models according to the neurobehavioral. The mechanisms of baicalein for PD are summarized as follows: (1) Correction of neurotransmitters: the pathological mechanisms of PD is closely related to the abnormal release of various neurotransmitters in brain, including monoamine neurotransmitters such as DA, DOPAC, NE and 5-HT, amino acid neurotransmitters such as Glu,  $\gamma$ -GABA and ACh, and peptide transmitters etc (Kulikova et al., 2018). In central nervous system, the main form of synaptic transmission is neurochemical transmission. The neurotransmitters released by presynaptic membrane can bind with the corresponding postsynaptic membrane receptors, and result in producing synaptic depolarization potential or hyperpolarization potential, which weaken or enhance excitability of postsynaptic neurons (Ztaoua and Amalric, 2019). Interestingly, the two chemical transmitters, DA and ACh are antagonistic to each other in the corresponding nerve cells. Although the level of ACh is normal in the brain of patients with PD, the decrease of DA content leads to the relative hyperactivity of cholinergic neurons, which causes some symptoms of PD (McKinley et al., 2019). The evidence available from the present study showed that baicalein could effectively rectify the content of monoamine transmitters and amino acid transmitters in animals with PD. (2) Regulation of enzyme activity: as we all know, the secretion of neurotransmitters in brain must be affected by the activity of

corresponding enzyme. TH, as the rate-limiting enzyme in the synthesis process of DA, is a specific marker of dopaminergic neurons (Liang et al., 2015). AChE is an essential enzyme for the selective hydrolysis of ACh, which can hydrolyze ACh into choline and acetic acid (Karumuri et al., 2019). GABA and GLu are metabolized by continuous action of GABA transaminase (GABA-T) and glutamine synthetase (GS) protein (Baber and Haghighat, 2010). Our data indicated that baicalein could balance neurotransmitter by regulating the activity of TH, AChE, GABA-T, and GS. (3) Anti-oxidative stress: oxidative stress plays a key role in the occurrence and development of PD. The content of MDA is an important indicator of the level of oxygen free radicals, which can indirectly reflect the degree of cell damage. As the main free radical scavenging enzyme in the body, SOD reflects the endogenous antioxidant capacity of the organism. And GSH-Px is a critical enzyme widely used in the body that can catalyze the decomposition of  $H_2O_2$  (Sharma et al., 2020). Our data demonstrated that baicalein had anti-oxidative stress effects by increasing the activity of antioxidant enzymes in brain tissues, improving the antioxidant capacity, scavenging free radicals, inhibiting lipid peroxidation, and protecting the structural and functional integrity of cell membranes. (4) Anti-inflammation: neuroinflammation is an intricate cascade of neurodegenerative changes in Parkinson's syndrome, including the activation of microglia and astrocytes and the release of inflammatory cytokines. NF- $\kappa$ B is widely expressed in microglia, astrocytes and neurons. In normal state, the endogenous inhibitor I $\kappa$ B inactivate NF- $\kappa$ B, while IL-1 $\beta$  and TNF- $\alpha$  can induce the phosphorylation and degradation of IKK- $\beta$ , which translocate NF- $\kappa$ B into the nucleus and promote the expression of inflammatory genes (Yan

et al., 2019; Wang et al., 2020). The pooled data showed that treatment of baicalein prominently suppressed the expression of NF- $\kappa$ B, GFAP (a biomarker of activated astrocytes), ED-1 (a biomarker of activated microglia), and mature cathepsin B (a cysteine lysosomal protease) (Zhao et al., 2018). (5) Restoration of mitochondrial dysfunction: mitochondrial dysfunction is an early signal in almost all neurodegenerative diseases, including PD (Angelova et al., 2018). Baicalein greatly increased the expression of the key regulators of mitochondrial biogenesis (PGC-1 $\alpha$ , NRF-1, and TFAM). In addition, baicalein could maintain the function of mitochondria by partially enhancing the activity of mitochondrial complex enzyme in brain, and ultimately delay the progression of PD. (6) The inhibition of abnormal protein aggregation: one of the characteristics of pathological changes in PD is the appearance of Lewy bodies which are composed of  $\alpha$ -syn (Reuland and Church, 2020). Furthermore, the mutation or overexpression of  $\alpha$ -syn gene can accelerate mitochondrial dysfunction, enhance sensitivity to oxidative stress and increase DAT-mediated toxicity, thus promoting cell death (Vekrellis et al., 2011). Our study indicated that baicalein could inhibit the formation of  $\alpha$ -syn oligomers and subsequently prevent the progression of  $\alpha$ -syn accumulation *in vivo*. (7) Antiapoptosis: Growing evidence suggests that another possibility for dopaminergic neuron loss is the abnormal occurrence of apoptosis (Liu et al., 2019). The caspases are a class of cysteine proteases, many of whose members are involved in apoptosis. Caspases convey the apoptotic signal through proteolytic cascade with caspases cleaving and subsequently activate other caspases that degrade cellular targets leading to cell death. Additionally, Bcl-2 family which is a core member of apoptosis gene families plays a critical role in apoptotic process (Schulz and Gerhardt, 2001). (8) Regulation of autophagy: Autophagy is a lysosome-mediated degradation process that involves degradation of redundant or defective cellular components within the cell, including both misfolded proteins and damaged organelles (Hou et al., 2020). Thus, autophagy activity is correlated with disease progression in neurodegenerative disorders such as AD and PD (Nobuhiro

et al., 2018). However, dysregulated or excessive autophagy could cause autophagic cell death, the type II programmed cell death (Thellung et al., 2019). LC3-II is currently considered to be a biomarker of autophagy, which reflect the extent of autophagy (Runwal et al., 2019). Systemic administration of baicalein for 2 days significantly attenuated MPP<sup>+</sup>-induced elevation in LC3-II in the infused substantia nigra (Hung et al., 2016). Our study indicates that baicalein prevents programmed cell death, mainly by regulating the expression of genes related to apoptosis and autophagy. To summarize, we present a schematic overview of the neuroprotective mechanisms of baicalein in PD (Figure 9).

## CONCLUSION

The present study showed baicalein could exert potential neuroprotective effects in experimental PD, largely through mechanisms involving antioxidation, anti-inflammatory, regulating neurotransmitters, adjusting enzyme activity, inhibiting protein aggregation, restoring mitochondrial dysfunction, inhibiting apoptosis, and autophagy. Thus, baicalein could be a candidate for further clinical trials of PD.

## AUTHOR CONTRIBUTIONS

YW and XL conceived this review and completed the manuscript. YW, NW, and XL performed the literature searches electronically and manually. All authors contributed to the article and approved the submitted version.

Deep brain stimulation (DBS) is an effective surgical therapy for Parkinson’s disease (PD). However, limitations of the DBS systems have led to great interest in adaptive neuromodulation systems that can dynamically adjust stimulation parameters to meet concurrent therapeutic demand. Constant high-frequency motor cortex stimulation has not been remarkably efficacious, which has led to greater focus on modulation of subcortical targets. Understanding of the importance of timing in both cortical and subcortical stimulation has generated an interest in developing more refined, parsimonious stimulation techniques based on critical oscillatory activities of the brain. Concurrently, much effort has been put into identifying biomarkers of both parkinsonian and physiological patterns of neuronal activities to drive next generation of adaptive brain stimulation systems. One such biomarker is beta-gamma phase amplitude coupling (PAC) that is detected in the motor cortex. PAC is strongly correlated with parkinsonian specific motor signs and symptoms and respond to therapies in a dose-dependent manner. PAC may represent the overall state of the parkinsonian motor network and have less instantaneously dynamic fluctuation during movement. These findings raise the possibility of novel neuromodulation paradigms that are potentially less invasiveness than DBS. Successful application of PAC in neuromodulation may necessitate phase-dependent stimulation technique, which aims to deliver precisely timed stimulation pulses to a specific phase to predictably modulate to selectively modulate pathological network activities and behavior in real time. Overcoming current technical challenges can lead to deeper understanding of the parkinsonian pathophysiology and development of novel neuromodulatory therapies with potentially less side-effects and higher therapeutic efficacy.

**Keywords:** Parkinson’s disease, cortical stimulation, motor cortex, phase-dependent stimulation, phase-amplitude coupling, neuromodulation

## INTRODUCTION

In Parkinson's Disease (PD), loss of dopaminergic input into the posterior striatum leads to disordered signaling throughout the basal ganglia-thalamo-cortical (BGTC) network that manifests itself as motor symptoms of bradykinesia, rigidity, and tremor (Hammond et al., 2007). Network-wide synchronized pathological neuronal activity is thought to cause dysfunction at the major nodes of the BGTC network (Bergman et al., 1994; Brown et al., 2001; Bevan, 2002; Hammond et al., 2007). Deep brain stimulation (DBS) is an effective surgical therapy for PD that targets the deep nodes of the BGTC network to ameliorate the pathological neuronal activities. However, current DBS therapies are limited by stimulation induced side-effects and mal-adaptive neuroplasticity from continuous electrical stimulation of the BGTC network at the major nodes (Chen et al., 2006; Tripoliti et al., 2011; Castrioto et al., 2014). Therefore, there has been a significant interest in identifying both parkinsonian and physiologically patterns of neuronal activities that can be used to adjust stimulation parameters in real-time to meet the concurrent therapeutic demand. This closed-loop or adaptive neuromodulation strategy has the potential to significantly improve upon the currently available open-loop DBS systems (Little et al., 2013; Rosa et al., 2015; Little et al., 2016a,b; Piña-Fuentes et al., 2017; Rosa et al., 2017).

Recently, beta-gamma phase-amplitude coupling (PAC) has been identified as a highly promising electrophysiologic biomarker of parkinsonian motor state that can be detected in the superficial node (i.e., the motor cortex) of the BGTC network (de Hemptinne et al., 2013, 2015; Shimamoto et al., 2013; Swann et al., 2015). Unlike the beta activities that represent local information processing, PAC is a type of cross-frequency coupling phenomenon that represents information transmission across multiple cortical and subcortical areas that are involved in both pathologic and normal brain activities such as cognition, perception, and movement (Shimamoto et al., 2013). Excessive PAC is associated with the parkinsonian motor state and can be normalized by both therapeutic dopaminergic medication and DBS therapy in a dose-dependent manner (de Hemptinne et al., 2015; Swann et al., 2015; Wang et al., 2018). These remarkable findings raise the possibility that PAC can serve both as a biomarker to drive adaptive neuromodulation of the deep nodes and as a therapeutic target in an adaptive cortical neuromodulation scheme.

In this article, we review recent evidence regarding PAC in the context of PD and present our perspective on how this biomarker could be leveraged to advance neuromodulation therapies, with an emphasis on utilizing phase-dependent stimulation techniques to target new structures with a lower risk of side-effects.

## Pathological Cortical Electrophysiology in Parkinson's Disease

Neural oscillations are essential for normal brain processing and are thought to play a critical role in coordinating activities within and across different regions of the brain

(Canolty and Knight, 2010; Hyafil et al., 2015; Salimpour and Anderson, 2019). As representations of rhythmic changes in neuronal excitability, oscillations exist in different frequencies across various spatiotemporal scales and have been implicated in attention, cognition, memory, and sensory integration (Gelperin, 2006; Wang, 2010; Watanabe and Hirono, 2016). These synchronous activities are thought to result from simultaneous input from common presynaptic neurons in a tightly regulated manner with each pattern reflecting the timing of separate information processing and integration (Heck et al., 2007). Because of their fundamental importance to the functioning of the brain, unsurprisingly, disturbances in the synchronous patterns have been implicated in various common neurological disorders (Allen et al., 2011; Goutagny et al., 2013; Bahramisharif et al., 2016; Zhang et al., 2017). In PD, a low dopaminergic state classically manifests itself as excessive beta-band power and synchrony throughout the BGTC network (Schnitzler and Gross, 2005; Hammond et al., 2007). However, the electrophysiology of PD is more complicated and may involve multiple functional modes in which there is excessive synchrony both within and between nodes of the BGTC network that are both associated with the severity of certain parkinsonian signs and symptoms (Ahn et al., 2015). This complexity may have resulted from complex interactions that are constantly occurring between neural oscillations across neural circuits and networks.

Indeed, neural oscillations possess unique coupling properties, such as cross-frequency coupling (CFC), in which components of the rhythmic patterns, such as amplitude, phase, and frequency, interact between different frequency bands within and across circuits and networks (Canolty and Knight, 2010). The exact origin of CFC is yet to be elucidated, but transient, mechanistic coupling (i.e., synaptic, electrical) between functionally distinct neuronal subpopulations has been suggested as a potential mechanism (Canolty and Knight, 2010; Salimpour and Anderson, 2019). Phase-amplitude coupling (PAC) is a class of CFC, and it involves coupling between phases of a low-frequency oscillation and the amplitude of a high-frequency oscillation. Low-frequency phases are often dynamically entrained by behaviorally relevant external sensorimotor events and internal cognitive processing implicated in learning, memory, motivation, and decision making (Lakatos et al., 2008; Schroeder and Lakatos, 2009). Therefore, PAC, which represents the modulation of high-frequency power by a low-frequency phase entrained and coordinated with slower external and internal events, is considered a key fundamental mechanism behind cognitive processing (Canolty and Knight, 2010). PAC is generally detected and quantified by first recording raw electrocorticography (ECoG) data from the cortical surface using a subdural electrode, processing the data to estimate the instantaneous power of each frequency band, then calculating the degree of amplitude modulation by phase measured in modulation index (Tort et al., 2010; Madhavan et al., 2015).

Phase amplitude coupling has been studied in both animals and humans and has been observed across multiple cortical and subcortical sites (Canolty and Knight, 2010; Miller et al., 2012; de Hemptinne et al., 2013, 2015). Implicated in PD is beta-phase and gamma-amplitude coupling in the motor cortex, also

known as “beta-gamma PAC.” PAC occurs when the low beta-frequency rhythm synchronizes with the amplitude of gamma oscillations (Miller et al., 2012; Yanagisawa et al., 2012). PAC level in the motor cortex normally fluctuates throughout the movement cycle, such that it elevates in the rest state and decreases in both planning and execution phases of movement (Miller et al., 2012; de Hemptinne et al., 2015). Exaggerated PAC levels are consistently detected in the motor cortex of PD patients both at rest and during movement (de Hemptinne et al., 2013, 2015; Kondylis et al., 2016; Malekmohammadi et al., 2018). Abnormal PAC levels in PD are thought to interfere with the innate CFC processes required for the coordination of action preparation, execution, and alert-rest phases of movement. Importantly, PAC levels increase proportionally to the severity of PD-specific motor symptoms, and therapeutic DBS and medical treatments normalize the PAC levels (de Hemptinne et al., 2015; Swann et al., 2015).

## Cortical Phase-Amplitude Coupling-Based Neuromodulation

At least two potential novel neuromodulation strategies powered by PAC are possible; surface-sensing deep stimulation, in which PAC drives adaptive neuromodulation of the deep nodes and surface-sensing surface stimulation, in which PAC serves as both the feedback and feedforward control signals in an adaptive cortical neuromodulation scheme (**Figure 1**). Surface-sensing deep stimulation is a viable strategy that has been attempted with other electrophysiological biomarkers. For example, the cortical gamma-frequency level, which is associated with the severity of dyskinesia, has been successfully used to drive a totally implantable adaptive DBS in PD patients. By means of a subdural cortical lead for sensing, narrow-band gamma power (60–80 Hz) in the motor cortex was used to adjust stimulation amplitudes applied to the subthalamic nucleus (STN) based on patient-specific thresholds (i.e., high and low). The authors demonstrated significantly reduced energy use without worsening clinical symptoms compared to the conventional STN DBS system (Swann et al., 2018). More importantly, they presented a practical and systematic approach to implementing a cortical electrophysiological biomarker to develop a fully implantable adaptive DBS system that future studies could consider. The study also underscored several key advantages of the surface-sensing deep stimulation strategy compared with adaptive DBS systems that sense and stimulate the deep nodes using the same electrodes: (1) good signal-to-noise ratio with minimal stimulation-induced artifact; (2) high fidelity electrophysiological data from subdural electrodes that can yield better quality and quantity of sensory feed forward data than DBS electrodes can; and (3) spatially independent sensing and stimulating elements that minimize inference and optimize placement.

As a cortical biomarker, PAC may also enable the surface-sensing surface-stimulation strategy. The goal of this PAC-based neuromodulation program would be to achieve and maintain a spatiotemporally ‘eu-PAC state’ in the motor cortex and to ameliorate parkinsonian motor symptoms. To develop clinically useful PAC-based neuromodulation strategies, first, a method

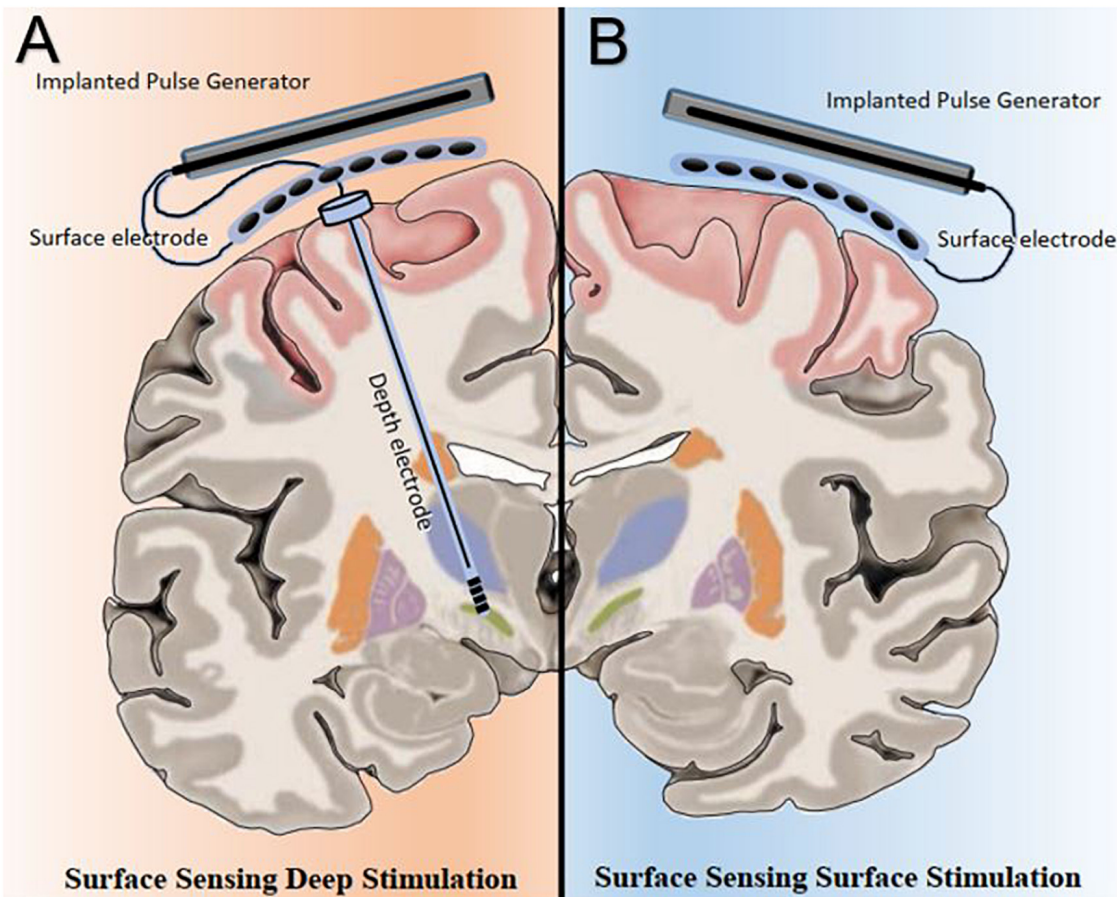

to detect and modulate PAC level in real time is necessary; and second, pathological and normal (i.e., physiologically and therapeutically) PAC levels and patterns must be defined on a patient-specific basis. The remainder of the article will focus on the PAC-based surface-sensing surface-stimulation strategy, which entails key future challenges in the field of neuromodulation.

## Motor Cortex Stimulation and Phase-Dependent Neuromodulation

As one of the major nodes and an output hub of the BGTC network, the motor cortex may be a high-yield target for neuromodulation. The motor cortex is relatively easy to access, localize, and map compared with the deeper nodes. Its larger size allows precise targeting of symptomatic body regions or movements. Also, concern for uncontrolled current spread to adjacent disparate neuronal populations and fiber tracts is significantly lower compared with the subcortical structures (Maks et al., 2009). Therefore, the motor cortex presents an opportunity for safer and more effective surgical neuromodulation compared to DBS. Nevertheless, motor cortex stimulation has largely been overlooked in neuromodulation research and therapeutics development in PD because of equivocal outcomes associated with cortical stimulation in PD (Canavero et al., 2002; Cilia et al., 2007; Strafella et al., 2007; Moro et al., 2011; De Rose et al., 2012). The unimpressive and variable results of motor cortex stimulation could be related to failing to account for electrophysiologic biomarkers. In all previous cortical stimulation studies in PD, electrical stimulation was delivered to the motor cortex without accounting for the underlying rhythmic activities and state of the BGTC network. A phase-independent approach has a high probability of yielding unpredictable and variable clinical results because the same stimulation pulse applied to the cortex can have a variable effect on PAC levels depending on which part of the beta phase it lands on (Anderson et al., 2009; Cagnan et al., 2013, 2017; Azodi-Avval and Gharabaghi, 2015). Based on network modeling studies, motor cortex neuromodulation should be done adaptively and may need to be based on phase-locked or phase-dependent stimulation techniques to be successful (Anderson et al., 2009; Azodi-Avval and Gharabaghi, 2015).

Phase-dependent stimulation (PDS) is a novel neuromodulation technique with a simple goal: to detect rhythmic brain activity and deliver precisely timed electrical stimulation pulses at a specific phase (Chen et al., 2011; Cagnan et al., 2013; Zrenner et al., 2018; Holt et al., 2019). The potential value of PDS is that, unlike medications or continuous electrical stimulation, it can selectively modulate pathological electrophysiological activities in the disease network without disrupting other physiological processes. The precise and selective nature of PDS may lead to improved symptom control without the stimulation-induced side-effects or maladaptive plasticity associated with continuous stimulation. PDS is relevant to PAC-based surface-sensing surface-stimulation strategy in PD because the technique could deliver the spatiotemporal

**FIGURE 1 |** Beta gamma phase amplitude coupling (PAC) levels and patterns measured over the surface of the motor cortex can be utilized in two potential adaptive neuromodulatory strategies. **(A)** In the surface sensing-deep stimulation paradigm, cortical PAC serves as control input to adjust stimulation at the subcortical targets, such as the subthalamic nucleus. **(B)** Under the surface sensing surface stimulation scheme, cortical PAC serves as both feedback and feedforward control signals to drive adaptive motor cortex neuromodulation.

accuracy and precision required to successfully modulate PAC levels in the motor cortex to meet the therapeutic demand in real time. PDS has been used in healthy animals to selectively and predictably modulate cortical oscillations (Zanos et al., 2018; Kanta et al., 2019; Peles et al., 2020). Zanos et al. demonstrated in non-human primates (NPH) that stimulation triggered from beta oscillations in the sensorimotor cortex not only induces synaptic plasticity, but the direction of the plasticity depends on the stimulated phase of the oscillations. Furthermore, a recent study developed an adaptive neuromodulation system based on a real-time cortical PDS algorithm to show that beta oscillations in the primary motor cortex can be controlled with volition and that PDS can differentially modulate the rhythmic patterns depending on the targeted phase of beta, which in turn, affects behavior (Peles et al., 2020). Similarly, another group used a rat model to adaptively modulate gamma oscillations in the amygdala and successfully affected memory strength (Kanta et al., 2019). The ability of real-time closed-loop PDS to predictably modulate beta oscillations in the subcortical regions in a bidirectional manner has been demonstrated in parkinsonian

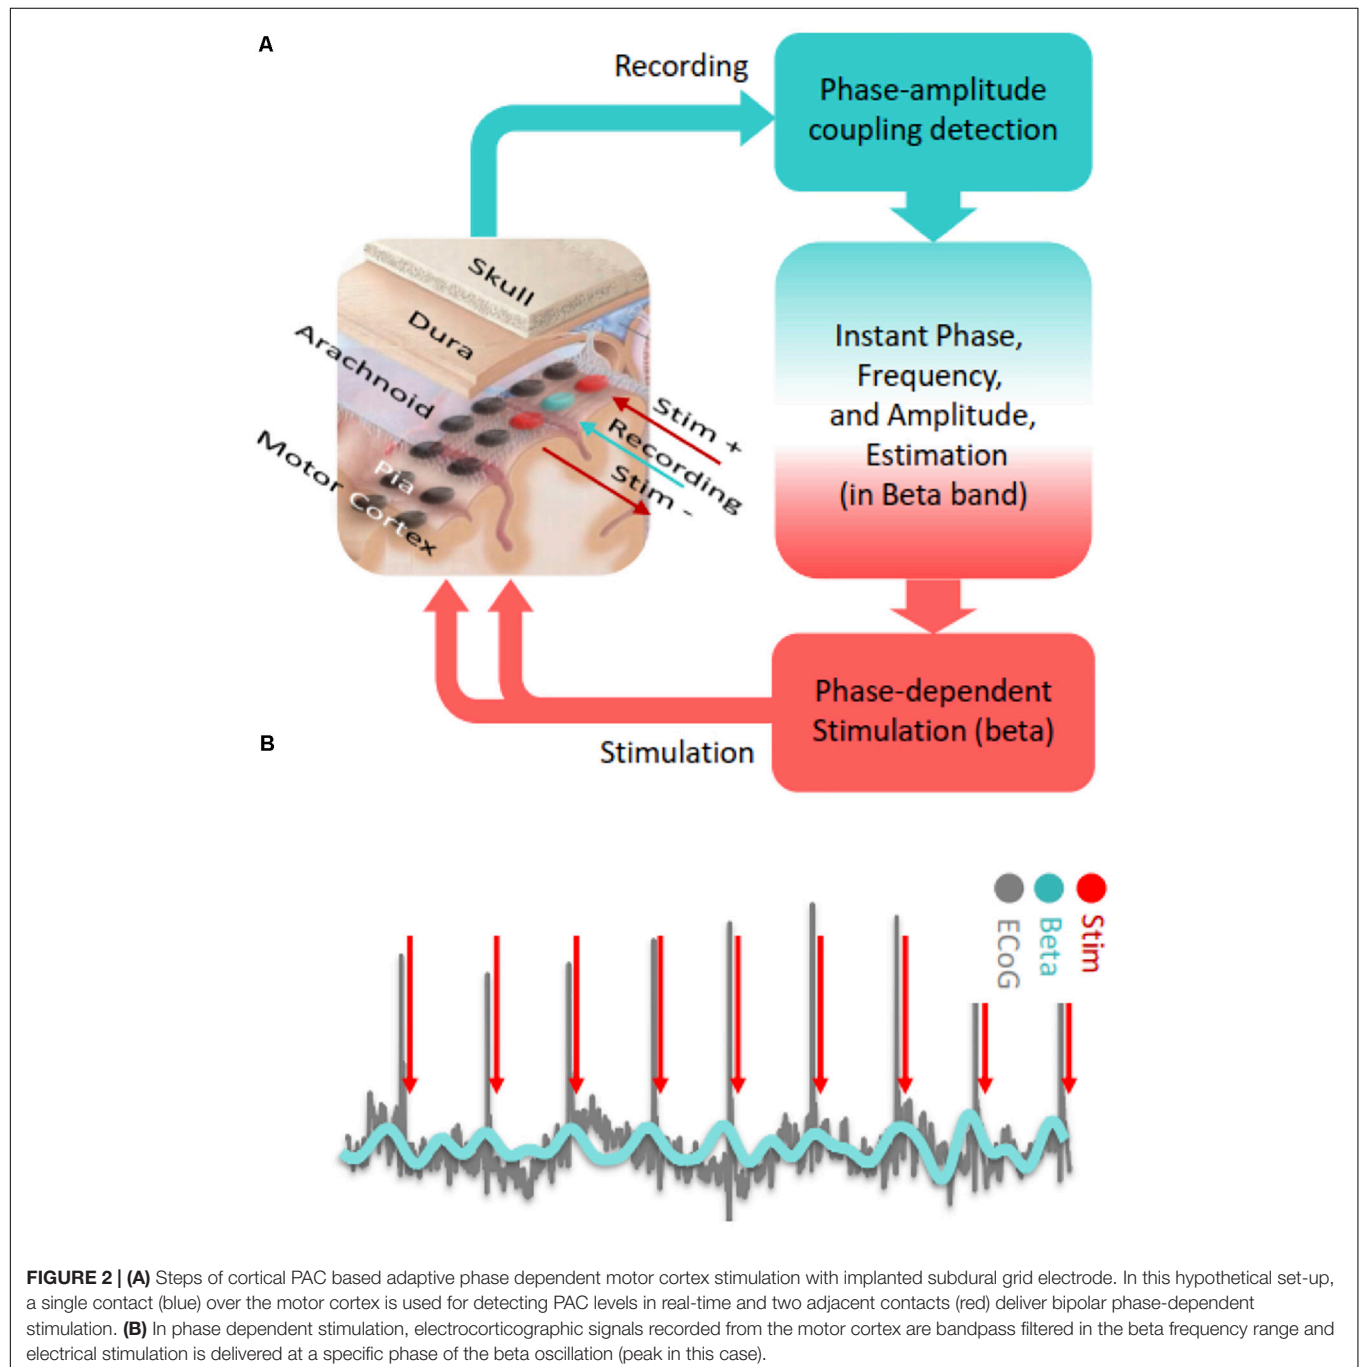

NPH (Sanabria et al., 2020, Preprint) and rat models (McNamara et al., 2020, Preprint).

Phase-dependent stimulation has also recently been used to selectively suppress pathological synchronized pattern of neuronal firing in the STN of PD patients (Holt et al., 2019). The authors demonstrated that PDS achieved beta suppression without altering the overall firing rate, and the degree of suppression correlated with the number of consecutive single-pulse PDS applied at or near the peak of the beta phase, suggesting that the observed neuromodulatory effect was likely from the PDS-induced alteration in the relative timing of beta activity (Holt et al., 2019). Thus, it is increasingly becoming evident that random or continuous stimulation of cortical and subcortical nodes of the parkinsonian motor network is suboptimal. However, continuous and random stimulation remains the predominant method in research. Future studies should strongly consider the implications of pathological oscillatory patterns in Parkinson's disease and incorporate PDS as a foundation for neuromodulation.

With regard to PDS in the motor cortex, it is possible to detect ECoG signals in real time and deliver timed electrical pulses to the cortical region of interest with low latency through fast estimation of phase and frequency of detected oscillations (Chen et al., 2011, 2013; **Figure 2A**). PAC based neuromodulation techniques can be accomplished through Hilbert transformation-based frequency band optimization, autoregressive (AR) spectral estimation and signal prediction. With this algorithm, it may be possible to detect and modulate PAC in near real-time

by targeting specific beta phases (**Figure 2B**). The AR signal modeling-based approach is robust against signal variabilities and inconsistencies (Chen et al., 2011, 2013). Using this algorithm, we consistently observed acceptable performance in modulating cortical PAC with cortical stimulation in a Parkinson's patient undergoing awake DBS surgery (Salimpour and Anderson, 2019).

Several critical issues must be considered with regards to a PAC-based PDS protocol. First, evaluation of PAC requires the accumulation of data over several rhythmic cycles, which

introduces latency into the stimulation protocol. Latency can be a significant problem in PDS because stimulation-pulse landing off the targeted phase can lead to unintended consequences. Therefore, devising effective strategies to overcome latency problems in PDS protocol is critical. In the context of PD, based on a mean beta-band frequency of approximately 20 Hz, a sliding-time window of 1 s should be sufficient to capture the dynamics of PAC to conduct an effective, near real-time PDS, as demonstrated a recent study (Peles et al., 2020). One solution to mitigating the computational technical demand is to utilize advanced circuit designs based on field-programmable gate array (FPGA), which can provide the speed to handle the high data throughput and processing, flexibility to readily modify algorithms, and machine learning capabilities to continuously improve performance.

Amplitude and time-domain characteristics (e.g., waveform shape) of beta oscillation correlate either with the severity of parkinsonian symptoms or with PAC levels in PD patients and may represent promising alternate biomarkers (Cole et al., 2017; Holt et al., 2019). Because they are technically simpler to work with, beta waveform-shape and amplitude levels may help overcome the latency issue. Nevertheless, we see a value in attempting a PAC-based neuromodulation despite current technical challenges because PAC may better represent the state of the BGTC network in PD. Also, PAC holds several advantages over other electrophysiological biomarkers of PD. First, PAC is strongly associated with parkinsonian symptom severity in a dose-dependent manner and responds predictably to both therapeutic medication and deep brain stimulation. PAC does not require physiological monitoring from deep brain structures, which potentially facilitates a less invasive system overall (de Hemptinne et al., 2013, 2015). Also, human recordings of PAC before, during, and after movement suggest that, compared to other brain disorders, PAC remains elevated even during movement in the parkinsonian state (Blumenfeld et al., 2015; de Hemptinne et al., 2015). We are optimistic that this persists in a stable manner through different movement phases more predictably than local field potential beta power. In comparison, subcortical beta oscillation may be influenced by normal physiological activities more dynamically than PAC and beta power dynamics during movement might now allow for clear thresholding throughout movement initiation and maintenance (de Hemptinne et al., 2015; Holt et al., 2019). Also, the shape of cortical beta oscillations might correlate with motor symptoms and signs of parkinsonism more strongly than the magnitude of beta power from local field potentials, and the atypicality of the waveform shape highly correlates with PAC (Cole et al., 2017). Stability and robustness of various components of the beta waveform shape during movement and against physiological perturbation are yet to be determined. It remains to be seen whether these and other promising biomarkers of PD will outperform PAC in closed-loop neuromodulation. Nevertheless, it is entirely conceivable to develop PAC-based phase-dependent neuromodulation algorithms that concurrently detect and analyze multiple time-domain and spectral features to provide

additional controls, such that variables such as waveform shapes and beta amplitudes can either supplement PAC or function as backup biomarkers in failure modes.

Another consideration involves stimulation-related artifact, which can hinder PAC based PDS, particularly in the context of a surface-sensing surface-stimulation paradigm. There are several techniques for reducing stimulation-related artifact both online and offline (Zhou et al., 2018). In our experience, use of separate recording and stimulation electrode contacts can significantly reduce the artifact level (Salimpour and Anderson, 2019). Additionally, the duration of a stimulus artifact is generally very short (3–5 ms), such that online artifact removal techniques can reduce the levels of artifact and noise during stimulation and provide sustained recording.

## Defining Normal Cortical PAC Level as a Therapeutic Goal

For PAC-based neuromodulation to become viable, it will be important to establish PAC patterns that are pathological and physiological for a specific PD patient. Although simple high and low PAC threshold levels can be used to trigger a stimulation pulse, such a system would be too simplistic to perform a dynamically adaptive neuromodulation to achieve the eu-PAC state. Patient-specific normal and pathological patterns would provide the therapeutic windows necessary for a PAC-based PDS neuromodulation system to be clinically safe, effective, and meaningful. Such endeavors have been undertaken with beta activities (Little et al., 2013, 2016a,b; Piña-Fuentes et al., 2017; Rosa et al., 2017). Using an experimental sensing implantable DBS system, beta oscillation patterns associated with specific activities performed outside of the operating room, such as walking and riding a bicycle, have been described (Quinn et al., 2015; Storzer et al., 2017; Syrkin-Nikolau et al., 2017; Hell et al., 2018). Such information is not available for PAC, but the technology exists to safely and chronically record and evaluate PAC patterns from the motor cortex of PD patients (de Hemptinne et al., 2013, 2015). Also, since PAC can be detected non-invasively, characterization of PAC levels and patterns can be achieved during a tuning period in an outpatient setting with minimal risk to guide early artificial intelligence (AI) driven algorithm training prior to electrode array implantation (Swann et al., 2015). Advanced machine learning can be employed to continuously optimize stimulation parameters based on output PAC levels and therapeutic efficacy as defined by the user. AI and machine learning will be critical in the development of next generation of intelligent brain stimulation devices and this topic has been discussed in detail elsewhere (Neumann et al., 2019).

## DISCUSSION

Phase amplitude coupling is expanding our understanding of PD pathophysiology and creating new therapeutic opportunities. Nevertheless, excitement must be tempered as we continue to improve our understanding of the BGTC network and

elucidate the relationships among different electrophysiological biomarkers and clinical outcomes. Also, we must continue to define the role of PAC in adaptive neuromodulation and develop creative ways to improve outcomes using the biomarker to define the role of PAC in adaptive neuromodulation and develop creative ways to improve outcomes using the biomarker. Efforts to define physiologically normal and pathological PAC are still needed in order to appropriately gate or modulate stimulation delivery. Going forward, collaboration among various fields, including computational sciences and engineering, is necessary in order to enable data-driven solutions to these remaining hurdles. AI and machine learning will be particularly useful in improving accuracy and speed of PAC detection and pattern recognition. Ultimately, the knowledge, techniques, and technologies that enable PAC neuromodulation may not only improve PD management but also play a significant role in advancing research and therapeutic development in other common neuropsychiatric conditions.

Mismatch negativity (MMN) is suitable for studies of preattentive auditory discriminability and the auditory memory trace. Subjective cognitive decline (SCD) is an ideal target for early therapeutic intervention because SCD occurs at preclinical stages many years before the onset of Alzheimer's disease (AD). According to a novel lifespan-based model of dementia risk, hearing loss is considered the greatest potentially modifiable risk factor of dementia among nine health and lifestyle factors, and hearing impairment is associated with cognitive decline. Therefore, we propose a neurofeedback training based on MMN, which is an objective index of auditory discriminability, to regulate sensory ability and memory as a non-pharmacological intervention (NPI) in SCD patients. Seventeen subjects meeting the standardized clinical evaluations for SCD received neurofeedback training. The auditory frequency discrimination test, the visual digital N-back (1-, 2-, and 3-back), auditory digital N-back (1-, 2-, and 3-back), and auditory tone N-back (1-, 2-, and 3-back) tasks were used pre- and post-training in all SCD patients. The intervention schedule comprised five 60-min training sessions over 2 weeks. The results indicate that the subjects who received neurofeedback training had successfully improved the amplitude of MMN at the parietal electrode (Pz). A slight decrease in the threshold of auditory frequency discrimination was observed after neurofeedback training. Notably, after neurofeedback training, the working memory (WM) performance was significantly enhanced in the auditory tone 3-back test. Moreover, improvements in the accuracy of all WM tests relative to the baseline were observed, although the changes were not significant. To the best of our knowledge, our preliminary study is the first to investigate the effects of MMN neurofeedback training on WM in SCD patients, and our results suggest that MMN neurofeedback may represent an effective treatment for intervention in SCD patients and the elderly with aging memory decline.

**Keywords:** mismatch negativity, neurofeedback, working memory, subjective cognitive decline, Alzheimer's disease, early intervention

## INTRODUCTION

Alzheimer's disease (AD) is slow and progresses with a presymptomatic course over several years to decades (Sperling et al., 2011). Controlling modifiable risk factors for AD at the preclinical stage remains the most realistic preventive strategy (Crous-Bou et al., 2017). Subjective cognitive decline (SCD) is a condition that is manifested by healthy older people who show unimpaired performance on cognitive tests and self-report a perceived cognitive decline in memory or other cognitive domains, such as executive function or attention (Rabin et al., 2015). SCD may represent the first symptomatic manifestation of AD before mild cognitive impairment (MCI; Koppara et al., 2015; Bubbico et al., 2019). Currently, there is no consensus on the best intervention or treatment for SCD with regard to psychological, cognitive, lifestyle, and pharmacological interventions described in a recent systematic review and a meta-analysis (Williams and Tanabe, 2016; Bhome et al., 2018). Given the heterogeneity of etiology of SCD and specifically considering individuals who have minimal manifestation of clinical symptoms, it is difficult to confirm a focal target of pharmacological intervention that does not cause an adverse reaction. Therefore, non-pharmacological intervention (NPI) may be a feasible method of treatment for patients with SCD (Smart et al., 2017; Bhome et al., 2018).

Elderly SCD subjects have a subtle decline in memory performance associated with accelerated memory decline, and SCD may predict future objective memory decline, even for incident dementia (Koppara et al., 2015). There is no authoritative method for treating early memory loss; however, a growing number of publications suggests that neurofeedback, which as a form of electroencephalogram (EEG) biofeedback used to self-regulate individual own brain activity, can directly alter the underlying neural mechanism of cognition and behavior (Enriquez-Geppert et al., 2017; Bhome et al., 2018). Neurofeedback has been successfully applied in the treatment of various diseases, such as attention-deficit hyperactivity disorder (ADHD; Van Doren et al., 2019) or epilepsy (Van Doren et al., 2019), enhancing memory for the healthy old adults with aging cognitive decline (Reis et al., 2016), and even in dementia or AD patients (Luijmes et al., 2016; Berman and Nichols, 2019; Kaufmann et al., 2019). For example, AD patients have an excess of slow frequency waves, such as delta and theta, and a reduction in the alpha waves compared with that in healthy aging individuals; thus, regulating the abnormal EEG frequency activity can have a positive effect on clinical performance, especially considering the effect of neurofeedback on cognitive ability (Luijmes et al., 2016). Here, we propose using neurofeedback as a NPI to improve the cognitive ability of SCD patients.

Hearing loss was considered to be the greatest potentially modifiable risk factor for dementia among the nine health and lifestyle factors according to a novel dementia risk model based on lifespan reported by the Lancet Commission (Uchida et al., 2019). If middle-aged hearing loss is eliminated, the risk of dementia may be reduced by 9% (Lin F. R. et al., 2013; Livingston et al., 2017). A 25-year study self-reported that hearing loss is linked to accelerated cognitive decline in older people (Amieva et al., 2015). A meta-analysis suggested

that hearing impairment is related to cognitive impairments (Taljaard et al., 2016). Auditory mismatch negativity (MMN) is a negative wave of event-related potential (ERP) typically obtained by the standard stimulus and is subtracted from the deviant stimulus in the oddball tasks (Näätänen and Alho, 1997), with MMN as an objective index of auditory discriminability (Garrido et al., 2009). Electrophysiological studies have shown that when any detectable change in a regular pattern of auditory stimulation occurs, a preattentive change-detection system in the auditory modality emits a signal called MMN (Molholm et al., 2005). Several studies have shown that the MMN peak latency is systematically prolonged and its amplitude is attenuated with aging (Molholm et al., 2005; Näätänen et al., 2011). In various neurological disorders, including schizophrenia, autism spectrum disorders, and dementia, MMN appears to provide an objective tool for investigation of auditory processing and memory trace attenuation (Chen et al., 2017). Recent studies have shown that MMN amplitude in AD patients for a long interstimulus interval (ISI) of 3 s is smaller than that for the shorter ISIs of 1 s, while the amplitude is stable in the control group of healthy subjects (Lindín et al., 2013; Laptinskaya et al., 2018). Moreover, the MMN amplitude was significantly lower in amnesic MCI adults compared with that in healthy people. MMN can be a relatively sensitive psychophysiological biomarker in identifying amnesic MCI (Lindín et al., 2013). Furthermore, auditory working memory (WM) is the major factor of neural processing of sound, and cognitive factors shape the brain networks for auditory skills (Kraus et al., 2012). Auditory training helps to compensate for the degradation of the auditory signals; the training demonstrated that cognitive function can be improved during the index executive process, competing speech, and dual-task performance. Importantly, auditory-cognitive training showed general improvements in speech, auditory WM, and processing speed, as well as enhanced self-reporting of communication difficulties (Sweetow and Sabes, 2006; Ferguson and Henshaw, 2015). At present, MMN neurofeedback has been successfully used in adults mainly for the adjustment of sensory abilities, such as improving auditory discriminability for two particularly similar tones and enhancing language ability and music level (Chang et al., 2014, 2017). Although the improvement of sensory ability can improve work memory by cognitive training, there are insufficient clinical data on optimization of cognitive ability by MMN neurofeedback training; to the best of our knowledge, no studies have investigated the effect of MMN neurofeedback on memory brain function.

In this study, we recruited patients with SCD mainly for the short-term tight MMN neurofeedback training. The present pilot study aims to investigate the neurofeedback training based on MMN amplitude to determine whether the training has a positive effect on the regulation of the MMN characteristic in SCD patients. It is hypothesized that the MMN amplitude can be improved by short-term close training based on neurofeedback. Second, we hypothesized that WM performance may be enhanced by MMN neurofeedback training in patients with SCD. MMN neurofeedback may be an effective intervention

method to enhance WM in SCD patients and the elderly with aging memory decline.

## MATERIALS AND METHODS

### Participants

A total of 17 right-handed patients with memory concerns were recruited from the memory clinic of the Department of Neurology, Xuanwu Hospital, Beijing, China. The study was approved by the Medical Research Ethics Committee and Institutional Review Board of Xuanwu Hospital. All subjects underwent a series of standardized clinical assessments, including a medical history interview, a neurological examination, a blood examination, and a series of neuropsychological tests. All participants provided a written informed consent before performing any experimental procedures. We performed neuropsychological tests to evaluate cognitive function, social and daily functions, mental behavioral symptoms, sleep, clinical characteristics, and various cognitive domain scales. The scale results of the participants are shown in **Table 1**. Experienced neurologists performed the diagnoses. The diagnosis of SCD was based on published SCD research criteria proposed by the Subjective Cognitive Decline Initiative (SCD-I; Jessen et al., 2014). SCD subjects were able to complete all neurofeedback training within 2 weeks.

### Experimental Design

The experiments included neurofeedback training, memory-based cognitive tests, and auditory frequency discrimination tests before and after the training (see **Figure 1**). The typical procedure for estimating auditory frequency discrimination was

using a frequency increment detection paradigm, where listeners are instructed to compare a reference tone with a series of lower or higher frequency tones (Kishon-Rabin et al., 2004). Memory tests included visual digital N-back, auditory digital N-back, and auditory tone N-back, which are mainly used to test the WM ability of the subjects. The neurofeedback training calculates the amplitude of MMN of the subjects in real time by giving the auditory tone stimulus and performing a visual signal feedback to allow the subjects to independently adjust the amplitude of MMN.

### Auditory Frequency Discrimination Test

In this experiment, 1,000 Hz was used as a standard (reference) tone, with a set of comparison stimuli varying from 500 to 1,500 Hz in 100 Hz steps (e.g., 500 Hz, 600 Hz, 700 Hz, 800 Hz, 900 Hz, 1,100 Hz, 1,200 Hz, 1,300 Hz, 1,400 Hz, and 1,500 Hz). Each subject received auditory stimuli transmitted by a GSI-61 audiometer with binaural presentation *via* headphones (TDH 50) at 65–70 dB HL. The whole experiment was performed using E-Prime (Psychology Software Tools Inc., Pittsburgh, PA, USA). Each subject received 10 sets of pretrials to become familiar with sound stimulation. The actual test lasted for approximately 30 min.

### Working Memory Test

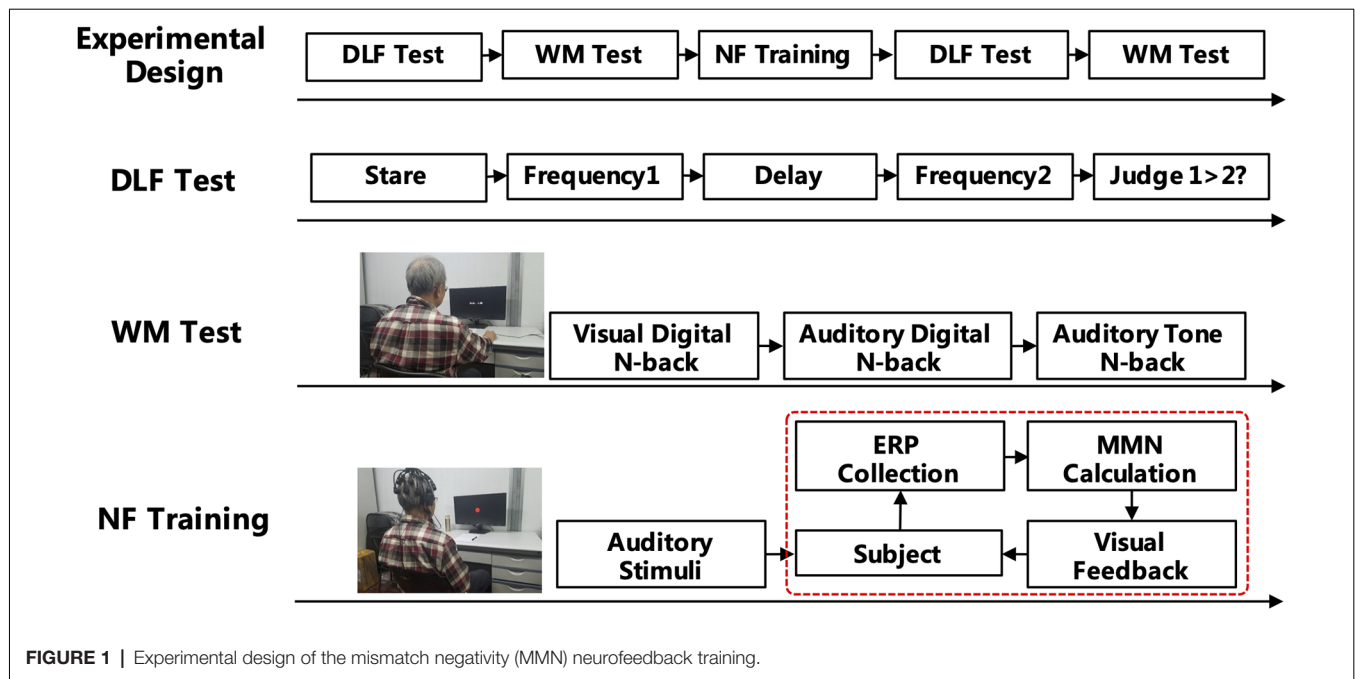

WM refers to the structures and processes used to temporarily store and manipulate information during ongoing processing and distraction. The N-back task is one of the most popular measures of WM in cognitive neuroscience. In a classical N-back task, subjects are presented with a series of stimuli, and the task is to determine if each stimulus is consisted with an Nth stimulus shown previously. By manipulating the value of N, the processing load can be changed systematically, which influences the changes in accuracy and reaction time (RT; Jaeggi et al., 2010). In this experiment, we adopted a visual digital N-back (1-, 2-, and 3-back), an auditory digital N-back (1-, 2-, and 3-back), and an auditory tone N-back (1-, 2-, and 3-back). N-back uses three types of stimuli: visual digits (digits from 1 to 9, except 7), auditory digits (digits from 1 to 9, except 7), and auditory tone (tone frequencies include 200 Hz, 400 Hz, 800 Hz, 1,000 Hz, 1,200 Hz, 2,000 Hz, and 4,000 Hz; Zhang et al., 2016). The digits were recorded from Google with Chinese pronunciation.

### Neurofeedback Training

The neurofeedback training was completed five times in 2 weeks with an interval of less than 3 days and more than 1 day by all participants. Each neurofeedback training contains five training sessions. The standard MMN was induced by a standard stimulus of 1,000 Hz (80%), and the deviant stimulus of 2,000 Hz (20%) was based on the oddball paradigm (Lin Y. et al., 2013). A modification of the MMN neurofeedback training protocol was used in this study (Chang et al., 2014). MMN was elicited by an auditory stimulus based on an oddball paradigm: 1,100 Hz was the standard stimulus; the deviant stimulus was two times the individual auditory discriminant threshold value (Restuccia et al., 2009). The standard stimulus accounted for 80% of the stimuli. The

stimuli were presented in a random order. The frontal (Fz), central (Cz), and parietal electrodes (Pz) were used as the training sites.

During each neurofeedback training session, the first MMN amplitude was used as the individual baseline threshold. Then, the amplitude of MMN was updated every 0.5 s. The amplitude of the real-time MMN was fed back as a visual disc signal, and the radius of the disc was proportional to the amplitude of MMN. When the real-time MMN amplitude was greater than the threshold, a red disc appeared; otherwise, a green disc appeared. Subjects were instructed to focus on the visual stimuli and silently count the red discs during training to ignore the auditory stimuli. During the neurofeedback training, the subjects attempted to use their strategies to try to increase the number of appearances of red discs (Pei et al., 2020).

## Data Processing and Statistical Analysis

The results of the auditory discrimination threshold test and the N-back tasks were analyzed by the E-Prime software. The curve fitting of the method is based on a weighted cumulative Gaussian distribution function  $f(p)$ , as shown in Equation (1):

$$f(p) = 0.5 \left[ 1 + \left( \frac{P - PStd.}{\sigma\sqrt{2}} \right) \right] \quad (1)$$

where  $\sigma$  is a parameter describing the steepness of the curve and can be considered as a qualitative measure of the 84% discrimination threshold and standard (1,100 Hz).  $R^2$  evaluates whether each psychometric function fits a cumulative Gaussian distribution (Wichmann and Hill, 2001a,b; Pei et al., 2020).

The EEG data were analyzed offline via EEGLAB, an open-source MATLAB toolbox for electrophysiological signal processing (Delorme and Makeig, 2004). The raw EEG signal

underwent 0.5 Hz high-pass and 45 Hz low-pass FIR filters. Independent component analysis (ICA) was used to reject artifacts of the EEG signals, and the main components are responsible for the eye movements and blinks.

Statistical analysis was performed by using SPSS 19 (SPSS, Chicago, IL, USA). Data are expressed as the mean  $\pm$  standard error. A pointwise paired  $t$ -test of the standards and deviants was performed from 100 ms to 300 ms of ERP.

The amplitude and latency of MMN during the training were statistically analyzed using a repeated measures analysis of variance (ANOVA) with the “training day” (day 0 to day 5) and “electrode” (Fz, Pz, and Cz). A paired  $t$ -test was performed to compare the pre/post neurofeedback training (day 0 and day 5). Auditory discrimination accuracy was statistically analyzed using a repeated-measure ANOVA within the assessment time (pre/post training) and “frequency” (500–1,500 Hz in 100 Hz steps). The auditory discrimination threshold and the behavioral results of the WM were analyzed with the paired  $t$ -test. The significance level was set at  $p < 0.05$ , and high significance was set at  $p < 0.01$ . The previously described methods of statistical analysis have been verified by other experimental studies (Zhang et al., 2018).

## RESULTS

We evaluated the standard MMN changes from ERP, auditory frequency threshold, and WM ability by cognitive behavioral tests. The amplitude of MMN was significantly increased with no significant change in latency after 5 days of MMN neurofeedback training at Pz. The accuracy of the subjects in the auditory tone 3-back test was increased significantly.

## ERP Analysis of MMN

We collected the standard MMN of the subjects before the first training and after each training day. The six ERP waveforms at the Fz, Cz, and Pz electrodes are shown in **Figure 2A**. The results demonstrate high signal-to-noise ratio of ERP waveforms of the subjects and a more pronounced MMN that appears at the last training (day 5) at all three midline electrodes. Assessment of the amplitude or latency of MMN during the neurofeedback training (from day 0 to day 5) by repeated measure indicates that the “training day” has no major effect (amplitude:  $F_{(5,80)} = 1.230$ ,  $p = 0.303$ ; latency:  $F_{(5,80)} = 1.230$ ,  $p = 0.303$ ). Therefore, the MMN characteristics of the subjects did not change significantly with increase in the number of training days. However, the amplitude of the MMN at the Pz electrodes was significantly improved after 5 days of neurofeedback training according to the paired  $t$ -test ( $t = 2.232$ ,  $p = 0.040$ ). There was no significant increase of day 5 in the Fz ( $t = 1.054$ ,  $p = 0.308$ ) and Cz values ( $t = 1.307$ ,  $p = 0.210$ ) compared with that observed on day 0. The latency of MMN showed no significant changes at each electrode after five training days (Fz:  $t = 0.358$ ,  $p = 0.725$ ; Cz:  $t = -1.917$ ,  $p = 0.073$ ; and Pz:  $t = -1.815$ ,  $p = 0.088$ ; **Figure 2B**).

**Figure 3** shows the amplitudes and latencies of MMN at 19 channels of each subject. In addition to three midline training electrodes, the amplitudes of the MMN at other locations after neurofeedback training were increased, especially in subject No. 13, in whom the whole brain was effectively improved. With regard to latencies, the number of electrodes with reduced signal is almost the same as that of increased signals.

## Auditory Discriminability

The auditory discrimination threshold of an individual was tested before and after the training, and the value before the training was used as the personalization parameter (deviant stimuli) of the MMN neurofeedback protocol.

The results of the threshold fitting curve indicate that the range and gradient of the test frequency in the auditory frequency discrimination test were suitable for the SCD patients; the  $\sigma$  value was almost 1 before ( $\sigma = 0.991$ ) and after ( $\sigma = 0.996$ ) the neurofeedback training (**Figure 4A**). The threshold value was reduced overall after the neurofeedback training (**Figure 4B**), but the reduction was not significant ( $t = 0.261$ ,  $p = 0.798$ ) due to individual differences (**Figure 4D**). The average accuracies of 1,100 Hz and 1,500 Hz detection declined; however, detection of all other test frequencies was improved compared to that before the training (**Figure 4C**). Assessment of discrimination accuracy of test frequency by repeated measure indicates that there is no major effect of assessment time (pre/post neurofeedback;  $F_{(1,16)} = 0.776$ ,  $p = 0.391$ ). There were large individual differences in the accuracy rate, although 10 of 17 participants have improved after the training (**Figure 4E**).

## Working Memory Performance

Considering the differences in the educational levels and cognition between the participants, we have conducted three types of WM for cognitive assessment, and the auditory tone 3-back test performance was significantly improved in accuracy after the neurofeedback training.

The accuracy and RTs of three types of the N-back tasks before and after the neurofeedback training were analyzed by a paired  $t$ -test. The results showed that the effect of the neurofeedback training was not significant for accuracies of visual digital N-back (1-back:  $t = -1.765$ ,  $p = 0.097$ ; 2-back:  $t = -1.676$ ,  $p = 0.113$ ; 3-back:  $t = -0.841$ ,  $p = 0.413$ ) and auditory digital N-back (1-back:  $t = -1.957$ ,  $p = 0.068$ ; 2-back:  $t = -1.001$ ,  $p = 0.332$ ; 3-back:  $t = -1.437$ ,  $p = 0.170$ ), although the values show an upward trend. However, for the auditory tone N-back, there was a significant improvement in accuracy in auditory tone 3-back ( $t = -2.947$ ,  $p = 0.009$ ); 1-back ( $t = -1.838$ ,  $p = 0.085$ ) and 2-back ( $t = -1.714$ ,  $p = 0.106$ ) showed no significant difference. No significant differences in RTs were found in visual digital N-back (1-back:  $t = -0.616$ ,  $p = 0.546$ ; 2-back:  $t = 0.676$ ,  $p = 0.509$ ; 3-back:  $t = 0.248$ ,  $p = 0.807$ ), auditory digital N-back (1-back:  $t = 0.198$ ,  $p = 0.846$ ; 2-back:  $t = 1.314$ ,  $p = 0.207$ ; 3-back:  $t = 0.258$ ,  $p = 0.799$ ) or auditory tone N-back (1-back:  $t = 1.259$ ,  $p = 0.226$ ; 2-back:  $t = 0.738$ ,  $p = 0.471$ ; 3-back:  $t = 1.318$ ,  $p = 0.206$ ; **Figures 5A–C**). Individual performance results showed that after the neurofeedback training, the accuracy was improved and the response speed was faster than before in various WM tests; however, most of the results were not statistically significant except the 3-back auditory tone task (**Figures 5D,E**).

The difficulty level of 1-back is the lowest, and thus, most of the participants did not obtain a significant improvement after the training because they had already achieved high scores before the training. The difficulty level of 2-back is medium, and the majority of the subjects clearly improved the accuracy of the tests. The most difficult task is 3-back; 13 subjects improved the accuracy, and the clinical effective rate (the number of improved/the number of non-improved) reached 76.47% (**Figure 6A**). The RTs of a task were increased concomitant to the difficulty of a task. In other words, the 1-back task is the fastest, and the 3-back task is the slowest. The neurofeedback training had no effect on RTs in 1-back, 2-back, or 3-back tasks (**Figure 6B**).

## DISCUSSION

In this study, we successfully used an MMN neurofeedback protocol in SCD patients. After five training days during 2 weeks, the training significantly strengthens the amplitude of MMN and increases performance of the patients in WM tests, especially in the auditory tone 3-back tasks. This study is the first to explore the effect of the MMN neurofeedback training on auditory frequency discriminability and enhancement of the working auditory memory in SCD patients by regulation of the MMN activity.

## Unconscious Learning and Personal Intervention Method

Recently, fMRI neurofeedback studies have shown that brain networks can be modified without intention and learning consciousness (Ramot et al., 2016). The activity of the visual cortex can be regulated to influence the visual perceptual learning with no stimulus presenting or the subjective consciousness of the subjects during the neurofeedback training

**FIGURE 2 |** Event-related potential (ERP) waveforms of the standard stimuli, deviant stimuli, and mismatch negativity (MMN; **A**), and the amplitudes and latencies of MMN at frontal (Fz), central (Cz), and parietal electrodes (Pz; **B**). **(A)** MMN waveforms were obtained by subtracting the ERPs in response to the standard stimuli from ERPs in response to the deviant stimuli. The gray shaded areas show the significant differences between the standard and deviant stimuli from 100 ms to 300 ms,  $p < 0.05$ . **(B)** Paired  $t$ -test; day 5 compared with day 0,  $*p < 0.05$ .

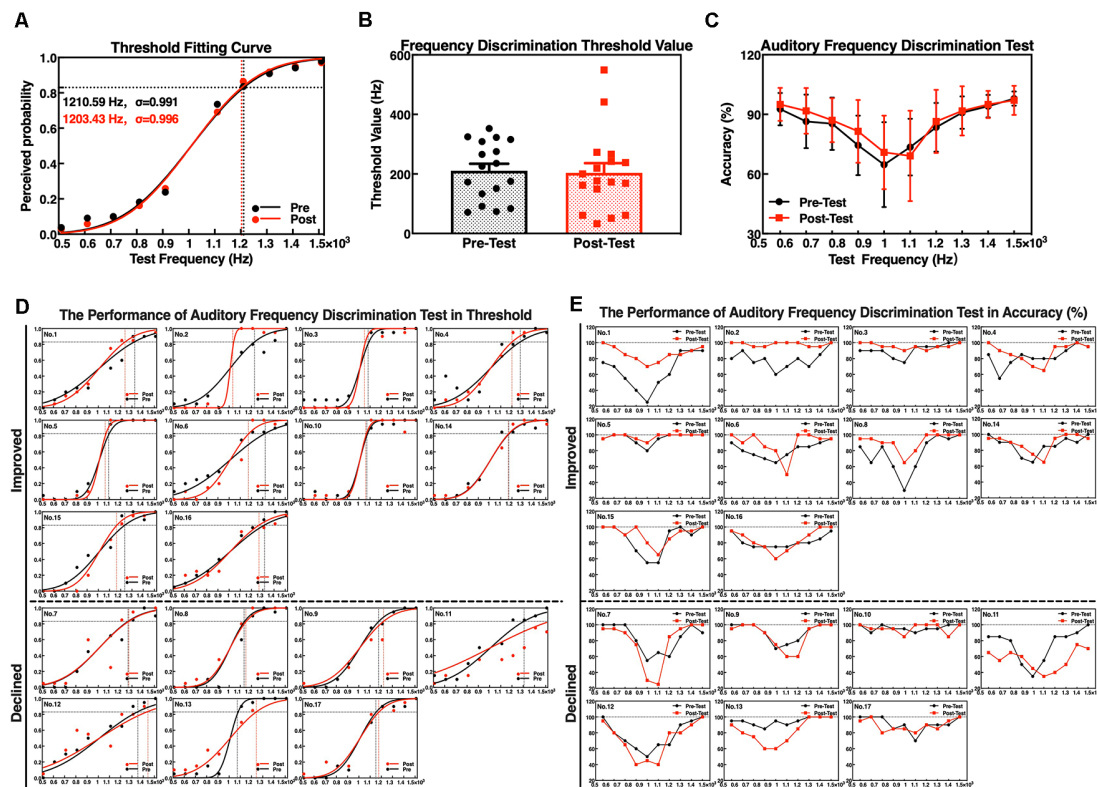

**FIGURE 3 |** Standard values of individual MMNs before and after the neurofeedback training. The amplitudes (**A**) and latencies (**C**) of the individual MMNs were normalized by processing the true values from 0 to 1. **(A,C)** The maximum value of the amplitude is shown in white, and the minimum is shown in black for each subject. **(B,D)** Statistics of the number of electrodes on day 5 performance amplitudes compared with that on day 0.

(Shibata et al., 2011; Chang et al., 2014). MMN responses are elicited by any discriminable auditory change that cannot be consciously discriminated. The healthy participants can unconsciously experience a significant improvement in the

auditory discrimination of the stimuli applied during a previous study. Each subject was asked to focus on the visual signal (red discs) during our MMN neurofeedback training, and the subjects were required to neglect the auditory stimuli of the experiment

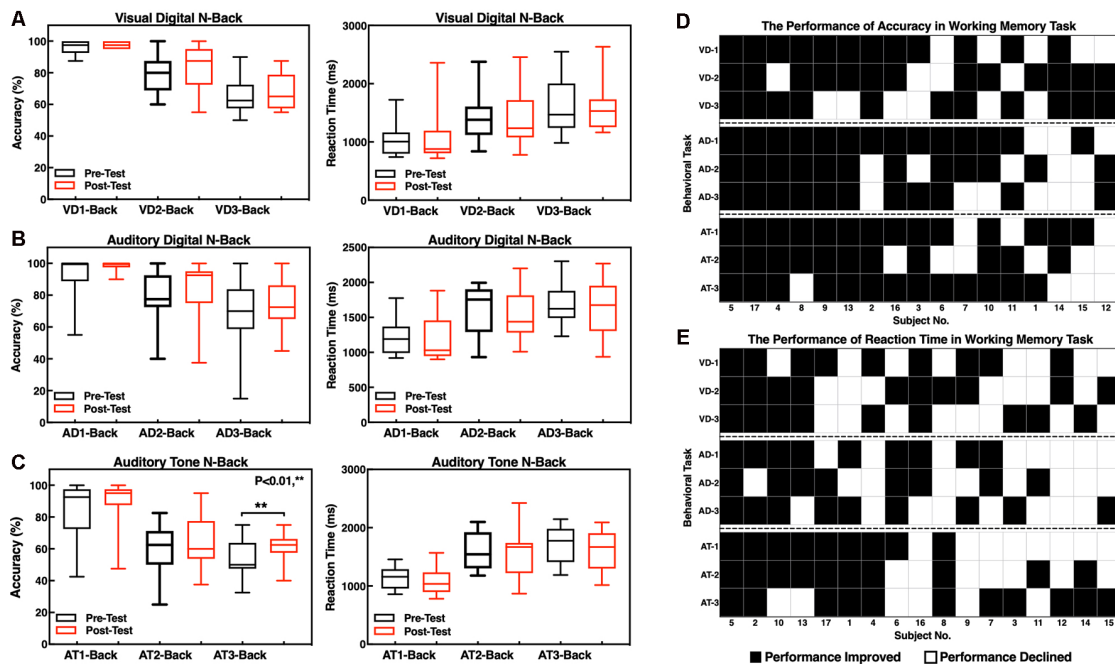

**FIGURE 4 |** Performance of auditory frequency discrimination task before and after the neurofeedback training. **(A)** Frequency threshold fitting curve; **(B)** discrimination threshold value; **(C)** discrimination accuracy. Individual performance of auditory frequency discrimination test as a threshold fitting curve **(D)** and as accuracy **(E)**.

as much as possible. Moreover, our results showed that the improvement of the amplitudes of MMN after the training is in agreement with previous studies (Chang et al., 2014). Numerous studies demonstrated that the parietal cortex is consistently linked to and involved in human memory processing, although early studies mostly focused on the medial temporal and frontal lobes (Gilmore et al., 2015). The intrinsic connectivity of the parietal memory network (PMN) reflects the familiarity of the stimuli in memory encoding and retrieval and is disrupted in AD (Hu et al., 2019). The Pz electrode may be a potential target site for memory regulation in the neurofeedback training. The latencies of MMN in SCD patients showed no significant differences after training. The individual auditory discrimination threshold was used as the deviation stimulus in our study while a previous study used a fixed frequency as the deviation parameters. Some of our results are inconsistent with the previous data, and the discrepancy may be caused by different paradigm parameters of the experimental design (Chang et al., 2014, 2017). Considering that the MMN index discrimination of various sound stimuli can result from a rigid matching similar to behavioral discrimination, the MMN signals are associated with the magnitude of deviation and involve perceptual discriminability (Näätänen et al., 2017). In SCD patients, auditory discrimination is different because we observed that the auditory frequency discrimination threshold ranges from

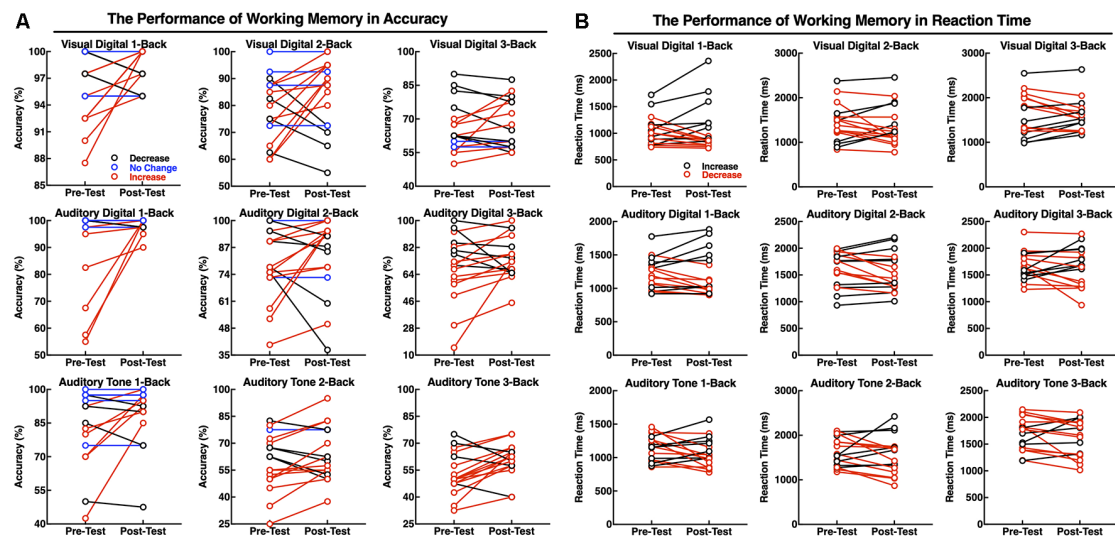

1,200 to 300 Hz. A personal protocol to regulate the amplitude of MMN may be more suitable in the clinical neurofeedback training. Therefore, our results generate additional evidence that MMN neurofeedback can be used as an EEG-specific unconscious and personal neurofeedback training in the SCD patients, thus raising a possibility for a clinical intervention even in the case of the states of altered consciousness.

## Improving the Auditory Discriminability

Previous studies in 2014 have shown that MMN neurofeedback training can improve discrimination between very similar tones, such as “1,000 Hz” and “1,008 Hz” by Chang et al. (2014). A study published in 2017 used MMN neurofeedback to successfully discriminate the English pronunciation between the letters “l” and “r” to facilitate the foreign language learning (Chang et al., 2017). These studies focused on the use of learning to discriminate the targeting of the similar stimuli, similar to discrimination between standard and deviant stimuli during the neurofeedback training to elicit MMN. However, in our study, the individual auditory discrimination threshold has to be considered because individual deviant stimuli were used in the training protocol. The thresholds decreased after the training indicating that auditory discrimination is improved; however, this effect was not statistically significant and only 60% of SCD patients ( $n = 10$ ) were successful. We found that the

**FIGURE 5 |** Accuracy and reaction times (RTs) of the N-back tasks. **(A)** Visual digital N-back, **(B)** auditory digital N-back, and **(C)** auditory tone N-back.  $^{**}p < 0.01$ ; red or black bars above and below the graph show the maximum and minimum accuracy or RT in each task, respectively. The statistics evaluation of the tasks based on the performance of individuals as accuracy **(D)** and RT **(E)**.

**FIGURE 6 |** Performance of the individuals in working memory (WM) tasks as accuracy **(A)** and RT **(B)**. The red line indicates that the accuracy was increased or that the reaction speed improved; the black line indicates that the accuracy was decreased and the reaction speed declined; and the blue line indicates no changes in performance accuracy.

accuracy of those SCD patients, which failed to decrease the auditory discrimination threshold, was lower than the accuracy in the successful tasks; the measurement of the threshold is based on the successful task statistics. Importantly, the subjects who demonstrated good training results have more compact

training time. Previous studies indicate that different training intensity will influence the training effect and excessive or insufficient training may actually reduce the effectiveness of the training. Monitoring the learning curves of the subjects to set the appropriate training cycles may be implemented in the future.

Moreover, the most successful subjects used the psychological strategies for recalling positive things or focusing on certain things during the neurofeedback training and were able to adjust their psychological strategies autonomously when their training scores were decreased. To improve the efficiency of the intervention, the optimal training intensity and psychological strategy are worth to be explored in the future studies (Enriquez-Geppert et al., 2017).

## Enhancing the Performance of Auditory Working Memory

At present, memory regulation based on the neurofeedback focuses on the regulation of the EEG frequency band. Training the alpha rhythm activity by neurofeedback to increase memory and attention has to consider that alpha activity inhibits the processes that are unnecessary or conflicting with the task being performed and thus can promote attention and memory by actively suppressing the distracting stimuli (Klimesch, 1999). Theta oscillations have been correlated with the memory encoding (Sauseng et al., 2010), and their excess is detected in AD patients; regulation of the theta activity always involved a neurofeedback protocol in the healthy subjects to enhance memory, even in the MCI, AD, and dementia patients (Luijmes et al., 2016). Previous studies have shown that in schizophrenic patients, MMN impairment is accompanied by poor WM performance (Kiang et al., 2007); a similar association is observed in the case of WM impairment in alcoholics and low performance of MMN (Bonetti et al., 2018). WM is considered a cognitive system, which is responsible for operating the information of various sensory modalities; and the neurons of the pre-supplementary motor area encode tactile and auditory information involved in the WM tasks, thus using a shared representation for both sensory modalities. A recent study indicated that individuals with higher visual WM performance have increased automatic neural responses to changes in the auditory characteristics (Bonetti et al., 2018). In older adults, automatic auditory processing guided by selection history was largely lacking (Sur and Golob, 2019). From the perspective of neurobiology, the generation of MMN is associated with N-methyl-D-aspartate receptors (NMDRs), which is the major molecular device for regulating the plasticity of the synaptic and memory functions (Li and Tsien, 2009). NMDRs are crucial in the activity-dependent synaptic changes, learning, and WM due to mediation of the excitatory postsynaptic potentials (Baez et al., 2018; Lisman et al., 1998). Moreover, auditory mismatches engage a hierarchical functional network of cortical sources, which are also interconnected by auditory white matter pathways. Neuroimaging studies have found that a disrupted pattern of the AD connectome that starts in peripheral regions, which refer to a set of cortical regions weakly connected in brain structural networks, and then hierarchically propagates to highly connected cortical brain regions, when patients show clinical symptoms. Moreover, peripheral regions might contribute to impaired memory performance in patients with SCD (Wang et al., 2017; Yan et al., 2018). Neurofeedback training can improve the auditory cortex plasticity by regulating neuronal synaptic plasticity and changing the neural networks of the

brain (Emmert et al., 2017). Neurofeedback is a safe and noninvasive intervention that can influence cognitive functions and behavioral changes. To date, no adverse reactions of the neurofeedback training have been reported; however, it is not recommended to train people with serious mental problems (Marzbani et al., 2016). Therefore, enhancing WM based on the MMN neurofeedback may be an effective method of intervention not only in SCD patients but also in healthy older people; however, the persistence of the training effects lacks the data of the clinical follow-up study.

In this study, we have designed three types of WM in the form of N-back with three types of levels to assess the effects of the training to account for the degree of completion of the tasks in SCD patients with various educational backgrounds. The results indicate that the accuracy scores were improved in all WM tests vs. baseline and especially in the auditory tone 3-back, which significantly increased after the training. The auditory tones are the stimuli to induce MMN; thus, there is a limit of the performance of the WM effect with regard to the visual and auditory digits. Previous studies have shown an impact of the stimulation task type training on the WM types (Chan et al., 2019; Linares et al., 2019). A behavior study showed that enhanced transfer of the auditory discrimination learning is mediated by WM, which reflects that WM updating is related to fine auditory discrimination (Zhang et al., 2016). Actually, SCD is not strongly correlated with the concurrent level of cognitive ability as measured by objective cognitive tests; previous studies have shown that subjective memory complaints are associated with subsyndromal or subclinical depression in community-dwelling older adults (Zlatař et al., 2018). Therefore, the targeting of specific interventions for the regulation of cognitive ability will be more helpful in the case of the intervention treatment of patients with heterogeneous SCD.

## Limitations and Further Research Directions

To assess the effectiveness of the clinical intervention, certain issues deserve further attention. For experimental design, setting up a double-blind experiment with a strict control group will be more convincing to demonstrate the effect of the training. Given the heterogeneity of patients, in addition to SCD heterogeneity, to include differences in the learning ability and living conditions, recruitment of a control group with similar subject characteristics is difficult considering that post-training activities that influence training results cannot be controlled. Current clinical intervention studies focus on small samples and the desired sample should be as large as possible. The timeline of the assessment of the clinical scales is usually longer than 3 months; hence, the methods and tasks for accessing the short-term intervention need to consider the operability and effectiveness of the patients. Moreover, we focused on discussion of the individual results while explaining the average results. Given the importance of SCD in diagnosis of the neurocognitive disorders and as potential predictor of a future cognitive decline, the individualization and targeted treatment of intervention methods will be explored in the future studies.

We propose a novel neurofeedback protocol based on the MMN amplitude to improve the performance of auditory WM in SCD patients. The preliminary results of our study may indicate that neurofeedback training based on MMN may be a potential treatment for the elderly with aging memory decline.

## DATA AVAILABILITY STATEMENT

The datasets for this article are not publicly available because the research in this article involves personal information from SCD patients. Request to access the datasets should be approved by the Medical Research Ethics Committee and Institutional Review Board of Xuanwu Hospital.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Medical Research Ethics Committee and Institutional Review Board of Xuanwu Hospital. The patients/participants provided their written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

Curative therapies or treatments reversing the progression of Parkinson's disease (PD) have attracted considerable interest in the last few decades. PD is characterized by the gradual loss of dopaminergic (DA) neurons and decreased striatal dopamine levels. Current challenges include optimizing neuroprotective strategies, developing personalized drug therapy, and minimizing side effects from the long-term prescription of pharmacological drugs used to relieve short-term motor symptoms. Transplantation of DA cells into PD patients' brains to replace degenerated DA has the potential to change the treatment paradigm. Herein, we provide updates on current progress in stem cell-derived DA neuron transplantation as a therapeutic alternative for PD. We briefly highlight cell sources for transplantation and focus on cell assessment methods such as identification of genetic markers, single-cell sequencing, and imaging modalities used to access cell survival and function. More importantly, we summarize clinical reports of patients who have undergone cell-derived transplantation in PD to better perceive lessons that can be drawn from past and present clinical outcomes. Modifying factors include (1) source of the stem cells, (2) quality of the stem cells, (3) age of the patient, (4) stage of disease progression at the time of cell therapy, (5) surgical technique/practices, and (6) the use of immunosuppression. We await the outcomes of joint efforts in clinical trials around the world such as NYSTEM and CiRA to further guide us in the selection of the most suitable parameters for cell-based neurotransplantation in PD.

**Keywords:** Parkinson's disease, dopaminergic neurons, transplantation, stem cells, imaging modalities, neuroimaging, clinical trials

## INTRODUCTION

Parkinson's disease (PD) is one of the most prevalent chronic neurodegenerative disorder characterized by the selective, progressive loss of nigrostriatal dopaminergic (DA) neurons in the substantia nigra pars compacta. The main hallmarks of PD include the presence of  $\alpha$ -synuclein positive Lewy bodies and neuroinflammation (MacGeer and McGeer, 2008; More et al., 2013)

that extends across many areas of the central nervous system (CNS), affecting the enteric and autonomic systems, in particular (Goedert et al., 2013), causing impairments in motor movements such as bradykinesia (slowed movements), tremors, postural instability, and muscle rigidity. Furthermore, PD patients have shown non-motor disease manifestations such as rapid eye movement (REM), sleep behavior disorders, depression, hyposmia, and constipation (Olanow et al., 2009). Unfortunately, there are no curative therapies available to modify or reverse the progression of the underlying disease processes to date.

The current gold standard for PD treatment is through the ingestion of levodopa, which has been approved by the US Food and Drug Administration in the 1970s and has continuously shown positive results in temporal amelioration of PD symptoms (Fahn, 2003, 2006). However, long-term exposure to levodopa results in a gradual decrease in drug effectiveness and shorter periods of benefit, leading to levodopa-induced dyskinesias (motor fluctuations), as well as psychiatric and cognitive problems. Alternatively, surgical strategies, such as deep brain stimulation (DBS), have shown to alleviate PD motor symptoms (Siegfried and Lippitz, 1994; Limousin et al., 1995) and offer symptomatic relief that cannot be controlled with medications (Alamri et al., 2015). However, its application is not only limited to early-to-mid PD stages but also loses efficacy after a few years (deSouza et al., 2013).

In the last few decades, cell-based therapy using human stem cells has made large strides in overcoming the abovementioned limitations in PD treatment. Also known as regenerative medicine, stem cell therapy is believed to replace diseased, dysfunctional, or damaged tissue in hopes to restore lost neuronal circulatory caused by focal degeneration of mesencephalic dopaminergic (mDA) neurons. Specifically, neural progenies from pluripotent stem cells (PSCs) are known to hold great potential as a succeeding treatment for neurodegenerative diseases (Hu et al., 2010; Kriks et al., 2011; Ma et al., 2012). Today, DA neurons differentiated from stem cells are paving the way as a new, alternative approach in the treatment of PD. In this review article, we briefly highlight the major sources of stem cells used in preclinical and clinical PD observations (have been thoroughly reviewed in various articles, refer to Stoker, 2018). We focus on key methodologies currently applied in cell assessment, imaging modalities, and also further discuss ongoing stem cell-based clinical trials in PD. This also includes key challenges that the field is encountering and the prospects of stem cell therapy in PD.

## CELL SOURCES

First, we briefly discuss the various types of stem cells currently being used as a source for cell-based therapy in PD. We also include the pros and cons of each cell line (Table 1), followed by the characterization of graft quality through various cell assessment methods (Cell Assessment of Differentiated DA Neurons section).

## Fetal Ventral Mesencephalic Cells

In the early 1970s, Olson and colleagues successfully transplanted adrenal chromaffin cells and embryonic DA neurons into the anterior chamber of the eye in rats and showed that the viability of grafted neurons was best achieved using developing embryonic neurons (Olson and Malmfors, 1970; Olson and Seiger, 1972). Parkinsonism rat and monkey models grafted with early gestational age dopamine-rich mesencephalic neurons formed neurite protrusions and synthesize dopamine (Dunnett et al., 1983; Brundin et al., 1986; Redmond et al., 1986; Stromberg et al., 1986; Bakay et al., 1987). Furthermore, successful integration of transplanted cells into the host brain neuronal network was demonstrated through synaptic integration using a rabies-based monosynaptic tracing method (Cardoso et al., 2018). Behavioral studies in PD rodents and primates with human fetal DA neuron transplantation showed higher efficacy in improvement of behavioral deficits as compared to conventional adrenal medullary tissue transplants (Bjorklund and Stenevi, 1979; Perlow et al., 1979; Freed et al., 1981; Moriguchi et al., 1984). Also, pioneering clinical studies in human fetal ventral mesencephalic (fVM) transplantation into the caudate and putamen of PD patients in Sweden, United Kingdom, and United States reported moderate amelioration of PD symptoms (Lindvall et al., 1988; Madrazo et al., 1988; Freed et al., 1990; Freed et al., 2001; Olanow et al., 2003). Moreover, normal striatal F-DOPA uptake was 3–5 years post-surgery, including gradual motor improvements that sustained up to 18 years post-transplantation (Kefalopoulou et al., 2014). However, the majority of successful cases were performed in PD patients under the age of 60 (Ma et al., 2010). Whether graft-induced dyskinesias are characteristics of neural transplantation has to be better studied and analyzed (Freed et al., 2001; Hagell et al., 2002; Olanow et al., 2003; Ma et al., 2010). Nonetheless, obtaining as many as up to seven human fetal donors (aged 6–9 weeks after conception) for each host raises many ethical concerns and logistical challenges for a disease affecting millions of people worldwide (Steinbeck and Studer, 2015; Barker and Consortium, 2019). Furthermore, the difficulty in preaccessing a cell type before transplantation is a major challenge in standardization as the heterogeneity of cell population within the graft is inevitable, contributing to high variability in the degree of symptomatic recovery. All in all, the additional risk in cell contamination of unwanted cell types during tissue extraction hampered the downstream translation of fVM transplantation as an alternative therapeutic option.

## Human Embryonic Stem Cells

Due to the abovementioned ethical controversies in utilizing hfVM tissues for cell-based therapy (and other limitations), human embryonic stem cells (hESCs) were identified as a prospective substitute (Thomson et al., 1998; Reubinoff et al., 2000; Barker, 2014). These subsets of pluripotent cells are located in the inner cell mass of early embryonic blastocyst commonly derived from *in vitro* fertilization (Evans and Kaufman, 1981; Thomson et al., 1998) and hold the capability to generate into a plethora of cell lines through a spontaneous differentiation

**TABLE 1 |** Cells used in transplantation for Parkinson's disease (PD).

Cell type	Clinical trial	Advantages	Disadvantages
Fetal ventral mesencephalic cells (fVM)	Yes/ongoing (TRANSEURO; NCT01898390)	<ul style="list-style-type: none"> <li>• Good long-term graft survival post-transplantation</li> </ul>	<ul style="list-style-type: none"> <li>• Unpredictable and limited supply of cell source</li> <li>• Ethical concerns</li> </ul>
Embryonic stem cells (ESC)	Ongoing (European-based STEM-PD, NYSTEM, NCT02452723, NCT03119636)	<ul style="list-style-type: none"> <li>• Indefinite expandability</li> <li>• Good graft survival post-transplantation</li> <li>• Advancement in GMP-grade cells</li> </ul>	<ul style="list-style-type: none"> <li>• Ethical concerns</li> <li>• Possible risk of tumorigenesis</li> <li>• Tissue rejection; pre- and post-operative immunosuppression</li> </ul>
Induced pluripotent stem cells (iPSC)	Yes/ongoing (CiRA)	<ul style="list-style-type: none"> <li>• Indefinite expandability</li> <li>• Easily accessible cell source</li> <li>• Immunologically matching cells</li> <li>• No need of immunosuppression treatment</li> </ul>	<ul style="list-style-type: none"> <li>• High heterogeneity of cell line between individual cell line resulting in complex procedures</li> <li>• Low reprogramming efficiency</li> <li>• High operative cost</li> <li>• Time consuming</li> <li>• Possible risk of tumorigenesis</li> </ul>
Neural progenitor cells (NPC)	Yes/ongoing (NCT03309514, NCT01329926)	<ul style="list-style-type: none"> <li>• Multipotent cells</li> <li>• Easy expansion and differentiation protocol</li> <li>• Large quantity</li> </ul>	<ul style="list-style-type: none"> <li>• Invasive tissue collection step</li> <li>• Limited proliferation</li> <li>• Low graft survivability</li> <li>• Limited proliferative ability</li> </ul>

protocol *in vitro* (Itskovitz-Eldor et al., 2000; Lee et al., 2000; Reubinoff et al., 2001; Zhang et al., 2001). In the case of neuroepithelial cell-derived DA neuron differentiation, cells showed an increase in a multitude of cellular marker expression for midbrain DA neurons with fiber outgrowth (Thomson et al., 1998; Kawasaki et al., 2000; Kim et al., 2002) and electrophysiologically active neurons that produced DA in an activity-dependent manner (Yan et al., 2005). In later years, it was identified that DA neurons unlike all other neurons are generated from the midbrain floor plate. With newly improvised DA neuron differentiation protocol (Fasano et al., 2010; Kriks et al., 2011; Kirkeby et al., 2012), a significant upregulation of midbrain DA neuronal markers was observed along with recovery in motor defects in preclinical studies (Kirkeby et al., 2012, 2017a; Grealish et al., 2014). Unfortunately, key limitations lie in the difficulty in controlling the maturation stage of embryonic cultures and cellular heterogeneity, which may lead to negative outcomes in therapeutic applications (Stewart et al., 2006; Roy et al., 2006; Cho et al., 2008; Koch et al., 2009). Other caveats include the associated risk in tumor generation and teratoma due to their high pluripotent phenotype (Ben-Hur et al., 2004; Roy et al., 2006; Brederlau et al., 2006; Sonntag et al., 2007; Yang et al., 2008). In 2001, ethical concerns in hESC research resulted in a restriction on federal fundings in the United States. Fortunately, this legislation has been revoked by President Barack Obama in 2007. With this advantage, New York Stem Cell Science Consortia at Memorial Sloan Kettering Cancer Center conducted ongoing projects such as the development of good manufacturing practice (GMP) clinical-grade hESC-derived DA neurons for FDA approval in future transplantation studies (refer to section “GMP cryopreservation of cells”), optimization of cell purification to enrich A9 type DA neurons, and also, active involvement in strategical planning for clinical trial of hESCs in Parkinson's disease.<sup>1</sup>

## Human-Induced Pluripotent Stem Cells (hiPSCs)

The field of stem cell research and regenerative medicine was revolutionized in 2006 when human fibroblast cells were successfully reprogrammed into pluripotent cell lines using four transcription factors: c-Myc (or Nanog, Lin28), Oct3/4, Klf4, and Sox2 (Takahashi and Yamanaka, 2006; Takahashi et al., 2007; Yu et al., 2007). Reprogrammed iPSCs have been a highly attractive cell source as they have the characteristics of hESCs (in terms of morphology and genetic profile) (Fairchild, 2010; Phanstiel et al., 2011), and they have a relatively simpler extraction process. Tissue collection is non-invasive as host cells from skin fibroblast (Pulecio et al., 2014), peripheral blood mononuclear cells, and umbilical cord mesenchymal cells (Park et al., 2008; Senju et al., 2011; Biju et al., 2013; Qin et al., 2013) could be used to differentiate into patient-specific neurons *in vitro* (Soldner et al., 2009; Beevers et al., 2013; Eigentler et al., 2013; Sison et al., 2018). This would also avoid allogeneic recognition and ethical concerns (Takahashi and Yamanaka, 2016). In PD studies, the quality of iPSC-derived DA neurons was highly similar to that of hESCs (Cooper et al., 2010; Doi et al., 2014; Kikuchi et al., 2017; Lehnen et al., 2017), and human leukocyte antigen (HLA)-matched allogeneic neural transplantation into monkeys increased the efficacy of cell survival and function (Morizane et al., 2017). Animal studies demonstrated successful amelioration of PD symptoms resulting from iPSC-derived DA neuron transplantation (Wakeman et al., 2017). Further refinement and characterization are necessary to achieve precise cell fate conversion of reprogrammed cells. Similar to ESCs, it is important that minimal manipulation is made during reprogramming prior to cell delivery.

## GMP Cryopreservation of Cells

The generation of good manufacturing practice (GMP)-compliant, deliverable midbrain DA (mDA) progenitors/neurons optimized for cell-based therapy for PD is a major challenge. Currently, a diverse collection of clinical-grade hESC lines are

available as starting material to generate GMP-compliant mDA progenitors/neurons. In fact, GMP compliant differentiation protocols and reagents have been successfully applied to generate GMP mDA neurons (Liu et al., 2013; Peng et al., 2014).

In comparison, the availability of clinical-grade iPSCs is relatively lesser due to the lack of technology that involves complex reprogramming methodologies. Major hurdles of the clinical translation of mDA cells therapy include (i) quality control of the identity, safety, and efficacy of cell product in a consistent and real-time manner, (ii) determination of the precise time points at which DA precursors/neurons can be cryopreserved and banked without affecting its' quality, (iii) good postthaw viability of mDA cells, and (iv) characteristics and functionality of the population of cells should have minimal to no alterations after thawing. XCell Science has generated GMP-compatible authentic DA neurons, which are functional when transplanted into PD animal model (Peng et al., 2014) where cells were cryopreserved at day 14 after neuronal stem cell (NSC) stage. Similar studies were also reported by Cellular Dynamics International using more mature mDA cells in postmitotic stage (Wakeman et al., 2017). Successful generation of GMP-grade cryopreserved cells would allow for storage of a large batch of DA neurons and also increase the flexibility in operational schedule organization without the dependence on GMP-manufacturing site.

## CELL ASSESSMENT OF DIFFERENTIATED DA NEURONS

Understanding the key type of DA neurons required to achieve downstream restoration of PD pathology is essential. The mesotelencephalic DA system in the midbrain contains two main groups: the A9 neuronal clusters of the nigrostriatal DA pathway located in the zona compacta, the substantia nigra involved in the control of posture, and the A10 neurons located in the ventromedial mesencephalic tegmentum that regulates the locomotor activity and emotional behavior (Dahlstroem and Fuxe, 1964; Anden et al., 1966; Ungerstedt, 1971; Lindvall and Bjorklund, 1974; Pijnenburg et al., 1976; Papp and Bal, 1986). Dysfunction of the nigrostriatal system has been linked to Parkinsonism and later to schizophrenia, drug addiction, and depression (Robinson and Berridge, 1993; Meyer-Lindenberg et al., 2002). Differences between the two DA cell populations have been observed in neurochemistry and in spontaneous neuronal firing (Grenhoff et al., 1988; Wolfart et al., 2001; Neuhoff et al., 2002). More importantly, A9 neurons display significantly enhanced levels of neuromelanin pigmentation as compared to other dopamine-producing neurons (Mann and Yates, 1983; Hirsch et al., 1988; Gibb, 1992; Kastner et al., 1992). This could account for the association of early loss of A9 DA neurons in Parkinson's disease with increased vulnerability upon disease progression with the relative preservation of A10 DA neurons (Hirsch et al., 1988; German et al., 1989; German et al., 1992; Damier et al., 1999; Halliday et al., 2005; Alavian et al., 2008).

Generally, stem cells are differentiated into specific nigra A9 DA neurons in large quantities prior to PD transplantation. This step has been thoroughly reviewed by many articles such as in Fan et al. (2020) and, thus, will not be further discussed here. However, we focus on developments in technology in cell assessment of differentiated DA neurons.

## Assessment of the Efficacy of Cell Transplants With Immunostaining Characterization

Prior to stem cell transplantation, it is important to be able to fully characterize differentiated cell types to avoid heterogeneity of cell population (also known as cellular contamination). Previous studies have shown that transplantation of fetal SN-A9 DA neurons suffices the requirement for striatal reinnervation and recovery of PD-like behavioral observations (Grealish et al., 2010). However, tumor formation (Roy et al., 2006; Brederlau et al., 2006; Elkabetz et al., 2008; Doi et al., 2012) and development of graft-induced dyskinesia could arise from the high heterogeneity of serotonergic neurons (Carlsson et al., 2007; Politis et al., 2010). As cells are normally transplanted as immature progenitor cells, developing methods that can characterize and predict its functional maturation and therapeutic efficacy is crucial. Hence, to circumvent these limitations prior to proceeding into clinical trials, methods to isolate homogenous population of DA progenitor cells have been closely evaluated (Fukuda et al., 2006; Pruszek et al., 2009; Jonsson et al., 2009; Ganat et al., 2012; Sundberg et al., 2013). This includes developing meaningful quality control assays to assess cell type to avoid having heterogeneous mixtures of cells (includes phenotypes and degree of maturity) and batch-to-batch variation. The quality of differentiated mesencephalic A9 DA neurons that represent those in the substantia nigral para compacta or into immature progenitor cells is vital to determine the therapeutic efficacy of cell transplantation in the Parkinsonian brain. It is well understood that the orchestration of specific gene expression patterns is highly correlated to DA cell differentiation and survival. Therefore, the establishment and determination of specific gene expression markers have been used to positively characterize differentiated cells *in vitro*.

In the case of mDA progenitor neuron specifications, positive gene expression of common transcription factors FOXA2, LMX1A, and OTX2 and negative markers (non-neural) such as Afp, Gata4, and Brachyury have been quantitatively analyzed (Chung et al., 2009; Lin et al., 2009; Jaeger et al., 2011; Kriks et al., 2011; Kirkeby et al., 2012; Salti et al., 2013; Doi et al., 2014). More importantly, the upregulation and downregulation of these markers at a given stage *in vitro* governs the efficiency of cell fate determination. Unfortunately, these markers have been shown to coexpress in the diencephalic progenitor cells of the subthalamic nucleus (STN) (Kee et al., 2017). Furthermore, the expression of the positive genetic marker for DA neurons, tyrosine hydroxylase (TH), a rate-limiting enzyme in dopamine synthesis (Daadi and Weiss, 1999; Sonntag et al., 2004; Kirkeby et al., 2017a), and the levels of GIRK2 have also been observed in many cell types *in vitro* (Thompson et al., 2005; Kirkeby et al.,

2012; Reyes et al., 2012; Grow et al., 2016). Moreover, common positive markers used to isolate high-quality DA progenitor cells include EN1 and SPRY1 (Simon et al., 2001; Alberi et al., 2004; Kirkeby et al., 2017a); Nurr1 (Le et al., 1999); FOXA2, LMX1B, and MSX1 (Andersson et al., 2006; Chung et al., 2011), and the bicoid-related homeodomain factor Ptx3/Pitx3 (Hargus et al., 2010). It is noteworthy that some discrepancies have been found with the requirement for the presence of floor plate-specific cell surface marker CORIN expression (Ono et al., 2007; Chung et al., 2011; Kriks et al., 2011; Kirkeby et al., 2012, 2017a; Doi et al., 2014; Arenas et al., 2015; Fan et al., 2020). A more recent study has identified a cell surface marker integrin-associated protein (IAP, CD47) as a positive marker for FOXA2-positive DA progenitor cells (Lehnen et al., 2017).

While these positive markers are required to narrow down the search for pure DA progenitor cells, negative markers such as Oct3/4, PAX6, and SOX1 for other midbrain neurons act as good controls to prevent introducing contamination with other neuronal subtypes during sorting. Last, terminal differentiation of DA neurons post-transplantation can be identified by the expression of neurotransmitter phenotype markers, namely, TH, dopamine transporter (DAT), Vmat2, Girk2, and Calbindin (Di Porzio et al., 1990; Sgado et al., 2006). It is crucial to take into consideration the wide genetic variation of iPSCs, which may harbor a large spectrum of genetic variation and even retain donor-specific gene expression pattern depending on multiple factors, such as the number of passages of the lineage or transcriptional factors introduced to induce cell differentiation (Rouhani et al., 2014; Thomas et al., 2015; Burrows et al., 2016; Carcamo-Orive et al., 2017). Nonetheless, growing evidence strongly suggests the need for heightened stringency in cell type evaluation. This is particularly important to avoid incomplete differentiation of cells, which could result in undesired reprogrammed cell lineages affecting functional deficits when transplanted into PD models (Park et al., 2005; Grow et al., 2016; Kirkeby et al., 2017a).

## Single-Cell RNA-Seq to Evaluate the Quality of Cells

More recently, high-resolution analyses of cell type specificity such as single-cell transcriptomic analyses of neuronal populations of induced stem cells have pathed its way to become a new tool to increase the specificity during DA neuron extraction. This method would allow gene expression profiling of individual cells to better understand population heterogeneity and to distinguish between distinct cell subpopulations to increase the purity of desired cell lines (Poulin et al., 2014; La Manno et al., 2016; Reid and Wernisch, 2016; Lang et al., 2019; Tiklova et al., 2019). However, to achieve this, a specific set of cellular and gene regulatory network contexts have to be determined (as mentioned in the Assessment of the Efficacy of Cell Transplants With Immunostaining Characterization section). Although the presence of the PITX3 gene expression in adult mDA neurons suffices the criteria (Smidt et al., 1997), PITX3 was later shown to be present in both TH-positive and TH-negative cells (Tiklova et al., 2019). In the same study, single-cell RNA sequencing (scRNAseq) analyses were used to

distinguish between several mDA subtypes with gene targeting. Moving forward, providing key proof-of-concept in utilizing scRNAseq as a tool for quality control would be the future for cell replacement therapies.

## Assessment of the Efficacy of Cell Transplants With Imaging

Last, concurrent with the high demand for the optimization of cell graft visualization in PD, growing emphasis has been placed on enhancing the sensitivity and precision of the spatiotemporal resolution of functional neuroimaging. En route to successful cell transplantation as a therapeutic regenerative method for Parkinson's disease, neuroimaging techniques have to be employed for better patient care. Some key features required to elucidate the therapeutic efficacy of transplanted cells for clinical diagnostics are (1) innervation, (2) survival, (3) differentiation, and (4) functional biochemistry composition. Furthermore, it is crucial that these imaging techniques are time efficient, safe, non-invasive, and allow repeated measures in an individual to determine longitudinal post-operative progression in patients with cell transplantation (Barrow et al., 2015; Ramos-Gomez et al., 2015). In this section, we summarize the pros and cons of current imaging modalities used in tracking cell grafts in PD and their respective biomarkers (Table 2).

Magnetic resonance imaging (MRI) is a popular method for examining brain tissue morphology that uses strong magnetic fields coupled with contrast agents such as paramagnetic contrast agent (Gadolinium [III] [ $Gd^{3+}$ ], Manganese [ $Mn^{2+}$ ]), perfluorocarbons, or superparamagnetic iron oxide (SPIO) despite its challenges in differentiating tissues with structures that naturally emits low MRI signals like bones. Its biggest advantage is its superior spatial resolution, non-invasiveness, and relatively cost efficiency compared to other neuroimaging methods discussed below. Various lines of evidence strongly suggest the reliability of MRI in visualizing prelabeled transplanted cells such as ESCs (Sykova and Jendelova, 2007), fetal rat cortical cells (Hawrylak et al., 1993), and fetal striatal tissues (Norman et al., 1992) in rats. Furthermore, MRI has been used to evaluate edema and inflammation in tissues surrounding cell-transplanted sites in mice and primates (Anderson et al., 2005; Iwanami et al., 2005). It is important to note that false MRI signals may result from the residual build-up of SPIO nanoparticles released from dead transplanted cells and engulfed by macrophages and activated microglia (Amsalem et al., 2007; Liu and Frank, 2009; Cupaioli et al., 2014; Ramos-Gomez and Martinez-Serrano, 2016). Additionally, cells prelabeled with contrast agents prior to transplantation may show diluted and faded contrast over time as cells proliferate within the transplanted site, which may lead to a reduction in signal. Finally, MRI technology is predominately used in multimodality neuroimaging of cell transplantation by combining both structural and functional readouts for the improved refinement of clinical diagnostics. To this end, it could be coupled with the high sensitivity but low-resolution bioluminescence imaging (Tennstaedt et al., 2013), an economical and non-invasive technique using enzymatic chemiluminescence that allows full temporal live tracking of viable transplanted grafts.

**TABLE 2 |** Imaging modalities used in cell transplantation for PD.

Relative representation ↑, high; ↓, low.

Single-photon emission computed tomography (SPECT) is a type of nuclear imaging technique that utilizes specific gamma-emitting isotopes (compounds derived from cocaine that bind to the dopamine transporter) to analyze the integrity of the nigrostriatal DA pathway in PD (Son et al., 2016). SPECT biomarkers allow for the detection of presynaptic neuronal degeneration (Marshall and Grosset, 2003) and D2-type post-synaptic receptor density (Thobois et al., 2001). The clinical utility of such metabolic and neurochemical changes in PD is reviewed by Wang et al. (2012). To improve the diagnostic accuracy of SPECT imaging, current studies have employed the combined evaluation of both pre- and post-synaptic measurements through striatal dopamine transporters (DAT) and dopamine D2 receptor analysis, respectively (Koch et al., 2007). Further refinements must be made for SPECT imaging modality to be able to differentiate diseases with impairments in presynaptic DA neuronal survival such as PD, progressive supranuclear palsy, multiple system atrophy, and others (Bajaj et al., 2013). Also, potential leakage of radiotracers into adjacent cells resulting in diluted signals during cell proliferation has to be rectified. More importantly, the optimal concentration of tracers must be determined to avoid tissue damage due to exposure to toxic radioactive reagents. One disadvantage of this technique is its inability to examine cell survival and function.

Positron emission tomography (PET) is also a common imaging tool that employs specific radionuclides to elucidate the functional consequences of transplantation on the DA system in the brain, such as receptor distribution, metabolic activity, and inflammation (Visnyei et al., 2006). The measurement of aromatic L-amino acid decarboxylase activity using [ $^{18}\text{F}$ ]FDOPA is regarded as the gold standard to examine DA function and disease severity in Parkinson's disease (Morrish et al., 1996; Punal-Rioboo et al., 2009), also shown in PD non-human primate model (Muramatsu et al., 2009; Emborg et al., 2013; Hallett et al., 2015) and clinical reports (Lindvall et al., 1990; Peschanski et al., 1994; Piccini et al., 2000, 2005; Ma et al., 2010) (refer to citation in Table 2). PET images can also be used in conjunction with SPECT data to further evaluate the negative association between striatal DAT and motor severity (Shih et al., 2006; Wu et al., 2014). Interestingly, recent clinical studies have shown that [ $^{11}\text{C}$ ]PE2I has higher predictive value and sensitivity toward the differential detection of motor impairments than [ $^{18}\text{F}$ ]DOPA imaging; hence, [ $^{11}\text{C}$ ]PE2I could be a prospective biomarker to investigate novel interventions (Fazio et al., 2015; Li et al., 2018). PET would be advantageous for studying the early maturation of cells transplanted *in vivo* and for follow-up examinations months after cell transplantation. A comprehensive and concise review on the development of functional neuroimaging is discussed in the cited works (Zheng et al., 2017; Helmich et al., 2018).

With no doubt, one of the most understudied limitations in neuroimaging is in deciphering the complexity of neuropathological overlap and clinical heterogeneity in the progression of individual neurological diseases. Improvements in bioimaging tools, such as the identification of specialized biomarkers for specific cell types to evaluate differential functional signatures, are important to circumvent the high level of variation in the prognosis of PD and its management by

patients. In addition, the paucity of imaging modalities available for quantitation and of their respective analytical tools continues to hinder the further development of cell-based therapeutics toward clinically competitive treatments for PD. As discussed above (also refer to Table 2), we cannot rely on a single imaging technique for clinical diagnosis especially post-transplantation; thus, researchers are actively searching for the development of multimodality imaging (Waerzeggers et al., 2008) along with the identification of novel biomarkers and tracers to escalate the accuracy of post-operative care. A better understanding of neuroanatomical and pathophysiological processes would be highly advantageous for cell-derived therapeutics.

## CLINICAL TRIALS FOR STEM CELL-DERIVED DA NEURON TRANSPLANTATION IN PARKINSON'S DISEASE

Historically, fVM cell transplantation showed varied outcomes in human clinical trials (Table 3) (Freed et al., 2001; Olanow et al., 2001, Olanow et al., 2003, Redmond et al., 2001; Barker et al., 2013). A double-blind study of bilateral injection of fVM transplantation and sham surgery into the putamen was first performed in 19 PD patients by Freed and colleagues in 2001 (Freed et al., 2001). Interestingly, only younger age groups showed clinical improvements compared to the sham control (Freed et al., 2001). Using available data extracted from individual clinical papers cited in Table 3, we have performed systematic statistical analysis of the clinical outcomes of PD patients with fVM transplantation against various parameters, namely, age of onset (old, > 40 years vs. young,  $\leq$  40 years), disease stage (severe vs. mild), and disease duration (long, > 10 years vs. short,  $\leq$  10 years). The fold change of PET readings post-transplantation from the baseline reading of individual patients was used to access graft survival. We show that graft survival is independent of the age of disease onset (Figure 1A) but is dependent on variations in disease stage (Figure 1B) and the length of disease duration (Figure 1C), where better graft survival was observed in mild stage PD and patients with shorter disease duration ( $\leq$  10 years). Moreover, we used the Unified Parkinson Disease Rating Scale (UPDRS) motor scores to examine clinical improvements post-transplantation of PD patients in various factors (Figure 2). We have demonstrated that in all three parameters (as mentioned above), PD patients with fVM transplantation have shown significant clinical improvements (correlated to the decrease in UPDRS motor scores) post-transplantation. Also, comparison between post-transplantation within each parameter (i.e., old vs. young or severe vs. mild or long vs. short) showed no significant differences. In summary, although clinical improvements can be observed throughout the wide spectrum of PD patients with fVM transplantation (Figure 2), the optimal condition with the most potential could be seen in mild stage PD patients with short disease duration (Figure 1).

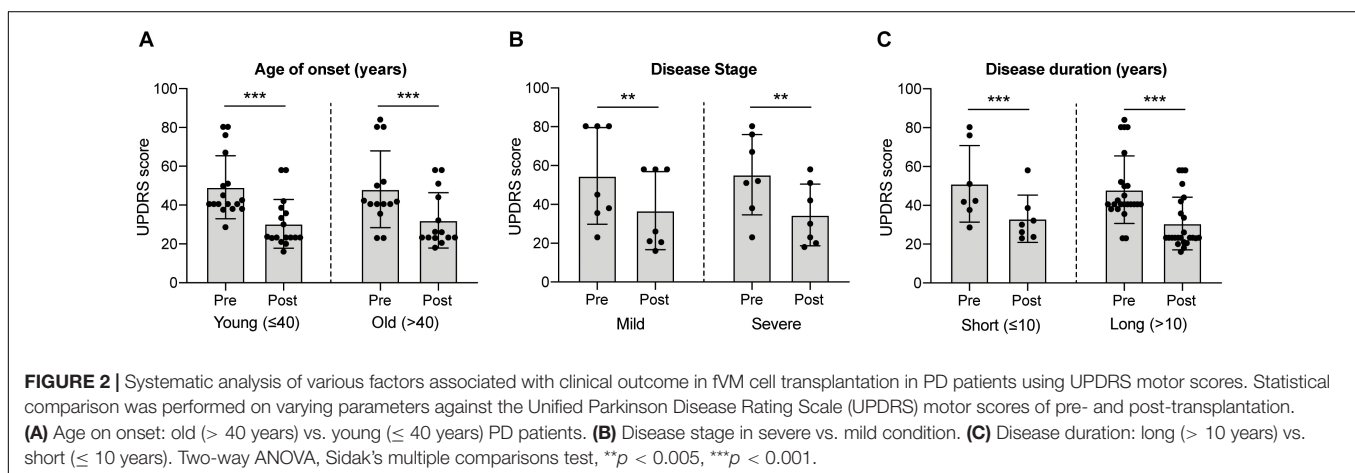

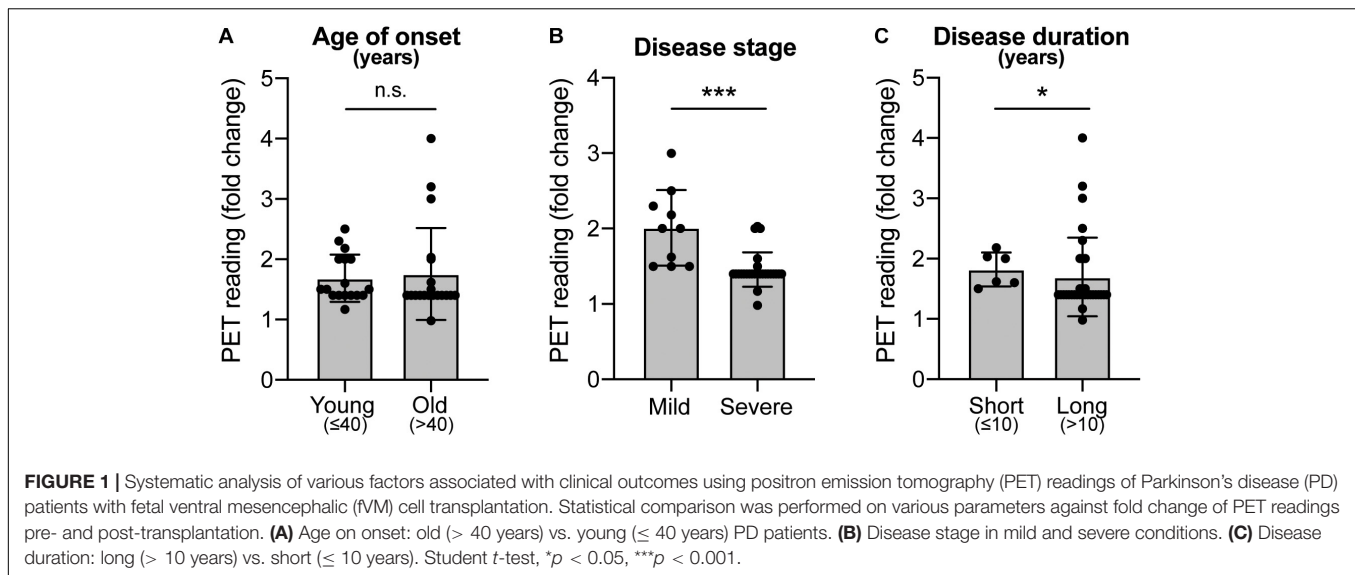

**TABLE 3 |** Summary of clinical studies in cell transplantation for PD.

Year of Publication	Patient info				Results			No. of patients	Lewy body in grafted cells	References

2020	69	Severe	10	2	iPSC	Yes	Yes	1	N.A.	Schweitzer et al., 2020

In line with our data, the high prevalence of long-term graft survival with low to no immune response in the majority of fVM recipients could be represented for future/ongoing stem cell-based clinical trials as a basis for host tissue innervation and reconnection to host DA circuitry. It is to note that occasional appearance of graft-induced dyskinesia cannot be attributed to cell transplantation as of date, as there are very limited follow-up studies. Upcoming clinical studies must include detailed surgical procedures, characterization of PD hallmarks such as  $\alpha$ -synuclein-positive Lewy bodies, ubiquitin expression, and imaging analysis for F-DOPA uptake in graft region in addition to clinical observations. It is believed that the differences in quality and heterogeneity in the transplanted cells, patient selection, and surgical methodologies could have been the reason for failures in some trials. The current status of the TRANSEURO trial (NCT01898390), a large collaboration between the European Union multicenters of fetal nigral cell transplantation, which started in 2012, has grafted 11 young patients with early-stage

PD in Cambridge, 2019, and will be subjected to clinical observations for 36 months post-surgery, which is estimated to be completed in early 2021.

With the improvement in the human DA neuron differentiation protocol (Nolbrant et al., 2017), more authentic midbrain DA neurons can now be derived from ESCs or iPSCs *in vitro*. These more defined ESC/iPSC-derived DA neurons show satisfactory therapeutic effectiveness in PD animal models (Studer, 2017), which has led to new waves of initiatives for cell transplantation in PD patients. Furthermore, with ES-derived DA neuronal transplantation being equipotent (Grealish et al., 2014) to that of the current gold standard for PD cell therapy (Li et al., 2016), stem cells rather than fetal neurons hold high expectation in the near future. However, we must bear in mind that animal models cannot fully reproduce human PD. Confounders, including aging, disease duration, disease severity, diabetes, and depression, should be taken into account when cell therapy is translated from preclinical models

to clinical trials (Aarsland et al., 2011; Athauda et al., 2017; Henchcliffe and Parmar, 2018). Currently, ongoing clinical trials of the GForce-PD Consortium include European-based STEM-PD trial, NYSYSTEM trial, CiRA trial;<sup>2</sup> Cyto Therapeutics Pty Limited founded trial (NCT02452723), and the Chinese Academy of Sciences founded trial (NCT03119636) lead by Qi Zhou. STEM-PD trial was designed to use GMP-grade hESCs as the clinical cell source, employing full GMP-grade production procedure (Kirkeby et al., 2017b), and transplanting 100,000 TH<sup>+</sup> D16 mDA progenitors per graft as a target dose. In contrast, CiRA was designed to develop clinical-grade DA cell therapy from autologous iPSCs taken from PD patients (Barker et al., 2017). More recently, iPSC-derived dopamine progenitor cells have been bilaterally injected into a 69 year old PD patient and have demonstrated signs of improvements in motor assessment 24 months post-surgery (Schweitzer et al., 2020). It is interesting to note that clinical improvements were significantly associated with the right (second) surgical

procedure than the left. One explanation would be the improved procedural efficiency including shorter time taken from cell harvest to implantation. Further double-blind studies will be essential to better understand the full potential of iPSC-derived dopamine cells in PD.

Notably, neural progenitor stem cells (NPCs) are an alternative cell source for cell replacement strategy. These multipotent cells can self-renew and differentiate into all mature neural cells in the CNS in large quantities (Ribeiro et al., 2013). The first autologous differentiated neural stem cell clinical trial was conducted using tissue samples collected in the prefrontal cortical and subcortical region along the trajectory of the electrode implant prior to further expansion and differentiation. The patient showed clinical improvements during the first 3 years post-transplantation with subsequent decline back to baseline by the fifth year (Levesque et al., 2009). Ongoing clinical trials sponsored by NeuroGenerations involves 12–20 PD patients at the age of 35–85 years (Hoehn and Yahr stage III or IV) with an estimated completion date by 2021 (NCT03309514, NCT01329926).

<sup>2</sup>[https://upload.umin.ac.jp/cgi-open-bin/ctr\\_e/ctr\\_view.cgi?recptno=R000038278](https://upload.umin.ac.jp/cgi-open-bin/ctr_e/ctr_view.cgi?recptno=R000038278)

Another factor we need to consider for PD cell transplantation clinical trials is the patient stratification. Since aging-induced BBB leakage can lead to infection and inflammation, age can greatly compromise the survival of DA neurons. Moreover, cell transplantation is usually less effective in patients with a longer and more severe disease progression (Barker et al., 2017). Discrepancies were also found in some patients with substantial survival of grafted DA neurons but no beneficial behavioral improvements (Barker et al., 2013, 2015a, 2017; Barker, 2014). These observations possibly indicate the degeneration of other brain systems, especially the post-synaptic component of the DA system. Thus, DA neuron transplantation clinical trials initiated by various organizations only include patients who 1) are younger than 65 years old, 2) have a disease duration of less than 10 years, and 3) are in the early stage of the disease (Kirkeby et al., 2017b; Studer, 2017; Takahashi, 2017). Moving forward, the identification of these confounders would be helpful for clinicians to be able to better stratify PD patients and suggest the most suitable treatment strategy for each patient.

## CONCLUSION AND FUTURE DIRECTIONS

We have highlighted four different types of cell sources and have addressed their pros and cons to better understand the characteristics of individual cell types and have also provided detailed analysis of the discrepancies observed in clinical outcomes of PD patients. This also includes methodologies in cell type specification and various imaging modalities. The emphasis on cell line availability, quality, and ability to innervate into host tissues, develop into functional A9 DA neurons, which would efficiently repair the host DA system is of topmost importance. Furthermore, long-term survivability for years after surgery without graft-induced dyskinesia or immune rejection by the host are some safety requirements and is the key to successful translation into large-scale therapeutic application

and also in biomedical research to better recapitulate *in vitro* disease models. To avoid further inconsistencies in clinical results, we need to ensure standardization across several aspects of transplantations, including tissue preparation for engrafts, surgical technique, patient selection, immune therapy, synaptic integration capacity of cells transplanted into the human brain, and ways to bypass ethical issues revolving around cell transplantation in humans and the usage of ESCs (more details can be found in Barker et al., 2015b). The need to develop minimal, but precise, surgical techniques and achieving a better understanding of striatal functions are necessary, and these improvements could be accomplished by acquiring higher-resolution diagnostic imaging with heightened specificity for targeted graft placement and post-op observational study. Clinical endpoint observations from aforementioned ongoing clinical trials would pave a way to develop a coherent and systematic blueprint for therapeutic strategies such as improved surgical methodologies, optimized and standardized protocols, development of appropriate safeguards, and objective long-term outcome measures. The field of stem cell-based therapies for PD has entered into an exciting era, and we believe there is greater optimism that neurotransplantation may provide a viable option for treatment of PD in the future.

**Methods:** Alzheimer's disease and Frontotemporal dementia are the first and third most common forms of dementia. Due to their similar clinical symptoms, they are easily misdiagnosed as each other even with sophisticated clinical guidelines. For disease-specific intervention and treatment, it is essential to develop a computer-aided system to improve the accuracy of their differential diagnosis. Recent advances in deep learning have delivered some of the best performance for medical image recognition tasks. However, its application to the differential diagnosis of AD and FTD pathology has not been explored.

**Approach:** In this study, we proposed a novel deep learning based framework to distinguish between brain images of normal aging individuals and subjects with AD and FTD. Specifically, we combined the multi-scale and multi-type MRI-base image features with Generative Adversarial Network data augmentation technique to improve the differential diagnosis accuracy.

**Results:** Each of the multi-scale, multitype, and data augmentation methods improved the ability for differential diagnosis for both AD and FTD. A 10-fold cross validation experiment performed on a large sample of 1,954 images using the proposed framework achieved a high overall accuracy of 88.28%.

**Conclusions:** The salient contributions of this study are three-fold: (1) our experiments demonstrate that the combination of multiple structural features extracted at different scales with our proposed deep neural network yields superior performance than

individual features; (2) we show that the use of Generative Adversarial Network for data augmentation could further improve the discriminant ability of the network regarding challenging tasks such as differentiating dementia sub-types; (3) and finally, we show that ensemble classifier strategy could make the network more robust and stable.

**Keywords:** differential diagnosis, magnetic resonance imaging, generative adversarial network, frontotemporal dementia (FTD), Alzheimer's disease

## 1. INTRODUCTION

As the first and third most common forms of dementia, Alzheimer's disease (AD) (Association et al., 2011) and Frontotemporal dementia (FTD) (Bang et al., 2015) are often mistaken as each other. This is due to the similarities in their clinical presentation, cognitive domains impairment, brain atrophy, and progressive alterations in language ability, behavior, and personality (Neary et al., 2005; Alladi et al., 2007; Womack et al., 2011). Despite significant efforts spent on establishing sophisticated clinical guidelines for their differential diagnosis, the diagnostic accuracy is still not satisfactory. Specifically, when diagnosing with the NINCDS-ADRDA criteria (Neary et al., 1998), the sensitivity of distinguishing AD subjects from FTD patients could reach as high as 93%; however, the specificity for FTD recognition is only 23% as most patients with FTD also fulfilled the NINCDS-ADRDA criteria for AD (Varma et al., 1999). With the necessity of applying different symptomatic intervention of treatment for various dementia subtypes in clinical practice (Pasquier, 2005), it is essential to develop a computer-aided diagnosis system for the improvement of the accuracy of differential diagnosis between these two dementias.

Patterns of brain atrophy observed in T1-weighted Magnetic Resonance Imaging (MRI) have been successfully used to capture structural changes in the human brain (Du et al., 2007; Davatzikos et al., 2011), specifically for using in developing computational systems that can identify the type of dementia pathology in the brain. Computer-aided diagnosis systems with MRI have been built for both AD and FTD (Suk et al., 2014; Jiskoot et al., 2018). In addition to binary classification with normal aging, T1-weighted MRIs have also been used for the differential diagnosis of AD and FTD by differentiating the atrophy pattern of these two types of dementia such as the affected regions and rate of change (Raamana et al., 2014). Various structural biomarkers have been explored to distinguish between AD and FTD, such as gray matter (GM) volume loss (Rabinovici et al., 2008), cortical thinning (Du et al., 2007), high-dimensional features based on GM and white matter (WM) volume distribution of whole brain (Davatzikos et al., 2008), as well as atrophy and shape deformity of individual structures (Looi et al., 2010).

Most previous studies on computer-aided diagnosis system for dementia classification emphasized on binary classification tasks, e.g., NC vs. FTD, NC vs. AD, or FTD vs. AD with few direct multi-class dementia classification methods in the literature. Raamana et al. compared multiple structural features, such as volumes, Laplacian invariants, and surface displacements

of the hippocampus and lateral ventricle, regarding the multi-class classification among NC, AD, and FTD subjects (Raamana et al., 2014). With PCA and multi-class support vector machine (SVM) classifier, they achieved a 0.79 AUC. Tong et al. applied the RUSBoost algorithm (Seiffert et al., 2010) for the multi-class classification of subjective memory complaints, AD, frontotemporal lobe degeneration (FTLD), dementia with Lewy bodies, and vascular dementia (Tong et al., 2017). With volume and grading features as well as CSF measures and age, they achieved 75.2% overall accuracy with 0.8 sensitivity for AD and 0.63 sensitivity for FTLD.

Recently, deep learning has been delivering astounding performance for many recognition tasks (Hinton and Salakhutdinov, 2006; Krizhevsky et al., 2012; Simonyan and Zisserman, 2014). Its applications in computer-aided diagnosis has also drawn attention and it has out-performed traditional classification methods for many clinical recognition tasks (Suk et al., 2014; Ronneberger et al., 2015; Litjens et al., 2017). However, to the best of our knowledge, there have been no deep-learning-based approaches developed and published yet for the differential diagnosis of AD and FTD.

In this study, we proposed a novel framework to combine multi-type and multi-scale image-based features from structural MRI scans. Local volume size and surface thickness features were extracted by segmenting the T1-weighted MRI images into patches of a hierarchical size based on brain anatomy in a coarse-to-fine manner. A multi-scale and multi-type feature deep neural network (MMDNN) was developed to learn the latent representation across each individual features, along with the Generative Adversarial Network (GAN) technique for data augmentation and ensemble classifier strategy to increase robustness of the framework. A comprehensive validation experiment with 1,954 images demonstrates the superior performance of the proposed framework with 88.28% accuracy.

## 2. METHODS

In the proposed framework, the original raw structural MRI images were first segmented into different anatomical structure region of interests (ROI) with FreeSurfer. Each ROI was further sub-clustered into smaller patches of super-pixels with multi-scales. The volume, cortical thickness at each level of the patch were extracted as multi-scale multi-type features. Finally, a Generative Adversarial Network with multi-type and multi-scale features was trained to achieve differential diagnosis to identify patients with AD and FTD from NC subjects.

**TABLE 1 |** Demographic information of the subject included from the databases.

Mean $\pm$ SD	NC	AD	FTD
Count (M/F)	1063 (533/530)	459 (270/189)	434 (266/168)
Age (Mean $\pm$ SD)	72.19 $\pm$ 8.28	75.91 $\pm$ 7.54	64.69 $\pm$ 8.51
Education (Mean $\pm$ SD)	16.66 $\pm$ 3.24	15.13 $\pm$ 2.58	19.05 $\pm$ 1.12
MMSE (Mean $\pm$ SD)	29.40 $\pm$ 1.39	23.20 $\pm$ 1.96	25.36 $\pm$ 6.12

First row (Count M/F): total number as well as number of male and female subjects in each clinically diagnostic group. Second row: the mean and standard deviation of subject age (unit: years). Third row: the mean and standard deviation of subject's years of education (unit: years). Forth row: the mean and standard deviation of subject's clinically evaluated MMSE score.

## 2.1. Materials

Data used in this study were obtained from two publicly available databases, i.e., the Alzheimer's Disease Neuroimaging Initiative (ADNI) database [adni.loni.usc.edu](http://adni.loni.usc.edu) and the frontotemporal lobar degeneration neuroimaging initiative (NIFD) database <http://memory.ucsf.edu/research/studies/nifd>. The primary goal of ADNI is to test whether serial MRI, PET, other biological markers, and clinical and neuropsychological assessment can be combined to measure the progression of mild cognitive impairment (MCI) and early Alzheimer's disease (AD). Frontotemporal lobar degeneration Neuroimaging Initiative (FTLDNI), also referred to as NIFD started in 2010 with the primary goals being to identify neuroimaging modalities and methods of analysis for tracking frontotemporal lobar degeneration (FTLD) and to assess the value of imaging vs. other biomarkers in diagnostic roles. More detailed information about FTLDNI can be found in [4rtni-ftldni.ini.usc.edu](http://4rtni-ftldni.ini.usc.edu).

Both ADNI and FTLDNI databases contain longitudinal scans for each participant. Subjects with who the diagnosis changes in any of their follow-up visits during the study period (i.e., MCI progressing to AD or reverting to NC), were excluded from the study to reduce the effect of potential misdiagnosis. A total of 1,954 Structural MRI were included in this study, 1,114 of which were from ADNI database, and the remaining 840 from the NIFD database. **Table 1** shows the demographic and clinical information of these subjects in both database. The numbers in the brackets of the second row are the numbers of male and female subjects, while number before each bracket is the total number of subjects belong to that group. The numbers in the remaining three rows represent the mean and standard deviation of age, education, and MMSE, respectively.

## 2.2. Multi-Level Multi-Type Feature Extraction

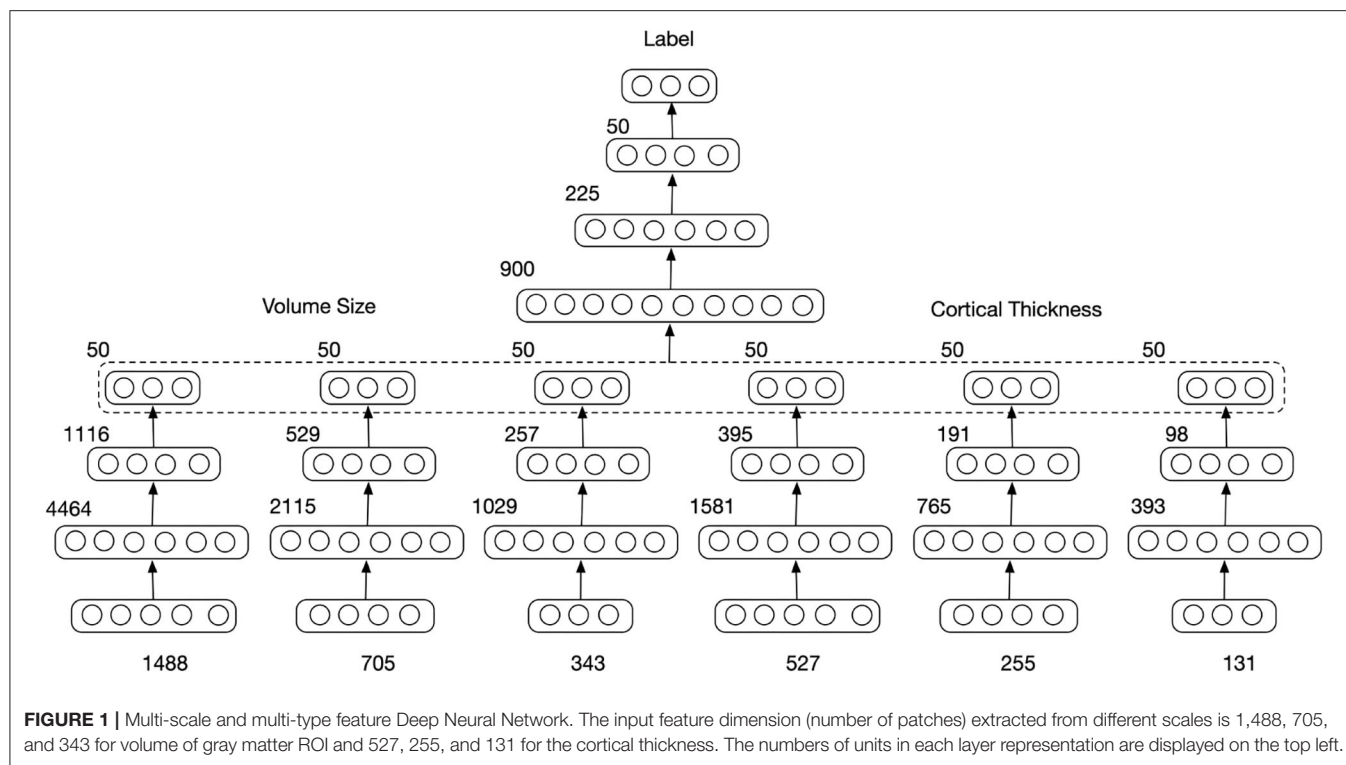

For image recognition problems, convolutional neural network (CNN) and its variants, such as VGG16 (Simonyan and Zisserman, 2014), ResNet (He et al., 2016), and Inception-ResNet (Szegedy et al., 2017), have achieved the state-of-the-art performance in various tasks. However, those networks require a large number of labeled samples for their training. Especially with high dimensional data, as used in this study ( $256 \times 256 \times 256$  3D images), larger kernel sizes or more layers are necessary to learn the latent representation, resulting in a larger network

that needs even more training samples. The dataset used in our data set is considerably larger in magnitude than many other studies in the neuroimaging context, it is however still relatively small in scale as compared with most of the natural image recognition tasks. Therefore, to reduce the dimension of input data and the size of network, each MRI scan was segmented into small regions based on brain anatomy, which we denoted as "patches" hereafter, and two types of primary structural features, volume size and cortical mantle thickness, were extracted for the differential diagnosis of NC, AD, and FTD. For MRI scan segmentation and volume size feature extraction, the following steps were applied: (1) structural ROI parcellation, (2) Structural-wise patch cluster-based segmentation, (3) Feature extraction and normalization.

Firstly, in the ROI segmentation step, the gray matter (both cortical and subcortical) of each T1 structural MRI image was segmented into 87 anatomical ROIs using FreeSurfer 5.3 (Dale AM, 1999). For some ROIs, in particularly larger ones such as the occipital cortex, the discriminant information for brain structural change could be localized within the ROI to smaller focal locations. Such localized differences could potentially provide important information to differentiate AD and FTD but could be lost in aggregating the features across the whole ROI. Therefore, each ROI was further subdivided into smaller patches in the second patch parcellation step. Parcellation or subdivision of a FreeSurfer ROI was performed on a template MR image using a *k*-means clustering algorithm based on their intensity similarity (Raamana et al., 2015). Following the *k*-means clustering step, a high-dimensional accurate non-rigid registration method, LDDMM (Beg et al., 2005), was applied to register each ROI of a target MRI to the corresponding ROI of the template. With the ROI-wise registration maps, the patch-wise segmentation of each template ROI was propagated back into the target space. Finally, in the feature extraction and normalization step, the volume of each patch was extracted as a primary feature for disease classification. The w-score, which represents the standardized residual of the chosen features, was computed to remove the effect of covariates such as the field of strength (1.5T or 3T), scanner type, scanning site, age, sex, and the size of the intra-cranial vault (ICV) of each individual (Ma et al., 2018 and Popuri et al., 2020). The normalized features as represented by the w-scores were input into the classifier.

The patch-wise cortical thickness features were extracted in a similar manner to the patch-wise volumetric features. The vertex coordinates in each of the 68 cortical ROIs were subdivided into smaller patches by grouping them with *k*-means clustering based on the pairwise Euclidean distance of their thicknesses in the template space (Raamana et al., 2015). The locally-clustered cortical patches were then propagated back to each of the target space following the backward deformation field that was derived during the LDDMM non-rigid registration step (Beg et al., 2005). The average thickness of the mantle within each patch was computed as features followed by the w-score normalization (Ma et al., 2018 and Popuri et al., 2020) to remove the confounding effect of covariates.

To avoid losing discriminant information during data down-sampling, multiple scale features were extracted in a

coarse-to-fine manner. Each ROI was parcellated into three different scales of patch-sizes: 500, 1,000, and 2,000 voxels per patch for the volume features and 500, 1,000, and 2,000 vertex per patch for the thickness features. Those sizes were predefined to retain enough detailed information while restraining the number of primary features with respect to the number of training data to prevent overfitting. The subdivision of ROIs into these three scales resulted in a total number of 1,488, 705, and 343 voxel patches for the gray matter volume feature, and a total number 527, 255, and 131 vertex patches for the cortical thickness feature, respectively. Together with the FreeSurfer ROIs providing volumes and thickness, this gives six feature sets containing 3,409 scalars that represent each brain MR image.

### 2.3. Deep Neural Network for Multi-Scale and Multi-Type Feature Combination

With the patch-wise volume size and surface thickness features extracted from MRI images, a multi-scale and multi-type feature deep neural network (MMDNN) was constructed to learn the latent pattern from both types of features for the classification of NC, AD, and FTD pathology, which achieved state-of-the-art binary classification of NC and AD subjects using both FDG-PET and MRI images in our previous study (Lu et al., 2018a).

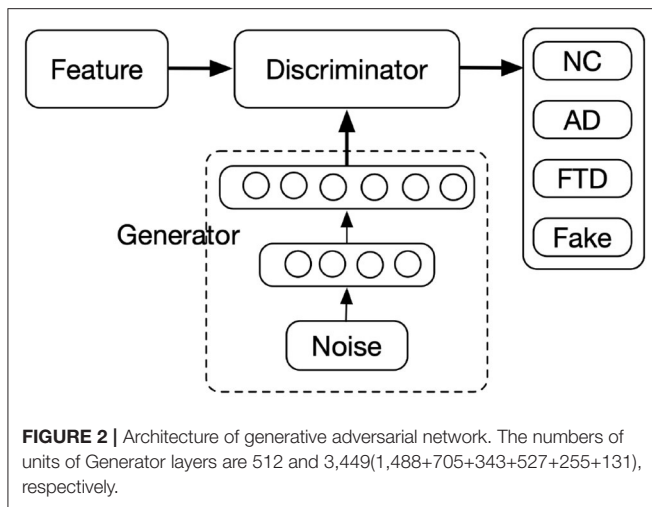

As displayed in **Figure 1**, the MMDNN consisted of two stages with a total of seven blocks Multilayer Perceptrons (MLPs). The first network stage consisted of 6 MLPs blocks, each corresponds to a single type of features extracted at a single scale. These MLPs were trained independently in the first stage, and their outputs were concatenated as the input feature vector to train the final MLP block in the second stage. The parameters of the

whole network were then fine-tuned together. For each image, the output was three probabilities with each corresponding to a subject group, i.e., NC, AD, and FTD, and the class with the highest probability was deemed to be the resulting classification. For each MLP, the number of units for each layer are displayed on its top left in **Figure 1**. If the dimension of input feature is represented with  $N$ , the number of units in a single MLP were predefined as  $3N$ ,  $\frac{3}{4}N$ , and 50 to increase the chance of exploring a larger range of potential hidden correlations across different patches in the first layer and gradually reduce the number of features in the following layers to avoid too many parameters Lu et al. (2018b,a).

To avoid overfitting, dropout layers (Srivastava et al., 2014) were added after each hidden layer. During the training stage, half of the units were randomly dropped to prevent complex co-adaptations on training data as well as to reduce the amount of computation and improve the training speed. During the validation or testing stage, all the units were retained to feed features to the next layer.

### 2.4. Data Augmentation With Generative Adversarial Network

In deep/machine learning, a common strategy to increase the number of training samples and prevent overfitting is data augmentation. Operations, such as rotation, flip, and zooming, are commonly used for 2D image recognition. However, those operations can hardly be used on a 1D feature vector. GAN (Goodfellow et al., 2014) have emerged to be a powerful tools to synthesize new data and have gained popularity in the generation of realistic natural images, and has also shown great potential to

be a powerful data augmentation technique to synthetic image data with more variation and improve the generalizability of the machine learning algorithm (Shi et al., 2018; Lata et al., 2019; Sandfort et al., 2019; Shao et al., 2019). Therefore, we investigated the possibility of applying GAN for 1D structural brain feature augmentation for the improvement of classification performance in this study.

GANs consist of two parts, the Discriminator (D) and the Generator (G), as displayed in **Figure 2**. In the proposed framework, the MMDNN was used as the discriminator with an additional channel of output for the recognition of data synthesized by the generator, denoted here as “fake,” while the generator aimed to generate feature vectors to “fool” the Discriminator, i.e., classified as NC, AD, or FTD by the discriminator. The input of the generator was a 1D random noise vector. By finding the mapping from the random variables to the data distribution of interest, the generator outputs a feature vector with the same dimension as the real data samples. It was worth mentioning that the fourth channel of output was only used during the optimization of GAN. For each testing sample, only the output probabilities of the first three channels were used to determine which of the three groups a subject belongs to.

To prevent potential problems due to vanishing gradients, the generator consists of two layers, a single hidden layer and an output layer. Both layers are fully connected layer with 512 and 3,449 units, respectively. The dimension of random noise was set to 100 with each element set to follow a normal distribution. The activation function for the first layer was a rectified linear unit (ReLU) to avoid gradients from vanishing, while the one for the second layer was tanh function to squash the synthesized data into the same range of the real data.

## 2.5. Network Optimization

For optimization of the GAN, the loss function was defined:

$$\min_D \max_G V(D, G) = \mathbb{E}_{x \sim p_{data}(x)} [\log D(x)] + \mathbb{E}_{z \sim p_z(z)} [\log(-D(G(z)))] \quad (1)$$

where  $x$  represents the input data and  $p_z(z)$  is the prior of input noise variables.  $\log(-D(G(z)))$  was used instead of  $\log(1 - D(G(z)))$  to avoid vanishing gradient and mode collapse (Arjovsky and Bottou, 2017). The  $E$  here stands for weighted cross entropy function, which is defined as:

$$E(\log D(x)) = -\frac{1}{N} \sum_{i=1}^N \sum_{j=1}^4 [\mathbb{I}\{y^i = j\} W^j \log(h(x^i)_j)] \quad (2)$$

where  $N$  is the number of input samples,  $j$  represents the class of samples,  $W^j$  stands for the weight of class  $j$  which is computed as the inverse proportion of the subject number for the current class over the entire sample data,  $x^i, y^i$  are the feature vector and label of sample  $i$ , and  $h$  represents the network function.

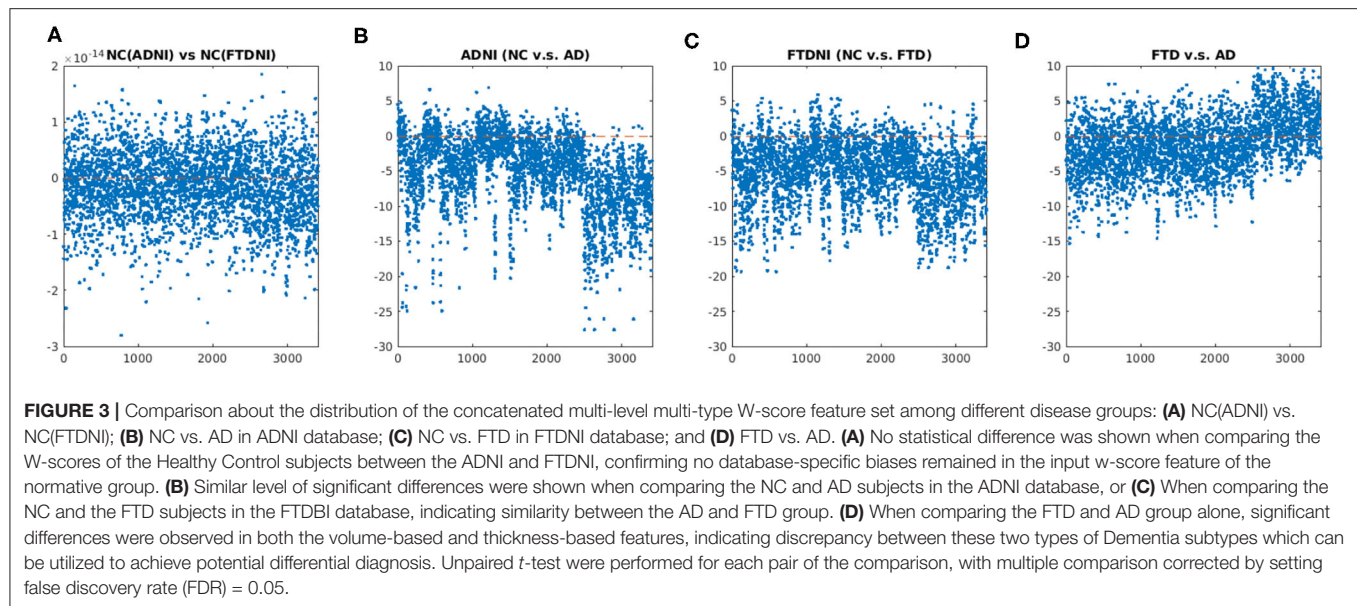

For the training of GAN, the discriminator and the generator were optimized alternately. During the optimization of the discriminator, the parameters of the generator were held constant, and when the generator was trained, the parameters of the discriminator were fixed. The minimax competition between  $G$  and  $D$  could drive both networks toward better performance.

Besides adding dropout layers, another strategy, early stopping, was applied during the training process to reduce the overfitting. During the training of the deep neural network, iterative back propagation could drive the network to co-adapt to the training set. After a certain point, reducing training error could result in increasing the generalization error. Early stopping was therefore useful to provide guidance for the number of optimization iterations before overfitting. Part of the training data was randomly selected as the validation set and were excluded from training. While the remaining data samples were used to train the network, the validation set was used to determine the early stopping time point: the iteration in which the network has the lowest generalization error for the validation set. In this study, optimization of the network was stopped when the generation error of the validation set ceased to decrease for a consecutive 20 epochs.

Furthermore, due to the limited number of available data and variation among different samples, there was still a chance that early stopping with a small validation set could result in biased classification toward the validation set, and the differential performance could be unstable with different splitting of training and validation sets. An ensemble classifier strategy (Lu et al., 2018b) was therefore used to improve the robustness, stability, and generalizability of the classifier. Similar to the 10-fold cross validation, the training set was randomly divided into 10 subsets. In each fold of the training process, one subset was retained for validation while the remaining nine subsets were used for training. With 10 repetitions, each set was used for validation once resulting in 10 different networks. For each test sample, each network would generate three probabilities corresponding to NC, AD, and FTD. The output probabilities of 10 networks were averaged followed with a softmax operation to determine the final classification result.

The proposed deep neural network was built with Tensorflow (Abadi et al., 2015), an open source deep learning toolbox provided by Google. For the optimization of network in all

experiments, Adaptive Moment Estimation (Adam) was used as the optimizer, batch size was set as 100 and the learning rate was fixed as  $5 \times 10^{-5}$ .

## 2.6. Performance Evaluation

To validate the discriminant ability of the proposed framework on NC, AD, and FTD pathology, 10-fold cross validation was performed on the 1,954 T1 MRI images. Because a single subject could have multiple scans at different visits, a split based on images could result in having scans from the same subject used for both training and testing. We therefore performed the split based on subject to ensure complete separation between training and test samples. As mentioned in the section 2.5, the training set was further sub-divided into 10 subsets for each cross validation experiment and 10 networks optimized with different training and validation set were used to “vote” for the classification result of testing samples. Such an experimental design ensures that the data samples in the training, validation, and testing set were mutually exclusive on a subject level. The performance of classification was measured via accuracy and the sensitivity of correctly identifying different groups, such as  $N(\text{TrueNC})/N(\text{NC})$  for NC group, where  $N(\cdot)$  denotes the number of data samples belonging to this group.

Other than the proposed deep-learning-based method, a standard classifier, support vector machines (SVM) were also trained for comparison. One vs. rest strategy was applied for this multiclass classification task. Principal component analysis (PCA) was used for the reduction of feature dimension and the eigenvectors accounting for 95% of the total data variance were retained. Radial basis function (RBF) kernel was used for SVM given its superior performance in classification tasks. The features extracted at different scales were concatenated as the input for PCA+SVM classifier. In addition, to validate the effect of patch-wise parcellation, we also trained the MLPs on FreeSurfer ROI-wise features, i.e., the surface thickness and volume size of each ROI based on the FreeSurfer segmentation.

## 3. RESULTS

### 3.1. W-Score Feature Extraction

Figure 3 showed the comparison of the distributions for the entire concatenated multi-level multi-type W-score feature set between different subgroups. First, no statistical difference was shown when comparing the W-scores of the healthy control subjects between the ADNI and FTDNI for either the volume-based or thickness-based features (Figure 3A), confirming no database-specific biases remained in the input w-score feature of the normative group. Similar level of significant differences were shown when comparing the NC and AD subjects in the ADNI database (Figure 3B), or when comparing the NC and the FTD subjects in the FTDBI database (Figure 3C), indicating similarity between the AD and FTD group. Finally, when comparing the FTD and AD group alone, significant differences were observed in both the volume-based and thickness-based features, indicating discrepancy between these two types of Dementia subtypes, which can be utilized to achieve potential differential diagnosis.

### 3.2. Cross Validation Experiment Results

The results of 10-fold cross validation experiment are shown in Table 2. When comparing the mean accuracy across 10-folds, the accuracy of PCA+SVM with both type of multi-scale features was only slightly higher (0.02%) than the multi-scale deep neural network (MDNN) with surface thickness feature. The accuracy of MDNN using volume size feature was higher than the one using surface thickness feature by 2.93%. The combination of both type of multi-scale features showed superior performance comparing with MDNN using a single type of feature, and it was further improved by 1.42% with the data augmentation using the proposed GAN technique.

Figure 4 showed the corresponding statistical comparison results among different experimental setup for the overall accuracy as well as the sensitivity for each class group. When

**TABLE 2 |** Comparison of classification performance over different experiments with multi-type features.

	Accuracy	NC sen.	AD sen.	FTD sen.
PCA+SVM (Multitype)	83.06	93.90	71.74	68.23
MDNN+Thickness	83.04	89.07	76.77	74.79
MDNN+Volume	85.97	91.05	83.88	74.20
MMDNN (Multitype)	86.81	93.76	81.94	73.59
GAN (Multitype)	88.28	93.40	84.66	77.82

The second column is the overall classification accuracy, while the third to fifth columns represent the sensitivity of NC, AD, and FTD, respectively. The second row represents the result with PCA+SVM using multi-type multi-scale features. The third and fourth rows are the classification performance of MDNN with multi-scale surface thickness or multi-scale volume size. Experiment results with both types of features using MMDNN are shown in the fifth row and the last row represents the result of multi-type multi-scale features along with data augmentation using GAN.

compared to the baseline method, PCA+SVM (multi-type), both the proposed MMDNN method with or without GAN showed significant improvement (indicated as **O**) for the overall accuracy (**Figure 4A**), as well as sensitivity for AD (C) and FTD (D). Training with multi-type feature showed improvement over the training with only single feature (for either thickness, indicated as **X**, or volume, indicated as **+**) in terms of overall accuracy (**Figure 4A**). Finally, data augmentation using GAN further improve the overall accuracy (**Figure 4A**) as well as sensitivity for the NC group (**Figure 4B**) and the FTD group (**Figure 4D**) (indicated as **+**).

For detailed classification result, the confusion matrices of experiments using the proposed multi-scale networks are displayed in **Table 3**. The presented four experiments show a similar pattern despite the differences in their accuracy and sensitivity. The networks had a good performance for the task of distinguishing between AD and FTD pathology. The discrimination between NC and FTD showed the least accurate performance, leaving room for potential future improvement.

### 3.3. Discrimination With Cortical Thickness Feature

The experiment performance with only cortical thickness feature was displayed in **Table 4**. MLP with only ROI-wise cortical thickness feature showed the least accuracy (76.48%), while better result was achieved with PCA+SVM using features extracted at all scales. As expected, the classification performance was sensitive to patch size change and a generalized reduction with increasing patch size was found on the overall accuracy. The combination of multi-scale features with MDNN yielded superior classification performance.

### 3.4. Discrimination With Volume Size Feature

The experiment performance with volume size feature was displayed in **Table 5**. Similarly, as the experiments with cortical thickness feature, MLP with only ROI-wise feature had the worst performance (79.78%), and PCA+SVM using features extracted at all scales showed better accuracy (82.28%). Unlike

the experiments with cortical thickness feature, MLP with a single scale of feature showed better performance comparing with PCA+SVM using features extracted at all scales. The combination of multi-scale features with MDNN also had the highest accuracy, while no generalized reduction of accuracy was found with increasing of patch size.

### 3.5. Ensemble Classifier

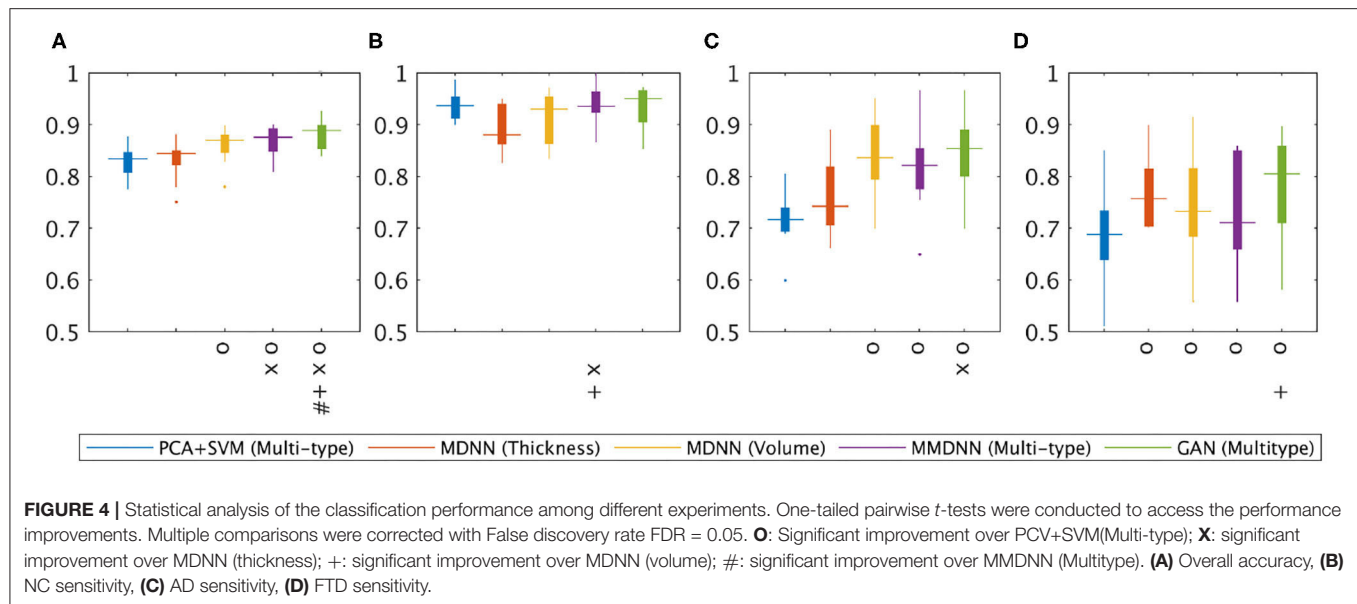

As described in section 2.5, the classification results presented in this study came through the “collective vote” of an ensemble of classifiers instead of a single network. The classification performance with or without ensemble classifiers of four different experiments, including MDNN with cortical thickness, MDDN with volume size, MMDNN with multi-type of features and GAN with multi-type of features, are shown in **Figure 5**. The *y* axis represents the mean classification accuracy from the 10-fold cross validation experiment, while the *x* axis stands for different classifiers. On the *x* axis, the number “1” to “10” represents the network trained with different split of training and validation set, while “ensemble” denotes the combined result of these 10 networks.

## 4. DISCUSSION

In this study, we proposed a novel deep-learning-based framework for the differential diagnosis of NC, AD, and FTD. Cross validation experiment indicate that the proposed network could learn the latent patterns representing the different dementias using multi-type and multi-scale features, which in combination with GAN-based data augmentation, achieved a high accuracy of 88.28%. Based on the confusion matrix displayed in **Table 3**, there were only three cases of misdiagnoses between AD and FTD out of 891 samples, suggesting the excellent performance of the proposed framework to distinguish these two dementias.

### 4.1. Differential Diagnosis Using MRI Biomarker

Brain MRI is an imaging modality widely used for detecting various types of dementia, as the image contrast between different tissue can reveal pathology-induced brain morphology changes. Due to variations in pathogenesis and phenotypes, dementia can further be categorized into different sub-types, such as FTD, AD, mild cognitive impairment, vascular dementia, and dementia with Lewy bodies. Differentiating among different dementia subtypes is crucial for to provide appropriate healthcare and potential treatment, but is challenging due to overlapping phenotyping and morphological heterogeneity with each subtype (Bruun et al., 2019), and accurate differential diagnosis requires both appropriate feature extraction technique combined with powerful classification model. Some recent studies attempted to differentiate dementia subtypes using different machine learning techniques, such as hierarchical classification (Kim et al., 2019), statistical learning with feature selection based on least absolute shrinkage and selection operator (LASSO), and support vector machine (SVM) (Zheng et al., 2019), but are limited from either the constrained feature set (e.g., structural-volume feature) or

**TABLE 3 |** Confusion matrix of GAN.

	NC	AD	FTD

relatively small validate with data for testing the robustness and generalizability of the classifiers. In our study, we proposed a framework to achieve accurate differential diagnosis by first building a multi-scale multi-type feature, followed with a deep neural network with the help of generative adversarial data augmentation technique, which was validated on a large sample (1,954 images), demonstrating a consistent overall high accuracy.

## 4.2. Multi-Scale Classification

Based on the results presented in **Table 4**, the accuracy of MLP decreased from 82.80% to 79.51% with patch size increasing from 500 voxels to 2,000 voxels, suggesting that cortical thickness feature is sensitive to the change of size of the ROI patch sizes, while less variation of accuracy was found with ROI volume feature (from 85.78% to 85.41%) as shown in **Table 5**. Contradicting our observations on using cortical thickness feature, the accuracy of volume size feature showed a slight improvement when the patch size increased from 1,000 to 2,000 voxels, suggesting that the volume change caused by brain atrophy may affect a large brain region in a similar

**TABLE 4 |** Comparison of classification performance over different experiments with cortical thickness feature.

	Accuracy	NC sen.	AD sen.	FTD sen.
PCA+SVM	81.12	91.04	73.78	63.43

MDNN	83.04	89.07	76.77	74.79

The second column is the overall classification accuracy, while the third to fifth columns represent the sensitivity of NC, AD, and FTD, respectively. The second row represents the result using PCA+SVM with multi-scale surface thickness features, while the third row shows the classification performance of a single MLP with ROI-wise features. The fourth to sixth rows are the result of a single MLP with features extracted at different scales, i.e., 500, 1,000, and 2,000 voxels per patch. The last row represents the MDNN result with multi-scale surface thickness features.

fashion. However, the combination of multi-scale features always resulted in a better classification performance, indicating that the proposed MDNN is capable of learning the hidden pattern across the small to large patch sizes regardless the feature type. The optimal scale with the best performance would be a potential tunable hyperparameter in an optimization framework.

## 4.3. Volume Size, Surface Thickness, and Other Morphological Features

Two types of features, ROI volume and cortical thickness, were used for differential diagnosis in this study. Cross validation experiments showed that volume size has better discriminant ability compared with surface thickness regardless of the scale of feature and the type of classifier, as presented in **Tables 4, 5**. In addition, the results in **Table 2** show that with the same classifier, the combination of these two features yields superior

**TABLE 5 |** Comparison of classification performance over different experiments with ROI volume Feature.

	Accuracy	NC sen.	AD sen.	FTD sen.
PCA+SVM	82.28	85.94	85.44	67.14
ROI MLP	79.78	83.44	79.79	69.67
500 MLP	85.78	91.60	82.83	73.31
1000 MLP	85.41	90.03	84.91	73.07
2000 MLP	85.45	90.34	82.26	75.06
MDNN	85.97	91.05	83.88	74.20

The second column is the overall classification accuracy, while the third to fifth columns represent the sensitivity of NC, AD, and FTD, respectively. The second row represents the result using PCA+SVM with multi-scale volume size features, while the third row shows the classification performance of a single MLP with ROI-wise features. The fourth to sixth rows are the result of a single MLP with features extracted at different scales, i.e., 500, 1,000, and 2000 voxels per patch. The last row represents the MDNN result with multi-scale volume size features.

classification performance comparing with single type of feature, regardless of whether they are concatenated as a single input feature vector for SVM or using a MLP to learn the latent representation of each scale of feature first.

In this study, we have explored the extraction volume-based and cortical-thickness-based features as an effort to improve the power of differential diagnosis. Other additional image-based morphological features could potentially also provide complementary information regarding brain pathology. Specifically, cortical folding has showed different aging-related patterns between healthy and diseased brain (Wang et al., 2016), including dementia such as AD (Cash et al., 2012). The combination of cortical folding with other shape-based descriptors such as local cortical thickness could potentially yield better characterization the cortical morphological changes that is induced by AD and other types of dementia (Awate et al., 2017). Therefore, the proposed framework could potentially be further extended to integrate other brain morphological descriptors, such as the cortical folding, into the multi-type input feature space to achieve better classification and differential diagnosis power.

In the current study, the proposed network was trained using structural-MRI-based patch-wise volume size and surface thickness features created with a combination of from FreeSurfer segmentation and k-mean clustering to balance the number of parameters trainable and the level of original image-based patterns that are preserved. A potential future direction is to learn the features directly from the raw structural image while maintaining a trainable number of network parameters, which still remains a challenge. This study with patch-wise FreeSurfer-segmentation-based features sets a baseline benchmark for future studies of deep-learning-based differential diagnosis studies with novel network-learned image-based features for comparison.

#### 4.4. Data Augmentation With GAN

As displayed in Table 2, the classification accuracy was further improved by 1.42% when using GAN for data augmentation. The sensitivity for detecting AD and FTD pathology was increased by a large margin with a slight decrease for detecting NC

samples. Instead of  $\log(1 - D(G(z)))$ , we used  $\log(-D(G(z)))$  in loss function to avoid vanishing gradient and mode collapse (Arjovsky and Bottou, 2017). Therefore, we did not specify what kind of data samples the generator should synthesize. We consider it as a “success” for the generator as long as the generated feature vector was classified as one of the three categories, i.e., NC, AD, and FTD, by the Discriminator. It would be interesting to train one or three Generators to synthesize data samples corresponding to specific groups, although this is beyond the scope of this study as our primary goal was to increase the differentiating accuracy.

For the generator, we only have a single hidden layer because of the low dimension of our data and potential gradient vanishing problem. Instance normalization or other kinds of normalization (Almahairi et al., 2018) was not performed because they caused mode collapse of the generator and resulted in synthetic data all close to 0. Contrasting with many other studies using GAN (Arjovsky et al., 2017), we found root mean square propagation (RMSprop) optimizer resulted in an 87.39% accuracy, which was lower than with Adam optimizer.

#### 4.5. Ensemble Classifier and Cross-Validation

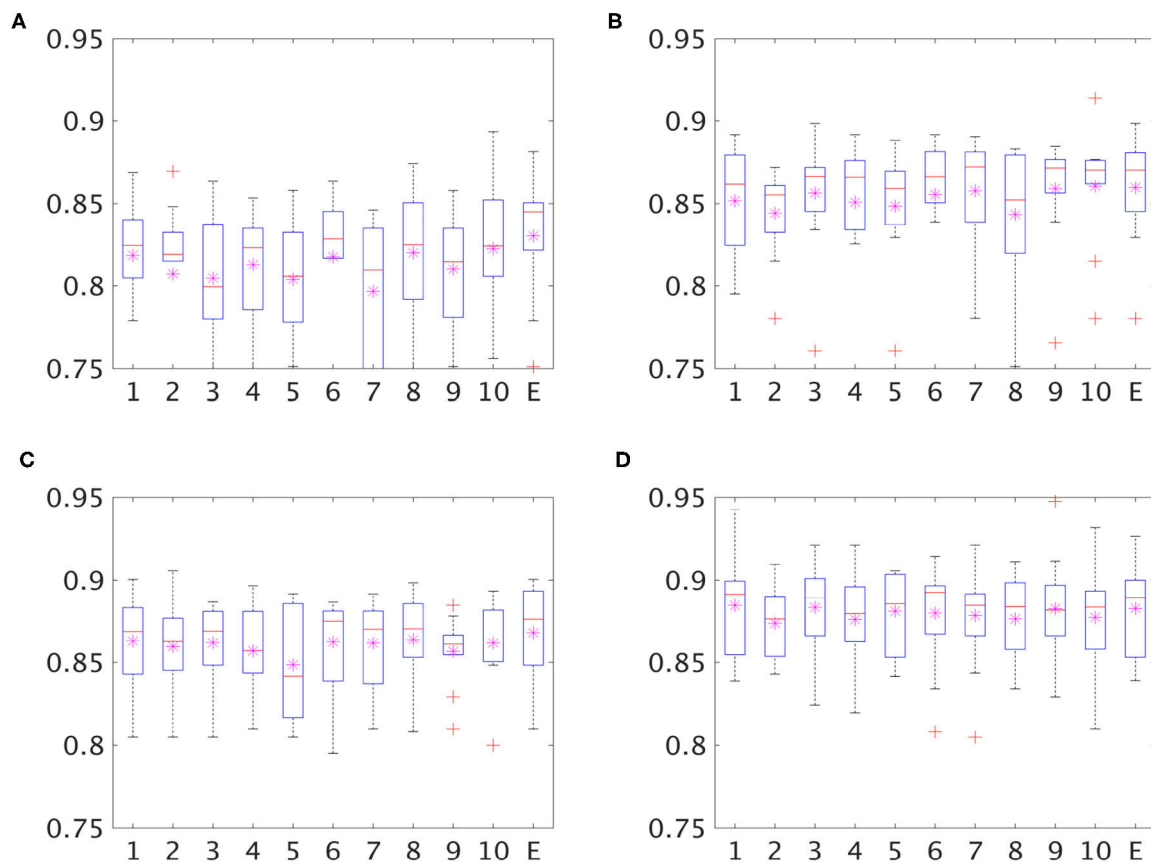

As shown in Figure 5, there can be as much as 3% difference in the classification accuracy (the seventh and the tenth bar of the top left image) across the individual classifiers trained with a different subdivision of the training and validation set, suggesting an unstable performance of each single classifier. In all four experiments, the ensemble classifier had the highest or close to highest accuracy, suggesting that the ensemble strategy improves the robustness and generalizability of the classifier.

It was worth mentioning that with the GAN, the variation of classification accuracy with individual classifiers decreased to 0.49% (from 87.98 to 88.47%) while the accuracy of ensemble classifier was 88.28%, suggesting that, with using GAN for data augmentation, the complex co-adaptations to training or validation set were reduced. The ensemble classifier strategy, although still effective, could therefore be optional with the application of GAN in light of limitations of available computational resources.

On top of the combination of GAN-based data augmentation and cross-validation-based ensemble classifier, an additional nested 10-fold cross validation was implemented to ensure the proposed method is properly validated. Nevertheless, it would be ideal to validate the proposed multi-class classifier on an entire independent and well-homogenized dataset to best evaluate its generalizability toward unseen dataset (Popuri et al., 2020; Yee et al., 2020).

### 5. CONCLUSION

In this study, a novel framework for accurate differential diagnosis among NC, AD, and FTD pathology has been proposed leveraging the multi-type and multi-scale feature fusion, ensemble classifier, and GAN strategy. The proposed

**FIGURE 5 |** Boxplot for classification accuracy of single classifiers (classifier 1–10 on x axis) and an ensemble of classifiers (E on the x axis). The stars in each box are the mean of accuracy and the red lines represent the median accuracy. **(A)** MDNN+Thickness, **(B)** MDNN+Volume, **(C)** MMDNN+Multitype, **(D)** GAN+Multitype.

framework achieved a high accuracy of 88.28%. The cross-validation experiments conducted on 1,954 MRI images demonstrate three salient observations. Firstly, the proposed network was able to learn the latent representation pattern across the different types of features (volumes and cortical thickness) extracted at coarse-to-fine scales. Secondly, using a Generative Adversarial Network for data augmentation could prevent overfitting and improve classification performance. Thirdly, the ensemble classifier strategy could result in a more robust and stable classifier, which has statistically better performance than an individual classifier. The promising high-accuracy results using the proposed framework, and the ability of deep networks to generalize to multiple classes, indicate that this approach can be potentially extended for the multiclass differential classification of brain images in other neurodegenerative dementias as well.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

## AUTHOR CONTRIBUTIONS

DM conducted the experiment, performed the data processing and analysis, and wrote the manuscript. LW and MB designed and supervise the experiments, guided, and revised the manuscript. KP performed the data processing and manuscript writing. DL conducted the experiment, designed the framework, performed the analysis, and wrote the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by Natural Sciences and Engineering Research Council (NSERC), Canadian Institutes of Health Research (CIHR), Michael Smith Foundation for Health Research (MSFHR), Brain Canada, the Pacific Alzheimer Research Foundation (PARF), Alzheimer Society of Canada (Alzheimer Society Research Program), the National Institutes of Health (R01 AG055121 and R01 EB020062), and the National Science Foundation (NSF 1734853 and NSF 1636893). Data collection and sharing for this project was funded by ADNI and NIFD. ADNI was funded by the National Institute on Aging, the National Institute of Biomedical Imaging and Bioengineering

and through generous contributions from the following: AbbVie, Alzheimer's Association; Alzheimer's Drug Discovery Foundation; Araclon Biotech; BioClinica, Inc.; Biogen; Bristol-Myers Squibb Company; CereSpir, Inc.; Cogstate; Eisai Inc.; Elan Pharmaceuticals, Inc.; Eli Lilly and Company; EuroImmun; F. Hoffmann-La Roche Ltd and its affiliated company Genentech, Inc.; Fujirebio; GE Healthcare; IXICO Ltd.; Janssen Alzheimer Immunotherapy Research & Development, LLC.; Johnson & Johnson Pharmaceutical Research & Development LLC.; Lumosity; Lundbeck; Merck & Co., Inc.; Meso Scale Diagnostics, LLC.; NeuroRx Research; Neurotrack Technologies; Novartis

Pharmaceuticals Corporation; Pfizer Inc.; Piramal Imaging; Servier; Takeda Pharmaceutical Company; and Transition Therapeutics. The Canadian Institutes of Health Research is providing funds to support ADNI clinical sites in Canada. Private sector contributions are facilitated by the Foundation for the National Institutes of Health ([www.fnih.org](http://www.fnih.org)). The grantee organization is the Northern California Institute for Research and Education, and the study is coordinated by the Alzheimer's Therapeutic Research Institute at the University of Southern California. ADNI data are disseminated by the Laboratory for Neuro Imaging at the University of Southern California.

Alzheimer's disease (AD) is a neurodegenerative disease with a high incidence rate and complicated pathogenesis. Currently, all anti-AD drugs treat the symptoms of the disease, and with currently no cure for AD. Flavonoid containing natural products, Myricetin (MYR) and Dihydromyricetin (DMY), are abundant in fruits and vegetables, and have been approved as food supplements in some countries. Interestingly, MYR and DMY have been reported to have anti-AD effects. However, the underlying anti-AD mechanism of action of MYR and DMY is complex with many facets being identified. In this review, we explore the benefit of MYR and DMY in AD patients from a molecular level. Their mechanism of action are discussed from various aspects including amyloid  $\beta$ -protein (A $\beta$ ) imbalance, neuroinflammation, dyshomeostasis of metal ions, autophagy disorder, and oxidative stress.

**Keywords:** Alzheimer's disease, natural product, Myricetin, Dihydromyricetin, mechanism of action

## INTRODUCTION

Alzheimer's disease (AD) is a neurodegenerative disease (Barnett, 2019), which can cause patients to gradually lose their ability to live independently, and change their personality and behavior. Most patients with AD die within 10 years of diagnosis, and those patients who survive past this, suffer from declines in cognition, language including speech, and memory. AD not only threatens the patients' lives and health but also causes serious societal problems (Guo et al., 2019), especially within countries with a growing aging population. Unfortunately, the incidence of AD has dramatically increased in the last few decades. According to the latest report from the Alzheimer's Association, the number of AD patients in the United States reached 5.8 million in 2020 (Association, 2020). At the same time, they predicted that this number would rise to 13.8 million by mid-century (Association, 2020).

The etiology of AD is complicated and remains unclear, with many factors being reported to be involved in the pathogenesis of AD. The excessive amounts of A $\beta$  and the abnormally phosphorylated tau peptide (Goedert and Spillantini, 2006) are the most studied pathogenesis of AD. The neurotransmitter imbalance in the central nervous system (Guo et al., 2019) such as acetylcholine (ACh) deficiency, the dyshomeostasis of metal ions (Ayton et al., 2015) and the overexpression of MicroRNA (Sarkar et al., 2019) are also thought to be closely related to

the development of AD. Furthermore, physiological function disorders, such as oxidative stress, inflammation (Meraz-Ríos et al., 2013), abnormal autophagy and the damage of insulin signaling pathway (Zhang and Hölscher, 2020) were also found to cause serious damage to the brain and can lead to the manifestation of AD (Butterfield and Halliwell, 2019). Other factors are also reported as a driving force in the genesis and development of AD, such as the long-term infections of bacteria and viruses (Bearer and Wu, 2019; Dominy et al., 2019), and the dyshomeostasis of intestinal flora (Friedland, 2015).

Currently, clinically used AD drugs treat the symptoms of AD in affected patients. Donepezil, Rivastigmine and Galantamine are AChE inhibitors while Memantine is an NMDA (N-methyl-D-aspartic acid) receptor antagonist. Notably, GV-971, an oligosaccharide derived from brown seaweed, was approved for use in China at the end of 2019. GV-971 is said to treat AD with a brain-gut axis as the target (Wang X. et al., 2019). In addition, given the crucial role of A $\beta$  in the pathological development of AD, many drugs were developed to control the abnormal accumulation of A $\beta$ . Verubecestat and Tarenflurbil inhibit enzymes within the A $\beta$  biosynthetic pathway, Tramiprosate and Azeliragon inhibit abnormal aggregation of A $\beta$ , monoclonal antibodies (such as Gantenerumab and Aducanumab) and vaccines (such as ACC-001) against A $\beta$  are also used as immunotherapy (Sevigny et al., 2016; Wu, 2019). Most of these candidates failed in phase III clinical trials, mainly due to lack of efficacy against placebo.

## MYRICETIN AND DIHYDROMYRICETIN

3, 3', 4', 5, 5', 7-Hexahydroxyflavone (Myricetin, MYR, **Figure 1**) is a flavonoid, which was first isolated from the bark of *Myrica nagi* Thunb. about 200 years ago (Semwal et al., 2016). The appearance of MYR is a light yellow crystal solid. 3, 3', 4', 5, 5', 7-Hexahydroxy-2, 3-dihydroflavanonol (Dihydromyricetin, DMY or DHM) is also known as ampelopsin (AMP) because it was first discovered from *Ampelopsis meliaefolia* (Hand. -Mazz.) W. T. Wang (an *Ampelopsis* Michx plant) in 1940 (Hou et al., 2015). DMY has a white appearance. MYR is the oxidation product of DMY, thus 2, 3-double bond of DMY is hydrogenated to form MYR (**Figure 1**).

MYR and DMY are produced in sizable quantities in plants, particularly in some commonly consumed fruits and vegetables. For instance, MYR, has been reported to be abundant in strawberries, apples, spinach, aloe vera, carrots (Zhang et al., 2015), mulberries (Mahmood et al., 2012), etc., and the content of MYR in red wine can reach twice that of resveratrol (Lee et al., 2007; Rodrigo et al., 2011). Dihydromyricetin is widely found in grapes, bayberry, ampelopsis (Clementi et al., 2015), ginkgo and other plants, with the content of DMY in rattan tea particularly is high, often reaching 30–40% (Liu et al., 2019). Moreover, MYR is listed as a health product in Europe, and has been approved by the FDA for pharmaceuticals, foods, and health products in the United States with FYI, a health product containing myricetin being successfully launched (Whitehouse, 2002). Meanwhile, MYR and DMY are the essential ingredients in

many health foods or drinks (Semwal et al., 2016; Martínez-Coria et al., 2019) and are known to have an excellent safety profile coupled with the fact that is suitable for human consumption.

Being one of the more well-studied polyphenols, MYR and DMY exhibit a range of interesting biological activities. MYR has been shown to have anti-cancer, anti-oxidant and anti-inflammatory effects (Kang et al., 2011; Zhang et al., 2011). DMY has shown to have better pharmacological effects than MYR, with its anti-temulence (Shen et al., 2012) ability and hepatoprotective qualities being well known (Murakami et al., 2004). Interestingly, both MYR and DMY have been found to exhibit anti-AD effects. Moreover, many MYR and DMY containing foods are also reported to have some neuroprotective abilities. Ginkgo and its extracts have long been considered to have a good effect on the treatment of AD (Bader et al., 2018; Li et al., 2018). Aloe vera and mulberry are often considered to have additional anti-dementia effects (Clementi et al., 2015; Liu and Du, 2020). Furthermore, moderate consumption of red wine is also often considered to have anti-aging and antioxidant effects as well as improving blood pressure.

## THE MOLECULAR MECHANISMS OF MYR AND DMY IN THE ALLEVIATION OF HALLMARKS OF ALZHEIMER'S DISEASE

Studies have shown that MYR and DMY can significantly improve the learning and memory abilities of animal model of Alzheimer's disease (Hirohata et al., 2007; Liang et al., 2014). In this section, we explore the underlying molecular mechanisms and potential mode of action of MYR and DMY against the symptoms of AD.

### MYR and DMY Interact With A $\beta$ to Exert Anti-AD Effects

A $\beta$  is a hydrolysate of the amyloid protein precursor (APP) (Thinakaran and Koo, 2008). APP has two main metabolic pathways: one is the continuous hydrolysis by  $\beta$ -secretase (BACE-1) and  $\gamma$ -secretase to produce A $\beta$ . In this process, BACE-1 is a key rate-limiting enzyme (Naushad et al., 2019), which is unsurprisingly a potential target for the treatment of AD. The other is the formation of harmless sAPP $\alpha$  and C83 after hydrolysis by  $\alpha$ -secretase. Typically, the formation and hydrolysis of A $\beta$  is in dynamic equilibrium. When this dynamic equilibrium is broken, the excessive production and abnormal deposition of A $\beta$  in the brain has been linked to the initiation and progression of AD. It is reported that MYR inhibits the activity of BACE-1 and hinders the production of A $\beta$  (Shimmyo et al., 2008). Inside the active center of BACE-1, the hydroxyl group at the C7 position of the A ring in the MYR structure binds to the aspartate dyad (Asp32 and Asp228) through hydrogen bonding (Chakraborty et al., 2011). Thus, MYR inhibits the activity of BACE-1 to digest APP and thus reduces the production of A $\beta$ . Additionally, MYR has been shown to have increased the level of  $\alpha$ -secretase (Shimmyo et al., 2008) which results in an increase in the levels of APP broken down to harmless APP fragments.

**FIGURE 1 |** The structures of MYR and DMY. MYR is a flavonol compound, and DMY belongs to dihydroflavonol. DMY is a derivative after introducing “H” to MYR’s 2, 3 binding sites, respectively.

This causes an overall decrease in the levels of APP that can be used to produce A $\beta$ , thereby indirectly reducing A $\beta$  production. Furthermore, studies also showed that DMY can increase the expression of neprilysin (NEP) (Feng et al., 2018). NEP is a M13 zinc metalloproteinase family protein that can cleave A $\beta$  peptide bonds to decompose A $\beta$  (Kanemitsu et al., 2003; Hersh and Rodgers, 2008). The upregulation of NEP by DMY accelerates the decomposition of A $\beta$  and results in the improvement of AD symptoms (Figure 2).

Secondly, A $\beta$  monomer has a neurotrophic effect, but the oligomers and fibrils of A $\beta$  have severe neurotoxicity (mainly including inflammation, oxidative stress, and destruction of cell membranes) (Jang et al., 2007; Umeda et al., 2011; Zhai et al., 2012). The oligomers and fibrils of A $\beta$  are generated by excess A $\beta$  through  $\beta$ -sheet (Jang et al., 2007) and MYR and DMY can inhibit the formation of this  $\beta$ -sheet (Shimmyo et al., 2008; Jia et al., 2019). The hydroxyl group of MYR forms a hydrogen bond with a carbonyl group and amino group in A $\beta$  (Andarzi Gargari et al., 2018). Secondary structure analysis showed that this interaction between MYR and A $\beta$  could inhibit the  $\beta$ -sheet formation of A $\beta$ , which can prevent A $\beta$  undergoing toxic changes (Andarzi Gargari et al., 2018). Moreover, MYR can also bind with two further sites in A $\beta$  fibrils and inhibit the extension of A $\beta$  (Hirohata et al., 2007; Andarzi Gargari et al., 2018). DMY can combine with the three sites on the A $\beta$  structure to block its molecular conformation and break its intramolecular hydrogen bonds. This not only blocks the  $\beta$ -sheet but also has a dismantling effect on the already formed A $\beta$  fibrils (Jia et al., 2019). Thus, MYR and DMY can hinder the formation of A $\beta$  oligomers, which will reduce the neurotoxicity of A $\beta$  oligomers, and release the symptoms of AD (Figure 2).

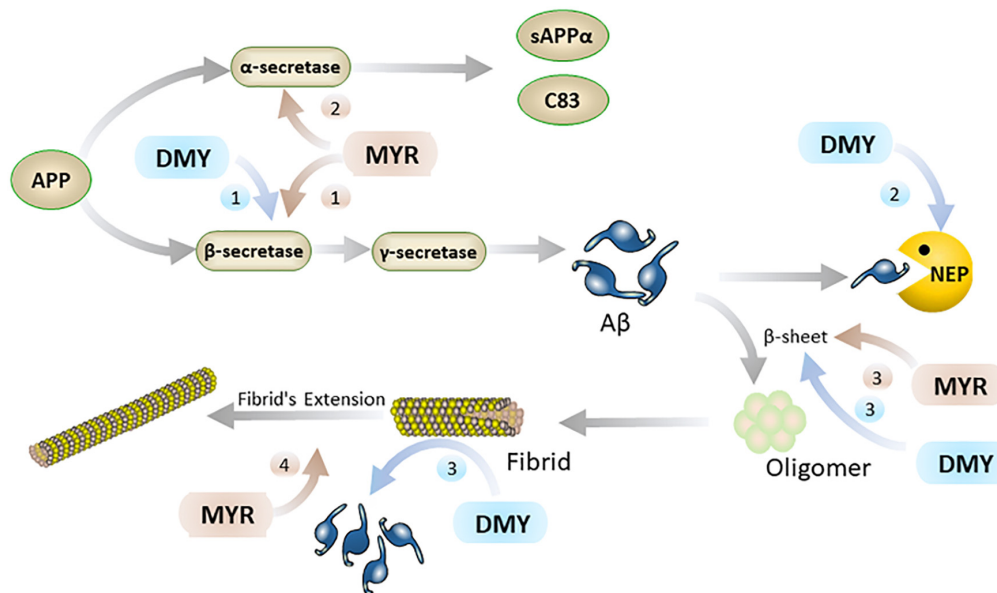

## MYR and DMY Show Anti-AD Effects Through Anti-inflammatory

Recent research has shown that inflammation is also one of the main causes of AD, although neuroinflammation is usually treated as the result of AD’s pathogenesis (Meraz-Ríos et al., 2013). Interestingly, MYR and DMY can directly reduce the levels of inflammatory factors, inhibit microglia activation, and

inhibit NLRP3 (nucleotide-binding oligomerization domain-like receptor protein 3) inflammasome (Figure 3). Eventually, these anti-inflammatory effects of MYR and DMY can help to reduce the symptoms of AD.

Firstly, MYR and DMY can effectively reduce the levels of inflammatory factors such as IL, TNF- $\alpha$ , NF- $\kappa$ B, etc (Jing and Li, 2019). Taking IL-1 as an example, it can not only damage nerve cells but also increase the level of APP to increase the production and accumulation of A $\beta$  (Shadfar et al., 2015). IL-1 can also accelerate the phosphorylation of tau peptide in the brain and further form neurofibrillary tangles (NFTs), and NFTs are another major pathological marker of AD besides A $\beta$  (Shadfar et al., 2015). In addition, IL-1 can also increase the level of other inflammatory factors (such as TNF- $\alpha$ ) to further aggravate the inflammatory response and cell damage caused by it (Shadfar et al., 2015). The anti-inflammatory effects of MYR and DMY are mainly to reduce the levels of IL, TNF- $\alpha$ , iNOS, COX-2, and other inflammatory factors in the brain by interfering with the NF- $\kappa$ B signaling pathway and alleviate the damage of these inflammatory factors to the nervous system (Jing and Li, 2019). It is also reported that DMY can inhibit neuronal inflammation in AD rats by activating the AMPK/SIRT1 pathway (Sun et al., 2019). It is through interfering with this signaling pathway, that DMY can exert its anti-inflammatory ability while inhibiting the apoptosis of hippocampal nerve cells. This is key to treating AD, as the hippocampus of the brain regarded as the main area which of the brain that controls memory.

Secondly, microglia are the smallest glial cells in the central nervous system. Under normal conditions, microglial cells have beneficial nutritional and immunological effects, but activated microglial cells play an essential role in the development of neuroinflammation in AD patients’ brains (Browne et al., 2013). Activated microglial cells have two types: M1 and M2. M1 can promote the development of inflammation, while M2 can inhibit the development of inflammation (Sondag et al., 2009). For microglia, DMY not only inhibits its activation (Jang et al., 2007) but also has an excellent inhibitory effect on the neuroinflammation caused by activated microglia (Weng et al., 2017). Specifically, DMY can

**FIGURE 2 |** MYR interacts with A $\beta$  through the following 4 pathways (brown): 1. MYR reduces the production of A $\beta$  through inhibition of  $\beta$ -secretase 1; 2. by increasing the level of  $\alpha$ -secretase and competitively decomposing APP; 3. inhibiting the  $\beta$ -sheet by binding to A $\beta$ , and preventing the conversion of A $\beta$  monomers into oligomers and fibrils; 4. Inhibiting the extension of the fibrils of A $\beta$  by binding to it. DMY mainly suppresses A $\beta$  in the brain through the following 3 paths (blue): 1. reduce A $\beta$  production by inhibition  $\beta$ -secretase 1; 2. increasing the level of NEP by promoting the expression of NEP gene; 3. inhibiting  $\beta$ -sheet and disassembling A $\beta$  fibrils by binding to A $\beta$ .

inhibit the transformation of microglia to M1 and promote its transformation to M2 (Jang et al., 2007). By reducing the level of M1, the inflammatory response is reduced; meanwhile, increasing the level of M2 can further reduce the damage caused by neuroinflammation by exerting its anti-inflammatory ability.

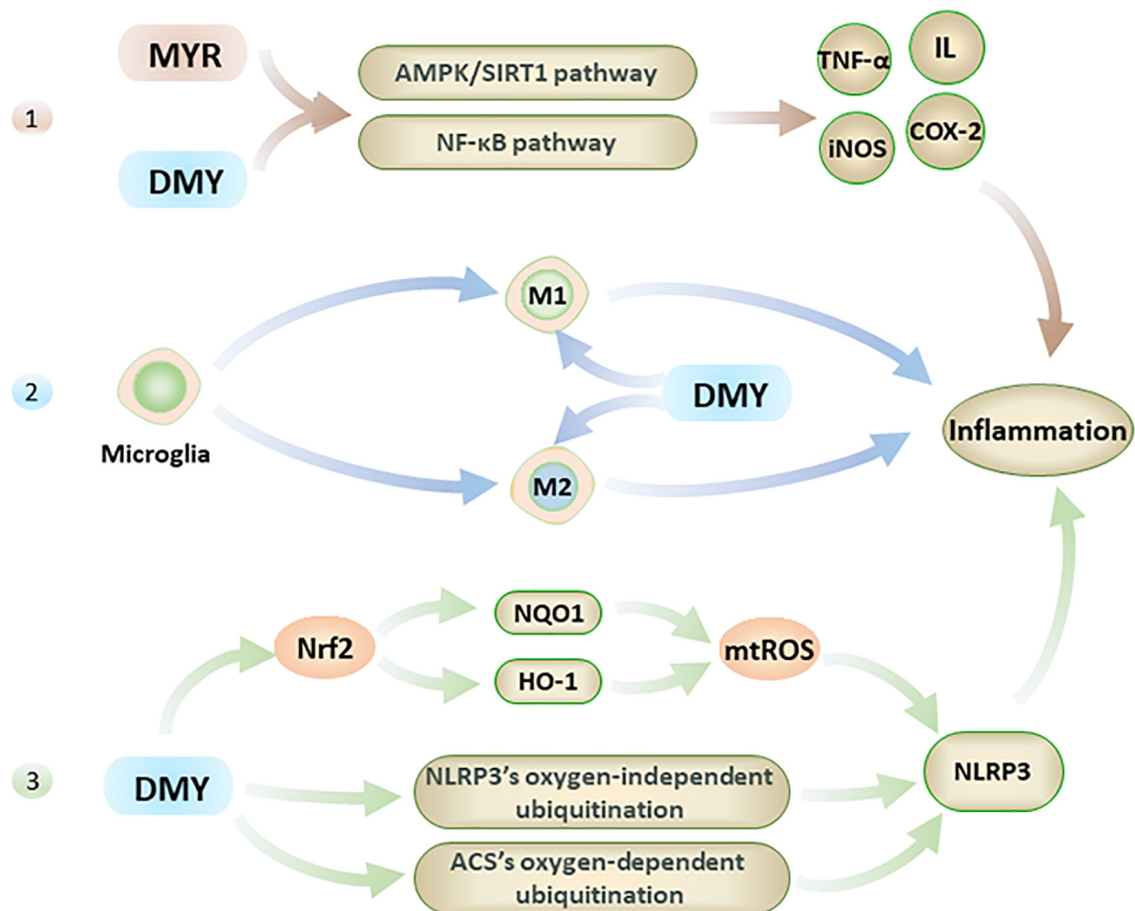

Lastly, in the pathological process of AD, NLRP3 in the central nervous system can be activated by A $\beta$  and aggravate symptoms of AD (Heneka et al., 2013). Studies have confirmed that A $\beta$  levels can be effectively reduced by inhibiting NLRP3 or knocking out related genes, and the impairment of spatial memory ability of mice with Alzheimer's disease also can be alleviated in this way (Heneka et al., 2013; Tan et al., 2013). At present, the NLRP3 in the central nervous system is considered an effective target for AD's treatment (Saresella et al., 2016). DMY can inhibit the expression and activation of NLRP3 (Jang et al., 2007) with DMY increasing the levels of HO-1 and NQO1 by activating Nrf2, which in turn reduces the level of mtROS which leads to the activation of NLRP3 being inhibited (Hu et al., 2018). Furthermore, MYR also can inhibit NLRP3 activation by inhibiting ACS's oxygen-dependent ubiquitination and promoting oxygen-independent ubiquitination of NLRP3 (Chen et al., 2019). The inhibitory effect of MYR and DMY on the NLRP3 can help reduce neuroinflammatory damage in the brain of AD patients and reduce the level of A $\beta$  to a certain extent.

## MYR and DMY Exert an Anti-AD Effect Through Antioxidant

Oxidative stress reflects an imbalance between the excessive production and incorporation of free radicals and the dynamic

ability of a biosystems to detoxify reactive intermediates (Jiang et al., 2016). It is one of the direct causes of aging and a known cause of AD (Jiang et al., 2016). The brain has high oxygen consumption and low antioxidant capacity, which makes it particularly vulnerable to oxidative stress (Guo et al., 2019). Free radicals and ROS are the two main pathways used by oxidative stress to directly damage nerve cells. The free radical contains unpaired electrons, making it in an extremely unstable and highly reactive toward neighboring molecules. This will cause the neighboring molecules to become a new free radical, which in turn reacts with neighboring molecules to produce a free radical chain reaction, causing severe oxidative damage to the brain.

As flavonoids, the pyrogallol structure in the B ring of both MYR and DMY is key to their antioxidant effect (Mendes et al., 2015). They can combine with radicals to form stable semiquinone radicals, thus interrupting the radical chain reaction (Zhang and Chen, 2000). *In vitro* experiments have shown that very low concentrations (0.1, 0.2  $\mu\text{mol/L}$ ) of MYR can effectively inhibit the generation of ROS and protect cells from damage caused by oxidative stress (Barzegar, 2016). When the concentration of MYR reaches 5  $\mu\text{g/mL}$ , it can achieve 50% clearance of ROS and 20% clearance of DPPH (1,1-diphenyl-2-picrylhydrazyl) radicals; when the concentration of MYR reaches 10  $\mu\text{g/mL}$ , it restores the levels and activities of antioxidant substances such as SOD, CAT, and GSH-Px in cells (Wang et al., 2010). Additionally, research has shown that in the  $\text{H}_2\text{O}_2$ -induced cell injury model, MYR can inhibit DNA and lipid damage caused by oxidative stress while regulating the PI3K/Akt and MAPK signaling pathways. This leads to an increase in the levels of anti-apoptotic factors such as Bcl-2 and reduction

**FIGURE 3 |** The anti-inflammatory effects of MYR and DMY occur through the following 3 pathways. 1. Through the NF- $\kappa$ B and AMPK/SIRT1 pathway 2. Regulation of microglia, through reduction in M1 levels and increasing M2 level. 3. Activation of Nrf2 to reduce mtROS, and interfere with the ubiquitination process to suppress NLRP3 inflammasome.

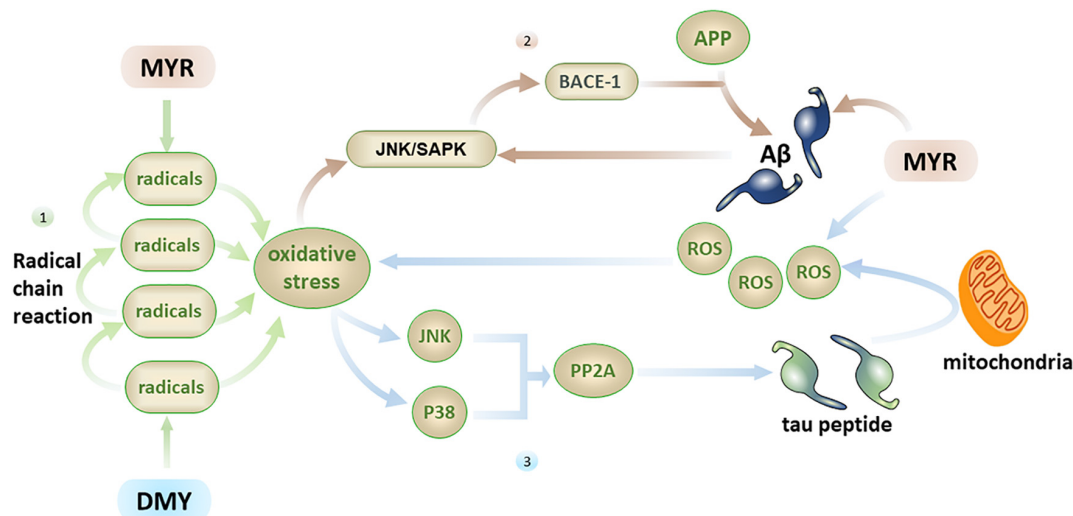

of pro-apoptotic factors like Bax, caspase-9, and caspase-3, ultimately leading to inhibition of apoptosis induced by oxidative stress (Wang et al., 2010; Li et al., 2016). DMY also has a very good free radical scavenging ability. The difference from MYR mainly lies in the fact that MYR has a better ability to clear ABTS [2, 2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid)] while DMY is better at clearing DPPH (Kang et al., 2010).

In addition to direct brain damage, oxidative stress is closely associated with multiple factors related to AD. (1) A $\beta$  has the ability to induce oxidative stress (Butterfield et al., 2010), and oxidative stress can also promote the production of A $\beta$  (Praticò et al., 2001). MYR can inhibit the free radical chain reaction from the source by inhibiting A $\beta$ , thereby reducing the central nervous system damage caused by oxidative stress (Shimmyo et al., 2008). (2) Oxidative stress can activate the JNK/SAPK pathway and subsequently cause elevated BACE-1 levels. Further, BACE-1 will break down the APP into A $\beta$ , which leads to elevated A $\beta$  levels (Tamagno et al., 2005), while an increase in A $\beta$  can further activate the JNK/SAPK pathway (Figure 4) and cause a vicious cycle. Oxidative stress can also promote the phosphorylation of tau peptide by inhibiting PP2A (Praticò et al., 2001; Su et al., 2010;

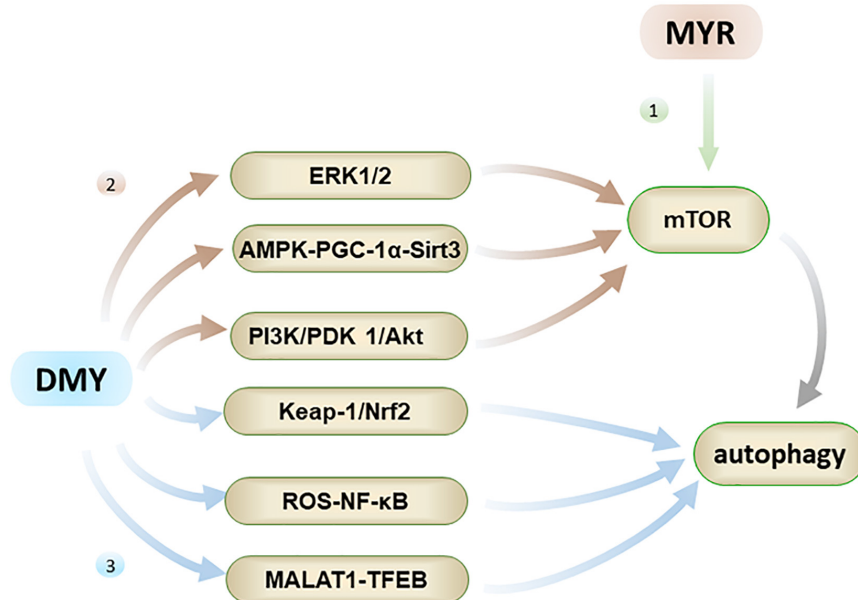

Tang et al., 2017), and oligomers of tau peptide can aggravate oxidative stress by destroying mitochondria (Lasagna-Reeves et al., 2011; Figure 4). MYR and DMY can, therefore, protect neuronal cells through their antioxidant abilities.

### MYR and DMY Play an Anti-AD Role by Regulating Autophagy

Autophagy is the process by which cells eliminate abnormal organelles or denatured protein through lysosomes. For nerve cells, it is difficult to dilute toxins through cell division, so autophagy is a particularly vital process for nerve cells. At the beginning of the autophagy process, the endoplasmic reticulum in the cell sheds part of the biofilm and forms autophagic vesicles (AVs). These AVs encapsulate harmful protein such as A $\beta$  and abnormally phosphorylated tau peptide to form autophagosomes. Subsequently, the autophagosomes are transported along the microtubules by the dynein to the lysosome resulting in harmful protein being degraded by the lysosome (Li et al., 2019; Figure 5). Moreover, recent studies have revealed that the mTOR (mammalian targets of rapamycin) is a crucial signaling factor

**FIGURE 4 |** Firstly, the free radical chain reaction can cause severe oxidative stress damage, with MYR and DMY inhibiting this process by scavenging free radicals; secondly, oxidative stress can increase the level of A $\beta$  by activating the JNK/SAPK pathway, and A $\beta$  can further activate this pathway, MYR's antioxidant and anti-A $\beta$  abilities can disrupt this vicious circle; thirdly, oxidative stress can promote the phosphorylation of tau peptide by inhibiting PP2A, and tau peptide oligomers can increase oxidative stress by destroying mitochondria, the ability of MYR to clear ROS can prevent the increase of oxidative stress.

**FIGURE 5 |** Autophagy has the effect of inhibiting AD. Firstly, MYR can promote autophagy by inhibiting phosphorylation of mTOR; Secondly, DMY can inhibit mTOR through ERK1/2 pathway, AMPK-PGC-1 $\alpha$ -Sirt3 pathway, and PI3K/PDK 1/Akt pathway, ultimately promote autophagy; Thirdly, DMY can also promote autophagy through the Keap-1/Nrf2, ROS-NF- $\kappa$ B and MALAT1-TFEB pathways.

that regulates cell proliferation, growth, and apoptosis, and it is the core cytokine that regulates cell autophagy.

Both MYR and DMY have an effect on regulating autophagy, which aids in the elimination of abnormal A $\beta$  and tau peptide produced in cells. MYR regulates autophagy mainly through the mTOR pathway by inhibiting mTOR's phosphorylation (Cao et al., 2018). It has been observed to dose-dependently increase

the level of autophagy marker LC3-II and induce formation of autophagosomes (Cao et al., 2018). Through the formation of a large number of autophagosomes, the clearance of A $\beta$  and abnormally phosphorylated tau peptide in the cells is accelerated, thereby alleviating the symptoms of AD (Díaz-Villanueva et al., 2015; Cao et al., 2018). On the other hand, DMY can promote autophagy by inhibiting mTOR, and again

this effect is dose-dependent. The regulation of autophagy by DMY is a comprehensive and complicated process, which involves the upstream pathway of mTOR including ERK1/2 (extracellular signal-regulated kinase 1/2), AMPK-PGC-1 $\alpha$ -Sirt3 (AMP-activated kinase-peroxisome proliferator-activated receptor coactivator-1 $\alpha$ -Sirt3) and PI3K/PDK 1/Akt (class III phosphatidylinositol 3-kinase/phosphoinositide-dependent protein kinase 1/protein kinase B) pathways (Xia et al., 2014; Shi et al., 2015). Furthermore, the regulation of autophagy by DMY also involves the Keap-1/Nrf2, ROS-NF- $\kappa$ B, and MALAT1-TFEB pathways (Qiu et al., 2017; Zhou et al., 2017; Tan et al., 2019). In short, DMY can affect the levels of A $\beta$  and tau peptide in the nervous system through multiple effects on autophagy, and thus has a therapeutic effect on AD.

### MYR and DMY Play an Anti-AD Role by Complexing Metal Ions in the Brain

The imbalance of metal ions in the brain can cause cytotoxicity, oxidative stress damage, abnormal deposition of A $\beta$ , and abnormal phosphorylation of tau peptide, which are closely related to AD. Initially, research conducted regarding AD-related metals generally focused on calcium ions, however, in recent years, an increasing number metal ions (such as copper, iron, and zinc) have been associated with the generation and development of AD (Bush, 2013). Studies have shown that there are many binding sites within A $\beta$  that can bind metal ions (Tian et al., 2018), and there is a notable increase in toxicity of A $\beta$  when this complexation occurs. For example, Zn<sup>2+</sup> has four binding sites on the structure of A $\beta$ , so even in micromolar concentrations, they can increase the aggregation of A $\beta$  (Boom et al., 2009). Additionally, Zn<sup>2+</sup> can change A $\beta$ 's structure after binding to A $\beta$  and promote the amyloidosis of A $\beta$  (Guo et al., 2017). Cu<sup>2+</sup> is also able to bind A $\beta$  and promote its accumulation and precipitation (Cristóvão et al., 2016). This effect is generally related to the relative levels of Cu<sup>2+</sup>/Zn<sup>2+</sup> and A $\beta$  content (Cristóvão et al., 2016).

As flavonoids, both MYR and DMY have an excellent ability to chelate metal ions (Xu, 2010; Jomová et al., 2019), which can inhibit AD by regulating the concentration of metal ions in the brain. The chelating sites with metal ions of MYR and DMY are shown in **Figure 6**. It is worth noting that the chelation products have better pharmacological effects (such as antioxidant and anti-inflammatory) than uncomplexed MYR or DMY (Li et al., 2016). MYR has been proven that it could inhibit A $\beta$  aggregation by chelating with Cu<sup>2+</sup> or Zn<sup>2+</sup> (DeToma et al., 2011). MYR can regulate the level of metal ions in the brain by complexing with metal ions, and this will reduce the chance of A $\beta$  to combine with metal ions. Moreover, MYR can not only prevent A $\beta$  from binding with metal ions but also disassemble the complexes of Cu<sup>2+</sup>/Zn<sup>2+</sup>-A $\beta$  that have been formed and plunder the metal ions (DeToma et al., 2011). Besides affecting the aggregation of A $\beta$ , Zn<sup>2+</sup> can also affect the production of A $\beta$ . It can increase the levels of  $\beta$ -secretase and  $\gamma$ -secretase by inhibiting the activity of  $\alpha$ -secretase, thereby increasing the level of A $\beta$  in the brain (Garai et al., 2006). This shows that the complexation of MYR and Zn<sup>2+</sup> can also reduce the level of A $\beta$  by suppressing this phenomenon.

Furthermore, and similar to other divalent ions, Fe<sup>2+</sup> can bind A $\beta$  and induce the formation of oligomers and fibrils (Boopathi and Kolandaivel, 2016; Lane et al., 2018). Concurrent to this, is the Fenton process (Simunkova et al., 2019), that acts to convert H<sub>2</sub>O<sub>2</sub> into highly toxic hydroxyl radicals and ROS (Wang T. et al., 2019), and Fe<sup>2+</sup> serves as a catalyst in this process. As is known these hydroxyl radicals and ROS can cause severe oxidative damage to the central nervous system, and the presence of Fe<sup>2+</sup> in the central nervous system can dramatically increase this damage. Upon complexation of Fe<sup>2+</sup> by MYR and DMY, the levels of free Fe<sup>2+</sup> drops, which results in a reduction in the Fenton reaction. This eventually leads to an overall reduction in oxidative stress damage in the central nervous system. Additionally, Fe<sup>2+</sup> can also lead to the activation of microglia, which again results in the damage to the nervous system caused by inflammation (Peters et al., 2018). Complexation of Fe<sup>2+</sup> by MYR and DMY can therefore reduce the risk of this inflammation occurring. Further to this, MYR can also regulate cell to metal ion transport. Wang et al. claimed that MYR could reduce iron levels by inhibiting the expression of transferrin receptor 1 (TrR1) (Wang et al., 2017). This is another way for MYR to adjust the level of metal ions in addition to directly chelating iron ions.

### MYR and DMY Play an Anti-AD Role by Regulating Insulin Signaling Pathways and Intestinal Flora

Insulin signaling pathway damage in the central nervous system can induce AD (Griffin et al., 2005), with AD being called type 3 diabetes. Insulin resistance will cause the levels of  $\beta$ -secretase and  $\gamma$ -secretase to rise, and increase the rate of A $\beta$  generation. Insulin resistance also causes the body to resort to a state of high insulin levels, which in turn causes the body to overexpress insulin degrading enzymes (IDE) which are designed to break down excess insulin. In addition to degrading insulin, IDE also degrades A $\beta$ . Too much insulin will compete with A $\beta$  for the opportunity of being degraded by IDE, resulting in the accumulation of A $\beta$  due to a lack of effective degradation (Dineley et al., 2014). Both MYR and DMY have been shown to effectively inhibit insulin resistance. PTP1 $\beta$  is a protein that negatively regulates the insulin signaling pathway (Lalitha et al., 2020) and can cause insulin resistance. A recent study showed that MYR has a good inhibitory effect on PTP1 $\beta$  (Lalitha et al., 2020). *In vivo* experiments have also shown that the treatment of MYR also increases the body's sensitivity to insulin by increasing the levels of pIR (phospho-insulin receptor), pIRS1 (phospho-insulin receptor substrate 1) and pAkt (phospho-Akt), thereby increasing the body's sensitivity to insulin. DMY can treat the dysregulation of insulin signaling pathway by inhibiting the phosphorylation of PPAR $\gamma$  Ser273 and regulating the ERK/CDK5 signaling pathway (Liu, 2017). Further studies have shown that DMY's ability to regulate intestinal flora also helps to improve insulin resistance (Tong, 2018) with the successful launch of GV971 in China proving the feasibility of treating AD with intestinal flora. Regulation of insulin resistance or other pathological processes in AD patients through intestinal flora may also be potential anti-AD targets of MYR and DMY.

**FIGURE 6 |** Sites that can complex metal ions in the structure of MYR and DMY. There are four main sites (location of M in the figure) that can be used to chelate metal ions in the structure of MYR since the double bond at the 2–3 position becomes a single bond. DMY is one less than MYR, which can be used to couple metal ions.

## MYR and DMY Play an Anti-AD Role by Inhibiting AChE

Acetylcholine is a neurotransmitter that plays an important role in the transmission of neural signals and memory formation and the lack of ACh in the central nervous system is a known cause of AD (Guo et al., 2019). AChE has been a major target for drug discovery in recent years with three of the current five AD clinical drugs being AChE inhibitors. Interestingly, both MYR and DMY have been shown to effectively inhibit AChE (Pepeu and Giovannini, 2004; Wang et al., 2017). In the mouse model of Alzheimer's disease induced by scopolamine, MYR effectively reduced the impairment of learning and memory ability of mice through its AChE inhibitory ability (Kou et al., 2016). The structural characteristics of DMY lead to stronger anti-AChE activity than MYR (Zhao et al., 2012) and exhibits similar inhibitory data when compared to clinical drugs (Tacrine) (Pepeu and Giovannini, 2004), with the added benefit that DMY, as a food materials, has a better safety profile. In addition to AChE, some inflammatory factors also affect the level of ACh, such as IL-1. IL-1 can improve the level of AChE and accelerate the decomposition of ACh (Shadfar et al., 2015), resulting in insufficient ACh content in the brain and affecting memory ability. The anti-inflammatory ability of MYR and DMY can also prevent the loss of ACh.

## MYR and DMY Play an Anti-AD Role by Inhibiting Bacteria and Viruses

Bacteria and viruses also can induce AD, with both *Porphyromonas gingivalis* and *Herpes simplex virus* (HSV) having confirmed links with AD initiation and progression (Bearer and Wu, 2019; Dominy et al., 2019). Gingipains, produced by *Porphyromonas gingivalis*, is a toxic protease related to the phosphorylation of tau peptide and the ubiquitin pathology which can also increase the level of A $\beta$ <sub>42</sub> in the brain (Bearer and Wu, 2019; Dominy et al., 2019). According to the results reported by Grenier et al., 62.5 to 125  $\mu$ g/ml of MYR

had good inhibitory effect on *Porphyromonas gingivalis*, and this effect may be related to MYR's ability to chelate iron ions (Grenier et al., 2015). Additionally, MYR can also inhibit the expression of protease and adhesin in *Porphyromonas gingivalis* to reduce the toxic effects of *Porphyromonas gingivalis* (Grenier et al., 2015). Furthermore, MYR also inhibits the inflammatory response caused by *Porphyromonas gingivalis* through activation of NF- $\kappa$ B (Grenier et al., 2015), which can play a role in the adjuvant treatment of AD. Some research data shows that patients with long-term infection with HSV have a higher risk of AD than those patients free of HSV infection. The reason may be that HSV can cause A $\beta$  accumulation and the phosphorylation of tau peptide, which then induces AD. Importantly, HSV was also found in the brain areas seriously affected by AD, which substantiates the above hypothesis (Mangold and Szpara, 2019). The inhibitory effect of MYR on HSV (Lyu et al., 2005) will help patients reduce the risk of AD and help control the status of A $\beta$  and tau peptide.

## Other

MiR (microRNA) is a small-molecule RNA, 21–23 nucleotides in length, which can regulate gene expression. Recent reports showed that overexpression of miR-34a could cause the accumulation of A $\beta$  and the hyperphosphorylation of tau peptide, and eventually lead to AD (Sarkar et al., 2019). Studies have shown that in the brain of Alzheimer's disease model rats induced by D-gal, DMY can regulate the SIRT1-mTOR signaling pathway by inhibiting miR-34a, and ultimately inhibit D-gal-induced hippocampal neuronal cell damage (Kou et al., 2016).

## Prospects

Alzheimer's disease is a disease-induced and promoted by a variety of factors. Due to the interaction of multiple reasons, unilateral treatment of AD will be challenging to achieve. As detailed in this review, we know that MYR and DMY can inhibit the excessive production and accumulation of A $\beta$ , inhibit the inflammatory response in the central nervous system, chelate

metal ions in the nervous system, regulate autophagy, and inhibit oxidative stress. At the same time, they can also increase ACh levels by inhibiting the activity of AChE, inhibiting the overexpression of miR-34a, reducing the promotion of AD by bacteria and viruses, and alleviating the state of insulin resistance in the central nervous system. They can even regulate the balance of the intestinal flora, which is also a good target for intervention in AD. These combined anti-AD effects also work to improve the symptoms in AD patients. For example, no studies have been shown that MYR and DMY can directly inhibit tau peptide hyperphosphorylation. However, MYR and DMY can also affect tau peptide and NFTs by regulating autophagy, inhibiting oxidative stress, and improving insulin resistance.

Health products and healthy diets are well accepted to regulate human health and prevent diseases. MYR and DMY have better toxicity profiles and exist in a variety of foods. FYT's approval by the FDA also shows the feasibility of using MYR and DMY for

health products. Therefore, we believe that the uptake of MYR and DMY in daily diets to develop health products or foods with the ability to prevent and improve AD has great potential.

## AUTHOR CONTRIBUTIONS

All the authors listed have made some contributions to the manuscript and approved for publication.

## FUNDING

This review was funded by the Shandong Provincial Natural Science Foundation, China (Grant No. ZR2019MH078); The Drug Innovation Major Project (Grant No. 2017ZX09301030); and Project for development of TCM science and technology in Shandong Province (Grant No. 2019-0031).

The objectives of this study were to compare the topographical subcortical shape and to investigate the effects of tau or amyloid burden on atrophic patterns in early onset Alzheimer's disease (EOAD) and late-onset Alzheimer's disease (LOAD). One hundred and sixty-one participants (53 EOAD, 44 LOAD, 33 young controls, and 31 older controls) underwent [18F]THK5351 positron emission tomography (PET), [18F]flutemetamol (FLUTE) PET, and 3T MRI scans. We used surface-based analysis to evaluate subcortical structural shape, permutation-based statistics for group comparisons, and Spearman's correlations to determine associations with THK, FLUTE, cortical thickness, and neuropsychological test results. When compared to their age-matched controls, EOAD patients exhibited shape reduction in the bilateral amygdala, hippocampus, caudate, and putamen, while in LOAD patients, the bilateral amygdala and hippocampus showed decreased shapes. In EOAD, widespread subcortical shrinkage, with less association of the hippocampus, correlated with THK retention and cortical thinning, while in LOAD patients, subcortical structures were limited which had significant correlation with THK or mean cortical thickness. Subcortical structural shape showed less correlation with FLUTE global retention in both EOAD and LOAD. Multiple cognitive domains, except memory function, correlated with the bilateral amygdala, caudate, and putamen in EOAD patients, while more restricted regions in the subcortical structures were correlated with neuropsychological test results in LOAD patients. Subcortical structures were associated with AD hallmarks in EOAD. However, the correlation was limited in LOAD. Moreover, relationship between subcortical structural atrophy and cognitive decline were quite different between EOAD and LOAD. These findings suggest that the effects of Alzheimer's pathologies on subcortical structural changes in EOAD and LOAD and they may have different courses of pathomechanism.

**Keywords:** Alzheimer's disease, subcortical shape analysis, tau, amyloid, cortical thickness, positron emission tomography, magnetic resonance imaging

## INTRODUCTION

Alzheimer's disease (AD) is a neurodegenerative disease associated with cognitive decline. Accumulations of neurofibrillary tangles and beta-amyloid ( $A\beta$ ) are the two pathologic hallmarks of AD, as well as structural changes in the brain cortices (Jack et al., 2016). Early onset AD (EOAD) is characterized by onset before 65 years of age and accounts for 10–15% of all cases (Panegyres and Chen, 2014; Wattmo and Wallin, 2017). Studies have found that EOAD patients have typical neuropsychological features with more progressive cognitive decline (Seltzer and Sherwin, 1983; Smits et al., 2012) as well as heterogeneous neuroimaging findings (Frisoni et al., 2007; Migliaccio et al., 2015).

Compared with LOAD patients, EOAD patients manifest with more widespread tau PET retention and heavier amyloid PET uptake in the brain cortices, and more severe gray matter loss suggesting different etiologies and predisposing factors for EOAD (Frisoni et al., 2007; Choo et al., 2011; Scholl et al., 2017; Wattmo and Wallin, 2017). Like gray matter change, more rapid volumetric declines in several subcortical structures including the caudate, putamen, and thalamus have been highlighted as distinct to LOAD patients (Cho et al., 2013; Pievani et al., 2013). It has also been reported that characteristic symptoms of EOAD such as severe extrapyramidal signs (Chui et al., 1985) and non-memory cognitive dysfunction such as executive function, visuospatial functioning, and attention (Smits et al., 2012) are related to deterioration of the basal ganglia and the thalamus, both of which play major roles in movement symptoms, brain connectivity, and memory function (Hahn et al., 2016; Dipasquale and Cercignani, 2017).

Although there have been previous investigations into the association between tau,  $A\beta$ , and atrophy in brain cortices, little is known of the relationship between the well-known AD biomarkers and subcortical structures. Unraveling the effect of tau,  $A\beta$ , and atrophy in the subcortical structures may contribute to a better understanding of the pathological mechanisms of AD and the different developmental paths of EOAD and LOAD. We sought to compare topographical changes in the subcortical structures in EOAD and LOAD patients and investigated their association with cortical tau and amyloid global retention, as well as cognitive functions.

## MATERIALS AND METHODS

### Participants

Ninety-one participants who had been clinically diagnosed with AD dementia (EOAD;  $n = 55$ , LOAD;  $n = 46$ ) and 66 cognitively normal (CN) participants were prospectively recruited. All participants underwent [ $^{18}\text{F}$ ]THK5351 PET scans, [ $^{18}\text{F}$ ]flutemetamol (FLUTE) PET scans, and 3.0-Tesla MRI scans at Gachon University Gil Medical Center, from October 2015 to June 2017. Of the 167 participants, 2 patients diagnosed with AD were excluded due to head motion issues during the [ $^{18}\text{F}$ ]THK5351 PET scan acquisition. An additional four participants (two AD and two CN) were excluded due to

errors with the FreeSurfer software. Thus, data from 161 participants (53 EOAD, 44 LOAD, 33 YC, and 31 OC) were used in the analyses.

All patients with AD dementia met the probable AD criteria as proposed by the National Institute of Neurological and Communicative Disorders and Stroke and the AD and Related Disorders Association (McKhann et al., 1984). Patients with familial AD with autosomal dominant inheritance were excluded. Participants with brain lesions on brain MRI such as intracranial hemorrhage, traumatic brain injury, hydrocephalus, territorial infarction, severe white matter hyperintensity (WMH) or WMH associated with radiation, multiple sclerosis or vasculitis were excluded. Severe WMH was defined as both periventricular WMH as cap or band  $\geq 10$  mm and deep WMH  $\geq 25$  mm using modified Fazekas visual rating scale (Fazekas et al., 1987; Noh et al., 2014). Secondary causes of dementia were ruled out through serum laboratory tests including for thyroid function, metabolic profile, vitamin B<sub>12</sub>, folate, complete blood counts, and syphilis serology. APOE genotyping was also performed. Clinical interviews with a neurologist or psychiatrist and standardized comprehensive neuropsychological tests were undertaken with all participants.

CN participants were either volunteers from the community or spouses of the patients (age range 44–92, female 45.31%). They had no history of neurologic diseases, psychiatric disorders, abnormalities on neurologic examination, structural lesions on brain MRI such as cerebral infarction, intracranial hemorrhage, traumatic brain injury, hydrocephalus, or severe WMH. Control participants had a clinical dementia rating (CDR) score of 0, and normal cognitive function defined as within 1.5 standard deviations of the age- and education-corrected normative mean on detailed neuropsychological tests. Written informed consent was obtained from each participant, and the Institutional Review Boards of Gachon University Gil Medical Center approved this study.

### Image Data Acquisition and Parcellation

3D T1-MPRAGE (Repetition time: 1,900 ms, echo time: 2.93 ms, flip angle: 8°, pixel bandwidth: 170 Hz/pixel, matrix size: 256 × 208, field of view: 256 mm<sup>2</sup> × 208 mm<sup>2</sup>, slice thickness: 1.0 mm, voxel size: 1.0 mm<sup>3</sup> × 1.0 mm<sup>3</sup> × 1.0 mm<sup>3</sup>, NEX: 1, total acquisition time: 4 min 9 s, GRAPPA acceleration factor: 2 along phase-encoding direction) was acquired with a 3.0T MRI (Verio, Siemens with a Siemens matrix coil). Images were analyzed using FreeSurfer 5.1<sup>1</sup> to define regions-of-interest (ROIs) in native-space for each participant and to support a correction of gray matter atrophy and white matter spillover in the PET data. In addition, subcortical region parcellation including the left and right of the amygdala, caudate, hippocampus, pallidum, putamen, and thalamus was also conducted using Desikan-Killiany atlas in MNI 152 space. After subcortical segmentation, each subcortical region on the template surface was sampled as a mesh surface with 2,562 vertices and then transformed into its own original surface. This procedure was conducted for every 12

<sup>1</sup>www.surfer.nmr.mgh.harvard.edu

subcortical regions as detailed in a previous study (Chung et al., 2017; Koo et al., 2017).

The pretreatment process for the PET images proceeded according to the process outlined in a previous study (Kang et al., 2017). [ $^{18}\text{F}$ ]THK5351 was synthesized and radiolabeled at Gachon University Neuroscience Research Institute. All participants underwent a 20-min emission scan beginning 50 min after 185 MBq of [ $^{18}\text{F}$ ]THK5351 was injected intravenously (50–70 min), and a 20-min emission scan 90 min after the intravenous injection of 185 MBq of [ $^{18}\text{F}$ ]FLUTE (90–110 min).

## PET Quantification

The quantification process for the [ $^{18}\text{F}$ ]THK and [ $^{18}\text{F}$ ]FLUTE PET images was conducted using the same methodology outlined in a previous study (Kang et al., 2017). After co-registration of PET images with the corresponding T1 image, region-based partial volume correction was performed. The regional mean values were then calculated and weight-averaged for pre-defined ROIs (Greve et al., 2014, 2016; Kang et al., 2017). Regional standardized uptake value ratios (SUVRs) were calculated using cerebellar gray matter as the reference region for THK images and the pons for FLUTE images (Okamura et al., 2014; Thurfjell et al., 2014; Lockhart et al., 2016). THK5351 global SUVR was calculated based on the AD-related regions including the frontal, parietal, precuneus, occipital, temporal, anterior cingulate, and posterior cingulate, and the cortical composite FLUTE SUVR was calculated based on AD-related regions including the frontal, parietal, lateral temporal, anterior and posterior cingulate cortices (Thurfjell et al., 2014).

## Assessment of Local Shape of Subcortical Structures

To measure the degree of deformation of the subcortical structures, a subcortical mesh was constructed similarly to that described in previous studies (Cho et al., 2011; Chung et al., 2017; Koo et al., 2017). The local shape at every location was then calculated using the surface-based method proposed by Shapira et al. (2008). Weighted sum of the depths at every location was measured in various directions at every location, using the weight as an angle with the normal vector (Chung et al., 2017; Koo et al., 2017). This depth value obtained at 2,562 locations for a single structure reflects local contraction or local shrinkage at that location (i.e., the smaller the value, the more shrinkage caused by atrophy occurred at that position, which expands as the value becomes larger). Therefore, these values were set as the subcortical local shape. This method was undertaken for each of the subcortical regions (amygdala, hippocampus, caudate, pallidum, putamen, and left and right areas of the thalamus).

## Neuropsychological Assessment

All participants underwent the Korean version of the mini-mental state examination (MMSE), CDR, and a detailed neuropsychological function test battery (Kang et al., 2003) including attention, praxis, language, verbal and visual memory, visuospatial function, frontal/executive function, and elements of Gerstmann syndrome. Details of the comprehensive test battery

are described in our previous study (Lee et al., 2018) and all scores were calculated as age- and level of education-matched z-scores.

## Statistical Analysis

A pairwise group comparisons comparing EOAD and LOAD, EOAD and YC, LOAD and OC, YC and OC for subcortical structure shape were performed by permutation tests with 5,000 iterations with ANCOVA. For the comparison between EOAD and LOAD, or between YC and OC, the local shape of the subcortical structures were adjusted for sex, years of education, and intracranial volume (ICV). Additionally, for the comparison between EOAD and YC, or between LOAD and OC, the values for the subcortical local shape were adjusted for age, sex, years of education, and ICV. After the permutation test, the Benjamini-Hochberg false discovery rate was used for region-wise multiple comparison (Benjamini and Hochberg, 1995). A *p*-value threshold (0.05) was applied to extract the regions showing significant differences between two groups. If the size of the statistically significant region was smaller than the specific size, it was regarded as noise and removed.

We calculated Spearman's rank correlation coefficient to identify the relationship between the deformity at every location in the subcortical structures and the three types of neuroimaging findings such as THK5351 SUVR, FLUTE SUVR, and cortical thickness (Han et al., 2013). The vertices with a stronger negative correlation of  $-0.3$  or a stronger positive correlation of  $0.3$  were then selected. The significance level of each vertex was corrected using the Cluster-Based statistics (Han et al., 2013). Through this process we examined the correlation between THK5351 global SUVR, FLUTE global SUVR, mean cortical thickness and the subcortex structures with age, sex, years of education and ICV as covariates separately within EOAD and LOAD groups. In this process, a *p*-value threshold (0.05) was applied to extract the regions with a significant correlation between the subcortical structure and neuroimaging findings. In cases where the size of the statistically significant region was smaller than the specific size, it was regarded as noise and removed.

To compare the effects of tau, amyloid, and mean cortical thickness on subcortical shape deformity, the relative importance for each factor was calculated using general linear model. For the general linear model, age, sex, education and ICV were used as covariates, and the degree of tau global retention, amyloid global retention, and mean cortical thickness were used as predictors, and local shape was encoded as dependent variable. The *r*-squared value of the model was calculated from the predictor combinations in all cases in which a specific predictor was included in the general linear model, and the accumulated value was called relative importance and is shown in the **Supplementary Figure 1**.

Comparisons of the demographic and clinical information were conducted using independent t-test and chi square test followed by Yate's continuity correction for nominal variables. For volumetric analyses, group comparisons were conducted using independent t-test and analysis of covariance. Correlations between volumes of each subcortical structure and other variables such as THK, FLUTE, cortical thickness, and cognitive function were evaluated using Pearson's correlation analysis and general

linear model. Volume data analysis was conducted with PASW Statistics 23 software (SPSS Inc., Chicago, IL, United States) with significance set at  $p < 0.05$  (two-way).

## RESULTS

### Demographics and Clinical Characteristics

**Table 1** shows the demographic information and clinical characteristics of the participants. There were no significant differences in MMSE scores or CDR-SOB between EOAD and LOAD patients. Global retention of THK5351 PET and mean cortical thickness were not different between EOAD and LOAD, however, the EOAD group showed significantly higher amyloid global accumulation than the LOAD group ( $p < 0.001$ ).

### Comparison of Subcortical Structures

**Figure 1** shows the results of group comparisons of the subcortical structural shapes. The EOAD group showed widespread subcortical shape difference in the bilateral amygdala, caudate, hippocampus, putamen, thalamus and the right pallidum relative to YC. The LOAD group showed significant regional shape difference in the bilateral amygdala, hippocampus, and putamen compared to OC. Comparisons of the subcortical structures between the EOAD and LOAD groups showed shrinkage in the bilateral thalamus, left amygdala and left hippocampus in LOAD group.

Volume analysis of the subcortical structures between the groups are presented in **Supplementary Table 1**. EOAD patients showed reduced volume in the bilateral amygdala, hippocampus, caudate, putamen, and the left thalamus compared to YC. LOAD patients showed reduced volumes in the bilateral amygdala and hippocampus compared to OC.

### Correlation Between THK5351, FLUTE, Cortical Thickness, and Subcortical Structures

**Figure 2** shows the correlation between THK global retention, FLUTE global retention, mean cortical thickness, and subcortical shape in the EOAD and LOAD groups. In EOAD patients, as THK global retention increased, subcortical structure showed contraction significantly in the bilateral amygdala, caudate, putamen, hippocampus, left pallidum and the left thalamus. In LOAD patients, as THK global retention increased, subcortical shape decreased in the bilateral caudate, putamen, left pallidum and the left amygdala and hippocampus.

As FLUTE global retention increased, subcortical shape deformity significantly increased in the bilateral hippocampus and the right amygdala and left putamen in EOAD. LOAD patients showed significant subcortical shape deformity in the bilateral putamen, the left amygdala and hippocampus, and the right caudate as FLUTE increased. There was no subcortical structure with positive correlation with THK or FLUTE global retention in EOAD or LOAD patients. Mean cortical thickness was positively associated with subcortical

structure shape in the bilateral amygdala, caudate, putamen, and the left hippocampus in EOAD.

**Supplementary Figure 1** shows association between THK, FLUTE global retention, cortical thickness and subcortical structures, which was analyzed using the general linear model. In EOAD group, similar to the results of our main correlation analyses, tau and mean cortical thickness were found to have great importance in the bilateral caudate and putamen, whereas amyloid showed little importance. On the other hand, in the LOAD patient group, the importance was higher in correlation with tau in both caudate. And mean cortical thickness was found to have importance than other variables in predicting the local shape in the left putamen.

**Supplementary Figure 2** shows the voxel-wise analyses results to evaluate the association between subcortical structural volume and THK or FLUTE global retention. In EOAD, decreased volumes of the amygdala, caudate, putamen had association with THK retention in the nearly whole association cortices. Hippocampal volume was associated with THK retention in the bilateral medial temporal region and the right precuneus and parietal regions in EOAD. The hippocampus was the only region with significant correlation with FLUTE global retention in EOAD. In LOAD patients, no subcortical structural volume showed significant correlation with THK or FLUTE global retention in voxel-wise analyses.

Volumetric correlation between THK global retention, FLUTE global retention, mean cortical thickness, and subcortical structures are presented in **Supplementary Table 2**. In EOAD patients, THK, FLUTE, and cortical thickness correlated with volumes of the subcortical structures except for pallidum. In LOAD patients, no correlation was found between THK, FLUTE, and mean cortical thickness and subcortical volume.

### Correlation Between Cognitive Function and Subcortical Structures

The neuropsychological test results are presented in **Table 2**.

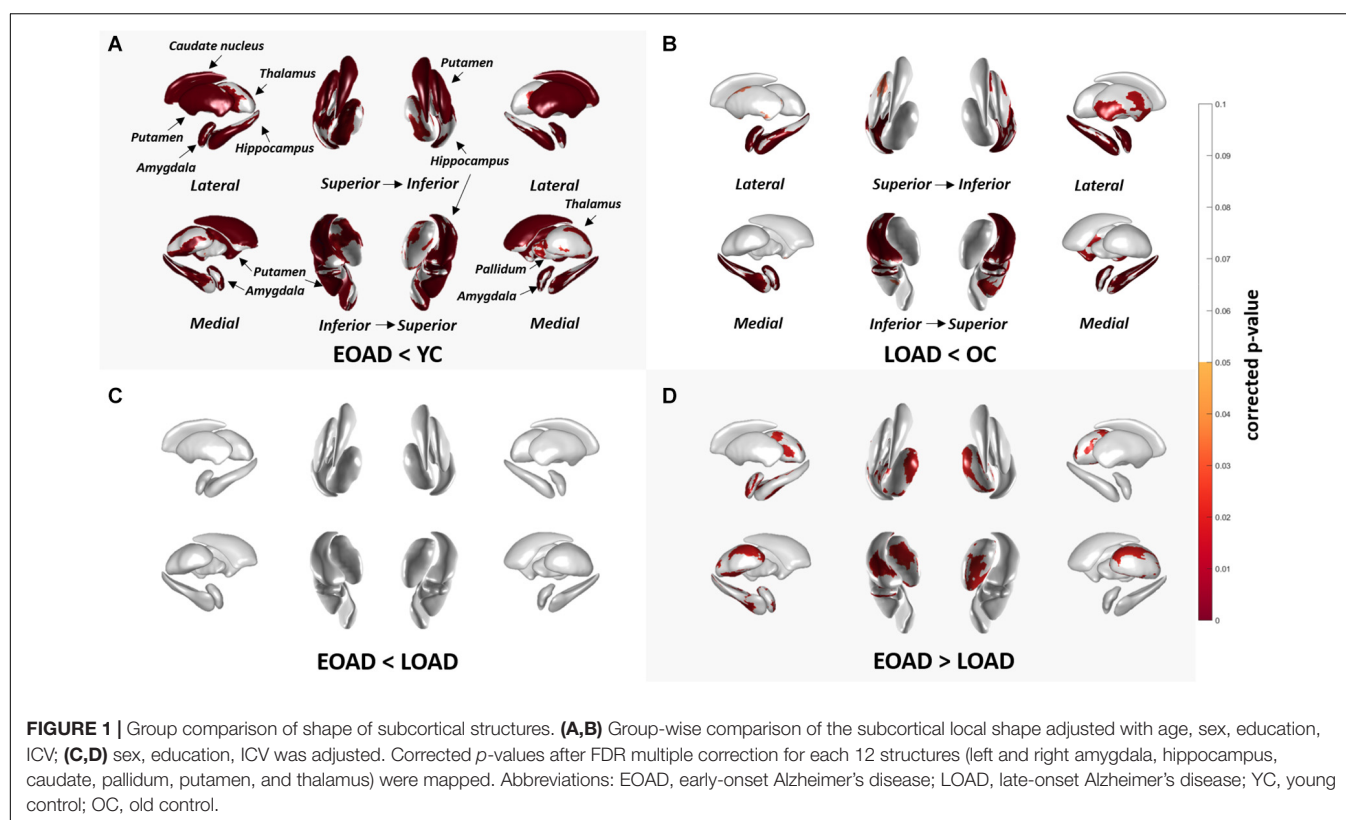

Patients with EOAD had significantly worse performance in digit span forward and backward, Rey-Osterrieth complex figure test (RCFT) copy memory test other than RCFT recognition, controlled oral word association test supermarket, Stroop test color reading, trail making test type A and B compared to LOAD patients.

**Figure 3** shows the association between subcortical shapes and neuropsychological test scores in the EOAD patients. MMSE scores were correlated with the bilateral amygdala, caudate, putamen, and thalamus and the left hippocampus (**Figure 3A**). CDR-SOB was correlated with the bilateral amygdala, hippocampus, caudate, putamen and thalamus (**Figure 3B**). Digit span backward was correlated with the bilateral amygdala, caudate, and putamen and the left pallidum (**Figure 3C**). BNT was correlated with the bilateral amygdala and putamen and the left caudate and hippocampus (**Figure 3D**). RCFT copy test was correlated with the bilateral caudate and putamen and right amygdala (**Figure 3E**). SVLT delayed recall showed correlation with the left thalamus (**Figure 3F**) and RCFT delayed recall showed association with the bilateral putamen

Abbreviations: EOAD, early-onset Alzheimer's disease; LOAD, late-onset Alzheimer's disease; YC, young control; OC, old control; MMSE, mini-mental state examination; CDR-SOB, clinical dementia rating-sum of boxes; APOE, apolipoprotein ε4 allele; CTh, cortical thickness; SUVR, standard uptake value ratio. Data is presented as mean (standard deviation) for continuous variables and number (%) for nominal variables. MMSE and CDR-SOB were compared between AD and control after adjusting for age and years of education and compared between EOAD and LOAD after adjusting for years of education. P-values refer to two-sample t-test for continuous variables and Chi square test followed by Yate's continuity correction for nominal variables. <sup>a</sup>P < 0.05.

(Figure 3G). Executive function measured by Stroop test color reading was correlated with the bilateral amygdala, caudate, and putamen and the left pallidum (Figure 3H).

Figure 4 shows the association between subcortical shape and neuropsychological test scores in LOAD patients. MMSE scores were correlated with the bilateral amygdala, hippocampus, and putamen and the left caudate (Figure 4A) and CDR-SOB was correlated with the bilateral amygdala, caudate, hippocampus, putamen, thalamus, and the left pallidum (Figure 4B). Digit span

backward was correlated with the left caudate and hippocampus (Figure 4C). BNT was correlated with the left amygdala and hippocampus (Figure 4D). RCFT copy showed no association with subcortical structural shape (Figure 4E). SVLT delayed recall was correlated with the bilateral hippocampus and the left caudate, and the right thalamus (Figure 4F), and RCFT delayed recall was correlated with the right hippocampus (Figure 4G). Stroop test color reading was correlated with the bilateral hippocampus and the left caudate (Figure 4H). Results of the

correlation analysis between volumes of the subcortical structures and the detailed neuropsychological test results were presented in **Supplementary Tables 3 and 4**.

## DISCUSSION

In this study, we evaluated the degree of subcortical structural shape deformity in EOAD and LOAD patients, in terms of association with tau and amyloid global retention, cortical thickness, and neuropsychological test results. We observed greater subcortical shape deformity in EOAD and more limited deformation especially in the amygdala and hippocampus in LOAD patients, compared to their age-matched controls. The associations between subcortical structural shape and THK global retention, mean cortical thickness, or cognitive functions were also more prominent in EOAD compared to LOAD patients.

Subcortical shape differed according to the age of onset. Compared to each age-matched control group, EOAD patients exhibited shape deformation in nearly all the subcortical structures, including the bilateral amygdala, hippocampus, caudate, putamen, and thalamus. Meanwhile, LOAD patients manifested decreased shapes in the more restricted region such as the amygdala, hippocampus, and putamen. We also found that the amygdala, hippocampus and thalamus were the major regions that differed in the direct group comparison with more shrinkage in LOAD patients than in EOAD patients. This observation is consistent with previous studies that have shown greater hippocampal atrophy in LOAD compared to EOAD (Frisoni et al., 2007). It was also previously found that EOAD patients mapped with subcortical deformity in wider regions including the amygdala, hippocampus, and putamen compared to LOAD patients with subcortical deformity mapped in the amygdala and hippocampus only, which was also

reflected in our findings (Cho et al., 2013). It has been previously reported that EOAD patients show more rapid declines in volume in the bilateral caudate, putamen, and thalamus compared to LOAD (Cho et al., 2013). In another study, researchers found putamen (dorsal striatum) atrophy in EOAD and atrophy in the nucleus accumbens (the ventral striatum) in LOAD patients (Pievani et al., 2013). The limbic area including the hippocampus and amygdala is well known to be affected in the initial stages and the basal ganglia and thalamus are affected in the later stages of LOAD (Braak and Braak, 1991). Our observations may be indicative of a dorsal atrophic pattern of the subcortical structures in EOAD and predominant hippocampal volume loss in LOAD (Pievani et al., 2013).

In terms of tau, amyloid, and cortical thickness, broad regions of the subcortical shape deformation in the caudate and putamen were associated with THK global retention and mean cortical thickness in EOAD patients. There was association with relatively low effect sizes between subcortical shape and FLUTE global retention in both groups. These results were expected because the mean cortical thickness and tau retention reportedly proceeds in a relatively parallel manner (Whitwell et al., 2008, 2018) compared to amyloid retention (Thal et al., 2002). A/T/N classification systems for AD biomarkers note a specific temporal ordering where A $\beta$  (A) precedes tau (T) and neurodegeneration (N), which correlate with clinical symptoms (Jack et al., 2016). Neurofibrillary tangle retention is also known to accumulate to a higher degree in most of

the cortical regions sparing the primary sensorimotor cortices in EOAD and in the confined regions including the medial temporal and lateral parietal regions in LOAD (Scholl et al., 2017) compared to age-matched controls. Our results appear to support these past findings and provide evidence that the dorsal subcortical structures such as the caudate and putamen are affected more in EOAD compared to LOAD and it is associated with tau global retention and cortical thinning more significantly than amyloid global accumulation. It was interesting result that amyloid global retentions were correlated with hippocampal shapes in EOAD. APOE e4 genotype might be associated with this correlation. Further study would be needed to investigate this issue.

Subcortical structures correlated with the neuropsychological test results, with greater association found more consistently in EOAD than LOAD patients. Specifically, attention, language, visuospatial function, frontal/executive function, and global cognition was correlated with subcortical shapes in most regions of the caudate and putamen. This corresponds the known function of the caudate and putamen (Koziol and Budding, 2009). The striatum, including the caudate nucleus and putamen, receives inputs from most of the major cortical regions including motor, sensory, perceptual and association, frontal executive, and affective and motivational regions (Koziol and Budding, 2009). The head of the caudate nucleus is known to receive inputs from the dorsolateral prefrontal cortex, while the tail of the caudate receives projections from the parietal cortex, and the putamen receives inputs from the motor cortex (Koziol and Budding, 2009). Regarding the circuitry of the striatum, our results indicate that the subcortical structures may associate with cortical region-specific cognitive impairment in EOAD patients. Contrary to EOAD patients, LOAD patients have shown more limited associations: language impairment was associated with shapes in the left amygdala and hippocampus, verbal memory impairment was associated with shapes in the bilateral hippocampus and the left caudate, and visual memory impairment was associated with shapes in the right hippocampus with lower levels of significance. A previous study found that EOAD patients showed more rapid cognitive decline as determined by the MMSE and frontal and total scores in the comprehensive neuropsychological test battery when compared to LOAD patients (Cho et al., 2013). Memory impairment is known to be a predominant phenotype of LOAD and non-memory impairment, including visuospatial dysfunction and apraxia, is predominant in EOAD (Koedam et al., 2010). The present findings are generally in accordance with these previous reports (Koedam et al., 2010; Cho et al., 2013) showing region-specific associations between subcortical structures and neuropsychological test results in the EOAD and LOAD groups.

We note several limitations to this study. The participants were recruited from a single memory clinic in a tertiary hospital, which may limit generalizability of the results. The lack of information on genetic mutations is also limiting because cognitive function and imaging biomarkers can vary according to genetic differences, especially for comparisons between EOAD and LOAD patients. Although we excluded participants with

familial AD with autosomal dominant inheritance, the possibility which participants with genetic mutation could not excluded completely as we did not perform PSEN 1, APP or PSEN2 gene tests to all participants. Another major limitation is the known off-target binding of the tracer used in this study. [18F]THK5351, a first generation tau tracer, is known to bind to monoamine oxidase-B (Ng et al., 2017), and thus can be reactive to both neurofibrillary tangles and reactive astrocytes (Harada et al., 2018). Due to its limited utility as a sole biomarker for tau retention, our results should thus be interpreted with some degree of caution. However, we believe our study remains the first to evaluate subcortical structural shapes in EOAD and LOAD patients, using the three major imaging biomarkers tau PET, amyloid PET, and MRI which can provide valuable evidence of *in vivo* findings in AD.

We observed pattern differences in subcortical structural shape between EOAD and LOAD. Widespread subcortical atrophy was associated with tau and cortical thinning in most of the cognitive domains, except for memory, in EOAD. In contrast, smaller subcortical regions were associated only with THK retention and restricted cognitive impairment including memory in LOAD. These results may be indicative of a different underlying pathomechanism between EOAD and LOAD. In addition, the imaging results are in close agreement with the known progression of the A/T/N *in vivo* biomarkers and differences in cognitive function in both groups. The employment of all available imaging biomarkers and age of onset in AD studies may be helpful in more clearly elucidating the association between changes in subcortical regions and other AD biomarkers.

## DATA AVAILABILITY STATEMENT

The data set generated and/or analyzed using the current study is available from the corresponding author, YN on reasonable request.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Institutional Review Boards of Gachon University Gil Medical Center. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

YN and J-KS conceptualized and designed the study. E-CL and JMK drafted the manuscript. JMK, H-ES, S-YL, KHP, DLN, and YN acquired the data. E-CL, JMK, and SS analyzed the data. J-KS took part in methodology. YN was in charge of funding acquisition and resources. YN and J-KS revised the manuscript for intellectual content. All authors reviewed and approved for publication.

## FUNDING

This study was supported by a grant from the Korea Healthcare Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (Grant No: HI14C1135), a grant from the Brain Research Program of the National Research Foundation (NRF) funded by the Korean Government (MSIT) (No. 2018M3C7A1056889); by Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korean Government (MSIT) [No. 2019-0-00079,

Department of Artificial Intelligence (Korea University)]; and by Brain Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science and ICT (No. 2020M3C7A101835721).

Type 2 diabetes mellitus (T2DM) has been clearly linked to oxidative stress and amylin amyloidosis in pancreatic  $\beta$ -cells. Yet despite extensive investigation, the biological significance of this is not fully understood. Recently, we proposed that Alzheimer's disease (AD)-relevant amyloidogenic proteins (APs), such as amyloid- $\beta$  (A $\beta$ ) and tau, might be involved in evolvability against diverse stressors in the brain. Given the analogous cellular stress environments shared by both T2DM and AD, the objective of this study is to explore T2DM pathogenesis from the viewpoint of amyloidogenic evolvability. Similar to AD-related APs, protofibrillar amylin might confer resistance against the multiple stressors in  $\beta$ -cells and be transmitted to offspring to deliver stress information, in the absence of which, type 1 DM (T1DM) in offspring might develop. On the contrary, T2DM may be manifested through an antagonistic pleiotropy mechanism during parental aging. Such evolvability-associated processes might be affected by parental diabetic conditions, including T1DM and T2DM. Furthermore, the T2DM-mediated increase in AD risk during aging might be attributed to an interaction of amylin with AD-related APs through evolvability, in which amylin protofibrillar formation presumably caused by adiponectin (APN) resistance could increase protofibril formation of AD-related APs in evolvability and subsequently lead to T2DM promotion of AD through antagonistic pleiotropy in aging. This suggests that targeting APN combined with an anti-T2DM agent might be therapeutic against neurodegeneration. Collectively, T1DM and T2DM might be linked through amylin evolvability, and a better understanding of amyloidogenic evolvability might also reveal clues to therapeutic interventions for AD comorbid with T2DM.

**Keywords:** Alzheimer's disease, diabetes mellitus, evolvability, antagonistic pleiotropy, adiponectin paradox

## INTRODUCTION

Accumulating evidence suggests that type 2 diabetes mellitus (T2DM) may drive the pathogenesis of various nervous system disorders, including ischemia, depression, and neurodegenerative conditions (Atlantis et al., 2014; Takamatsu et al., 2017). In Alzheimer's disease (AD), T2DM may increase the risk of mild cognitive impairment and subsequent progression to dementia

(Watts et al., 2013; Ng et al., 2016). Additionally, T2DM has been linked to other neurodegenerative disorders, including Parkinson's disease (PD) and Huntington's disease (HD; Aviles-Olmos et al., 2013; Montojo et al., 2017). Yet despite a plethora of such observations, the precise mechanistic underpinning of the comorbidity between T2DM and neurodegeneration remains elusive.

Our recent work suggests that the evolvability of amyloidogenic proteins (APs) relevant to neurodegeneration, such as  $\beta$ -amyloid ( $A\beta$ ) in AD,  $\alpha$ -synuclein ( $\alpha S$ ) in PD, and huntingtin in HD, might be physiologically important (Hashimoto et al., 2018a,b,c; Takamatsu et al., 2018). More specifically, APs might act as vehicles to transgenerationally deliver information regarding diverse biological stressors to cope with such forthcoming stressors in offspring's brain (Hashimoto et al., 2018a). On the contrary, evolvability might also cause aging-associated neurodegenerative disease through the antagonistic pleiotropy mechanism during the course of parental aging (Hashimoto et al., 2018b). Since evolvability is critical for reproduction, neurodegenerative diseases in aging have evaded "weeding out" by natural selection during evolution.

Given analogous pathology between T2DM and neurodegenerative disorders in terms of amyloidosis-associated stressors (Abedini and Schmidt, 2013; Singh et al., 2015), common mechanisms might form the basis for both groups of disorders. In this context, the main objective of this article is to discuss the mechanisms by which T2DM might increase AD risk from the viewpoint of amyloidogenic evolvability. We hypothesize that amylin protofibrils might confer resistance against multiple stressors in  $\beta$ -cells in the pancreas, which might be transgenerationally transmitted *via* the germ line to offspring, the absence of which might lead to type 1 DM (T1DM), and where T2DM in parents might promote amylin evolvability, while T1DM in parents might increase T1DM in offspring. Furthermore, we assume that the comorbidity of AD and T2DM in aging might be attributed to cross seeding of APs, which may stimulate evolvability. Yet the increased risk of AD from T2DM during aging might be due to upstream amylin activity relative to other more prominent APs, such as  $A\beta$  and tau, in evolvability, where the adiponectin (APN) paradox might be important. Collectively, DM and AD might be connected through amyloid evolvability, which might shed light on novel therapeutic strategies against such comorbid disorders.

## EVOLVABILITY OF AMYLOIDOGENIC PROTEINS RELEVANT TO TYPE 2 DIABETES MELLITUS

Since T2DM is associated with increased biological stressors and formation of amyloid-like fibrils of amylin in pancreatic  $\beta$  cells, we propose that amylin evolvability might be involved in the pathogenesis of T2DM.

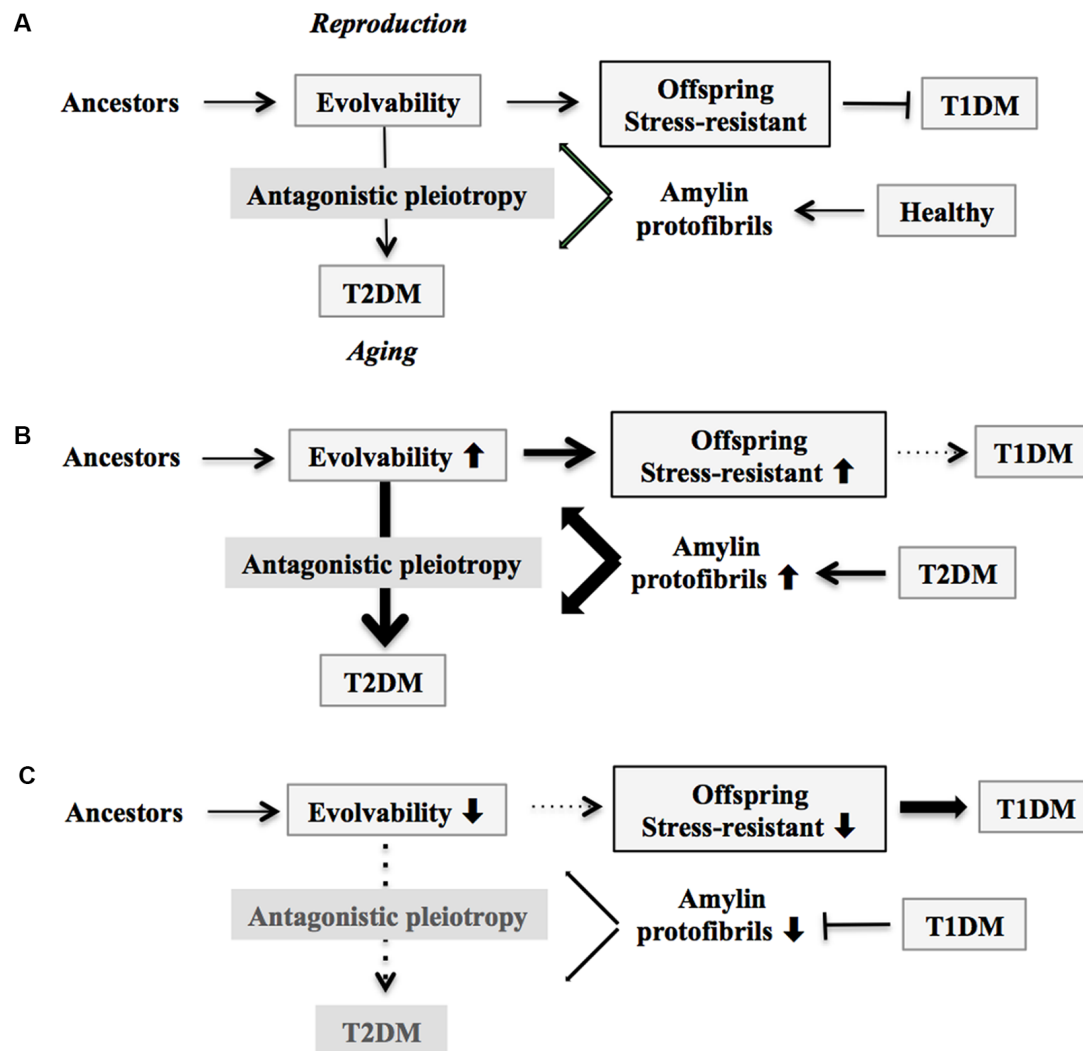

### Amylin and Insulin Are Amyloidogenic Proteins

Amylin, also called islet amyloid polypeptide, is a 37-residue peptide that is co-secreted with insulin by pancreatic  $\beta$ -cells

(Mietlicki-Baase, 2016). The normal functions of amylin include inhibition of glucagon secretion and reduction of the gastric emptying rate, effects that contribute to the maintenance of postprandial glucose homeostasis (Mietlicki-Baase, 2016). Amylin is prone to aggregate, leading to the formation of amyloid fibrils with characteristic  $\beta$ -sheet structures (Jaikaran and Clark, 2001). Consistent with this, amylin is the major component of the islet amyloid found in the pancreas in T2DM, suggesting that amylin may play a significant role in the pathogenesis of T2DM (Luca et al., 2007). In addition, insulin, a 51-residue protein that is composed of a dimer of an A- and a B-chain linked by disulfide bonds (Brange and Langkjoer, 1993), also forms amyloid fibrils. Insulin, and its related peptide, insulin-like growth factor-1 (IGF-1), are essential to multiple physiological processes, including cell proliferation, differentiation, and survival, in addition to the regulation of energy storage and glucose metabolism (Stewart and Rotwein, 1996; Dadon et al., 2012). In contrast to amylin, the biological role of insulin fibril formation remains unclear. Therefore, our article will henceforth refer exclusively to amylin in this context.

### Evolvability of Amylin

Because APs such as amylin are intrinsically disordered proteins composed of heterogeneous structures (Moore et al., 2018), APs might be involved in resistance against diverse stressors (Takamatsu et al., 2018). In addition, amylin toxicity in pancreatic  $\beta$ -cells has been well described in the pathogenesis of T2DM (Bharadwaj et al., 2017). Collectively, this may be comparable with the hormesis conferred by amyloidogenic evolvability (Hashimoto et al., 2018a). Because evolvability is defined as the capacity of a population of organisms to generate not only genetic diversity, but also adaptive genetic diversity, often overriding natural selection (Kirschner and Gerhart, 1998), both hormesis and heredity are critical steps in evolvability. In humans, AP protofibrils that encode information regarding biological and environmental stressors might be transmitted to offspring *via* germ lines (Hashimoto et al., 2018a). Although monomers of APs are unstable due to their intrinsically disordered nature (Takamatsu et al., 2018), formation of protofibrils might confer greater stability, which might provide an advantage for the transgenerational transmission of APs to offspring (Takamatsu et al., 2018). The presence of circulatory amylin is consistent with the transgenerational transmission *via* germ cells, although little is known about the expression of amylin in gonadal tissues. Yet given that amyloid fibrils are abundantly expressed in the semen (Roan et al., 2017), further exploration of this is definitely warranted. Taken together, our concept proposes that amylin protofibrils may convey stress information from parental pancreatic  $\beta$ -cells to an offspring's pancreas. By virtue of amylin evolvability, offspring can then better cope with the forthcoming stressors, reducing the risk of developing T1DM (Figure 1A). Indeed, it was previously shown that amylin-knockout mice developed a more severe form of alloxan-induced diabetes (Mulder et al., 2000), which is consistent with our hypothesis that amylin protofibrils might be involved in evolvability of  $\beta$ -cells in the pancreas.

**FIGURE 1 |** Schematic of disease manifestation caused by alterations in amylin evolvability. **(A)** Amylin protofibrils might confer resistance against multiple stressors in parental  $\beta$ -cells in the pancreas under the healthy conditions and are transgenerationally transmitted to offspring during reproduction to deliver the stress information. By virtue of this, the  $\beta$ -cells in the pancreas in offspring can cope with forthcoming multiple stressors in  $\beta$ -cells in the pancreas. Thus, amylin evolvability is an epigenetic phenomenon that is beneficial in evolution. However, amylin protofibrils might lead to type 2 diabetes mellitus (T2DM) during parental aging through the antagonistic pleiotropy mechanism. **(B)** Increased evolvability of amylin protofibrils by various causes, such as T2DM (thick bold line), may result in an efficient delivery of information about stressors for offspring, leading to reduced frequency of T1DM in offspring (thin dot line) and increased frequency of T2DM in parents (thick bold line). **(C)** In contrast, inefficient delivery of the information of stresses due to decrease of amylin evolvability caused by type 1 diabetes mellitus (T1DM) in parents may result in the increased frequency of T1DM in offspring (thick bold line) and the decreased frequency of T2DM in parents (thin dot line).

On the other hand, T2DM might manifest in later life through the mechanism of antagonistic pleiotropy during parental aging (Figure 1A). Briefly, according to the antagonistic pleiotropy hypothesis, a prominent theory of aging proposed by G. C. Williams a half-century ago, certain genes whose functions are beneficial during reproductive stages may in turn exert adverse effects later in aging (Williams, 1957). Such a view may explain why T2DM, a primarily post-reproductive and biologically disadvantageous disorder, has emerged and persisted across evolution. Yet it is recognized that T2DM is a complex disorder further modulated by interaction of a combination of

susceptible genes and perhaps lifestyle factors such as exercise and diet.

## CONNECTING TYPE 1 DIABETES MELLITUS AND TYPE 2 DIABETES MELLITUS THROUGH AMYLOIDOGENIC EVolvABILITY

Although it is generally believed that T1DM occurs during youth and may be etiologically distinct from T2DM, which emerges during later adulthood, we alternatively propose that

the two types of DM might actually be closely linked through amyloidogenic evolvability.

## The Conventional View of Type 1 Diabetes Mellitus and Type 2 Diabetes Mellitus Pathogenesis

In T1DM, which accounts for 5–10% of all diabetes cases and occurs in approximately 0.3% of young individuals, amassed evidence suggests that various etiologies, such as autoimmune dysfunction and viral infection, might be pathogenetically involved (Daneman, 2006; Menke et al., 2013). Furthermore, recent genome-wide association studies have shown that the major susceptibility for the T1DM locus maps to the HLA class II genes at 6p21, which accounts for up to 30–50% of genetic risk of T1DM, with minor contributions to disease risk from several other non-MHC loci (Steck and Rewers, 2011). On the contrary, the more common T2DM, estimated to be ~7% of the general population, in contrast to early-onset T1DM, most often begins in those over the age of 65 years (although some early-onset T2DM cases are reported; Deshpande et al., 2008). Despite similar pathology in terms of dysfunctional pancreatic  $\beta$  cells, T1DM and T2DM are understood to be etiologically different entities.

## Equilibrium Between Type 1 Diabetes Mellitus in Offspring and Parental Type 2 Diabetes Mellitus Through Amylin Evolvability

Based on our evolvability concept, stress information from parental/adult pancreatic  $\beta$ -cells could be delivered to their offspring through amylin protofibrils. The resulting pancreatic  $\beta$ -cells in offspring should therefore become more resistant against such stressors (Figure 1A).

According to our view, the greater the stress information from parental pancreatic  $\beta$ -cells that is delivered through amylin protofibrils to offspring through increased evolvability, the more resistant the pancreatic  $\beta$ -cells in offspring become against stressors, and the less prone they are to developing T1DM. This could result from various factors, including amylin missense mutation (Akter et al., 2016), T2DM in both parents, and maternal gestational diabetes mellitus (GDM). Consistent with our view, it was previously shown that parental history of T2DM is associated with a later onset of T1DM, the metabolic syndrome, and a metabolic profile related to insulin resistance (Thorn et al., 2009). Because of the action of antagonistic pleiotropy, T2DM is expressed more prominently during aging (Figure 1B).

Yet if the parents are afflicted with T1DM, then reduced evolvability associated with the down-regulation of amylin protofibrils might result in the delivery of less stress information to offspring, and as a consequence, T1DM risk may dramatically increase in offspring (Figure 1C). Supporting this, T1DM is preferentially transmitted from parents to offspring, although the mechanism of gender difference is obscure (Guo and Tuomilehto, 2002). Of interest, the inverse relationship between T1DM in offspring and parental T2DM is reminiscent of the

concept of transgenerational equilibrium previously described between parental AD and schizophrenia in offspring related to amyloid evolvability (Takamatsu et al., 2019), raising a possibility that certain chronic disorders in offspring and their aging-associated amyloidogenic disorder counterparts in parents may exist in an inverse relationship through amyloidogenic evolvability.

## Are There any Roles for Gestational Diabetes Mellitus in Amylin Evolvability?

The third diabetic subtype, GDM, occurs among pregnant women without a previous history of DM (Kampmann et al., 2015). GDM, with a prevalence of ~39% of pregnancies, correlates with increased maternal obesity (Carpenter, 2007; Egan et al., 2017). GDM shows a complex etiology, with genetic and environmental factors implicated across mechanistic and epidemiological studies. Compared with T1DM and T2DM, there have been fewer studies on the etiological basis of GDM, because of its transient nature and resolution upon delivery of the infant. Thus, a possible etiologic role for GDM might also relate to evolvability. Given that GDM is associated with increased insulin resistance (Catalano, 2014), GDM might be involved in transmitting amylin protofibrils encoding stress information from parental pancreatic  $\beta$ -cells to offspring in order to mitigate the risk of T1DM in offspring. On the other hand, symptomatic T2DM might emerge later during parental aging. If this notion can be verified, GDM may become central to linking T1DM in offspring and parental T2DM through amylin evolvability. Yet, presently, there is no evidence that amylin can cross the transplacental barrier, which is generally believed to be permeable to only small molecules (Berveiller et al., 2016). Therefore, it would be fair to conclude that GDM might be unlikely to promote amylin evolvability. As will be described later for T2DM, GDM might represent an antagonistic pleiotropy of amylin evolvability. Consistently, after the occurrence of GDM, there is a higher likelihood of developing subsequent maternal T2DM, as well as possible abnormal cardiometabolic phenotypes in offspring (Carpenter, 2007; Kawasaki et al., 2018).

Moreover, pregnant women often experience memory dysfunction through the course of their pregnancy (John et al., 2018), which is generally attributed to elevated hormone levels affecting the brain, although the precise mechanism is unknown. Similar to GDM, gestational dementia might be relevant to amyloid evolvability, perhaps involving A $\beta$  and tau. To the best of our knowledge, limited information is currently available regarding changes in brain APs during pregnancy.

## COMORBIDITY OF ALZHEIMER'S DISEASE AND TYPE 2 DIABETES MELLITUS

Supposing that both T2DM and AD are antagonistic phenomena derived from amyloidogenic evolvability during reproduction, it follows that comorbidity of T2DM with AD in aging

might be attributed to the synergistic interaction of amylin with APs, including A $\beta$  and tau, in regulating evolvability during reproduction.

## The Conventional View of the Comorbidity of Alzheimer's Disease and Type 2 Diabetes Mellitus

With regard to the mechanisms underlying increased neurodegeneration related to T2DM, numerous studies have shown that both T2DM and AD are associated with various common pathological features, including impaired insulin resistance, endoplasmic reticulum stress, oxidative stress, protein aggregation, inflammation and altered gene expression (Vannuvel et al., 2013; Hokama et al., 2014; Singhal et al., 2014; Rosales-Corral et al., 2015). Furthermore, it was described that vascular dysfunction caused by T2DM might be relevant to AD (Wang et al., 2014). These results, however, were pathological observations, and do not necessarily explain the rationale for the emergence of these two comorbid aging-related disorders in evolution.

## Comorbidity of Alzheimer's Disease and Type 2 Diabetes Mellitus From the Viewpoint of Evolvability

In this regard, evolvability might then underlie these biological phenomena. Provided that both T2DM and AD might be antagonistic phenomena derived from evolvability, it follows that amylin and amyloid- $\beta$  (A $\beta$ ) and/or tau might interact cooperatively rather than function independently. Given the prevailing concept of cross-seeding (CS) of APs (Morales et al., 2013), perhaps the CS of amylin and A $\beta$  and/or tau may be more potent than either monomer to stimulate various aspects of evolvability, such as hormesis and transgenerational transmission. Yet CS of these APs may manifest later in life as comorbid T2DM and AD through antagonistic pleiotropy in parental aging. Indeed, amylin interacts with A $\beta$  and tau in both the pancreas and hippocampus in the brain of diabetic patients with AD (Figure 2A; Jackson et al., 2013).

## Importance of Common Modifiers of Alzheimer's Disease and Type 2 Diabetes Mellitus From the Viewpoint of Evolvability

Notably, abnormally high levels of D-ribose have been observed in both T1DM (Yu et al., 2019) and T2DM (Su and He, 2014). Since administration of D-ribose induces the yield of A $\beta$  and hyper-phosphorylated tau in the brain (Wu et al., 2015, 2019; Li et al., 2020), D-ribose might be also important for induction of AD. Thus, D-ribose might affect evolvability of amylin and A $\beta$ , the dysmetabolism of which might lead to manifestation as comorbidity of AD and T2DM in aging. Indeed, it is possible that there might be many factors/stressors that may be attributed to the comorbidity of AD and T2DM. These include formaldehyde and amylin glycation.

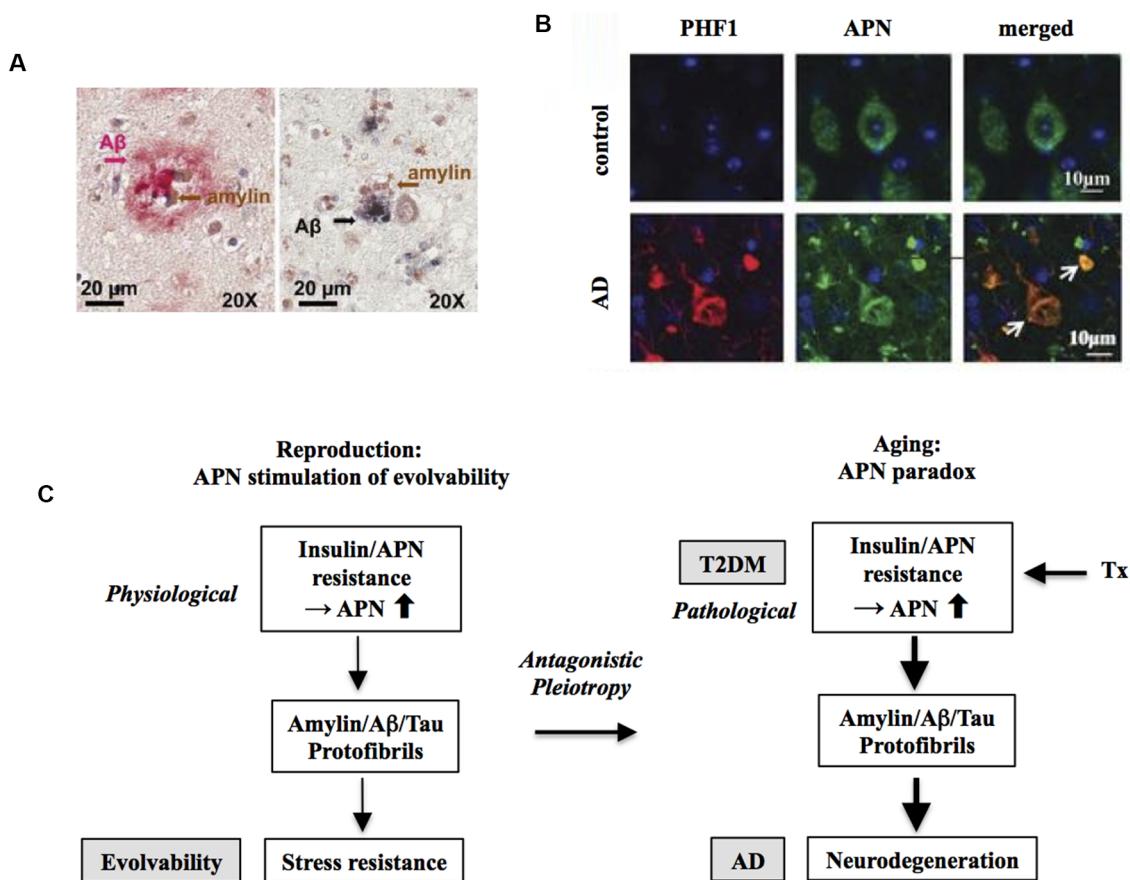

## Comorbidity of Alzheimer's Disease With Other Metabolic Disorders

Considering that AD is frequently comorbid with many other types of aging-associated diseases, similar mechanisms might be applied to the comorbidity of AD with these other conditions. Indeed, an increasing prevalence of associated metabolic disorders, including obesity, hypertension, hyperlipidemia, and atherosclerosis, is associated with an expanding adult and elderly population worldwide (Takamatsu et al., 2017). One may argue, however, that metabolic disorders other than T2DM are not always associated with amyloid fibril formation yet frequently promote neurodegeneration (Pugazhenth, 2017). In this regard, evolvability of APs, including A $\beta$  and tau, might be increased through mechanisms other than aggregative protein-protein interactions. For instance, cholesterol, which may play a central role in dyslipidemia, might stimulate misfolding and aggregation of APs in evolvability as well as in neurodegeneration and T2DM (Singh et al., 2015). Also, catecholamines possibly related to essential hypertension might be relevant (Goldstein, 1983). A $\beta$  was shown to undergo regulated co-secretion with neuropeptide and catecholamine neurotransmitters (Toneff et al., 2013), and catecholamines were also shown to stimulate protein deposition in AD and PD (Bharath and Andersen, 2004). Thus, catecholamines might be involved in evolvability, which may manifest as essential hypertension as an antagonistic pleiotropy relationship in aging. Collectively, it is possible that the comorbidity of AD with metabolic disorders might represent antagonistic pleiotropy attributed to increased evolvability due to the CS of APs and other factors.

## ROLE OF ADIPONECTIN PARADOX LINKING TYPE 2 DIABETES MELLITUS AND ALZHEIMER'S DISEASE

The concept of the CS of APs suggests that the pathogenesis of T2DM might be equivalent to that in AD but fails to explain how T2DM could be upstream of AD. Given that AD risk might be increased by T2DM, perhaps the mechanistic action of amylin in evolvability may be situated upstream to APs, including A $\beta$  and tau.

In this regard, we hypothesize that APN might be involved. APN is a multifunctional adipokine that is important in insulin receptor signaling sensitization and an anti-inflammatory role (Waragai et al., 2017). Although APN is generally protective, it has been well characterized that APN might be critically involved in promoting aging-associated chronic diseases, such as chronic heart failure and chronic kidney disease, the so-called APN paradox (Menon et al., 2006; Kizer, 2014). Notably, a recent study suggests that the APN paradox is also observed in the nervous system (Waragai et al., 2020). APN is neuroprotective and mitigates neurodegeneration in both cellular and animal experimental systems. Nonetheless, in cohort studies, it was shown that hyperadiponectinemia correlates well with neuropathological features, such as amyloidosis and cognitive deficits, suggesting that APN paradox might

**FIGURE 2 |** Increased risk of Alzheimer's disease (AD) by T2DM as an antagonistic pleiotropy of evolvability. **(A)** Co-localization of amylin and amyloid- $\beta$  (A $\beta$ ) is shown in brain parenchyma of AD patients with anti-amylin and anti-A $\beta$  antibodies. The left panel shows a brain section from an AD patient without clinically demonstrated T2DM, while the right panel is derived from a diabetic patient with AD. Clusters of small amylin plaques adjacent to, or surrounded by larger A $\beta$  deposits, are present. Modified from Jackson et al. (2013) with permission. **(B)** Adiponectin (APN)-positive neurofibrillary tangles (NFTs) in AD brain. Confocal laser scanning microscopy of double immunofluorescence of control and AD brains using anti-tau antibody PHF-1 (lower) and anti-APN antibody showed that APN co-localized with tau in AD. White arrows indicate NFTs identified by the presence of PHF-1 immunoreactive abnormal fibrous inclusions, which were within the perikaryal cytoplasm of neurons. Scale bar = 10  $\mu$ m. Modified from Waragai et al. (2016) with permission. **(C)** Schematic diagram of the mechanism underlying the APN paradox in T2DM-mediated increased AD risk. Presumably, amylin protofibrillar formation caused by APN resistance could up-regulate AP protofibrils in evolvability, which might manifest as T2DM stimulation of AD as the antagonistic pleiotropy in aging.

be involved in AD pathogenesis (Wennberg et al., 2016; Waragai et al., 2020). Consistent with this notion, it was shown that APN associated with phospho-tau in the AD brain, suggesting that APN might be involved in the tangle formation (Figure 2B).

Given that the APN paradox might be critical in promoting AD (Waragai et al., 2020), it is possible that the APN paradox in aging might be an antagonistic pleiotropy phenomenon derived from evolvability during reproduction (Waragai et al., 2020). In this context, APN resistance/insulin resistance might be a physiologically caused by fibrillar amylin in evolvability, which might later be manifest as T2DM stimulation of AD (Figure 2C). Consistently, insulin resistance was previously shown in cavefish as an adaptation to a nutrient-limited environment (Riddle et al., 2018), indicating that insulin resistance can be beneficially activated under the physiological conditions. Notably, it was recently described that large-scale proteomic analysis of AD

brain and cerebrospinal fluid revealed early changes in energy metabolism associated with glial activation (Johnson et al., 2020), which is consistent with involvement of the APN paradox in the pathogenesis of AD (Waragai et al., 2020).

Similar to AD, a recent prospective cohort study showed that higher serum APN concentrations were observed in incident cancers and are associated with cancer-related deaths in T2DM, suggesting that the APN paradox might be significant in cancer related to T2DM (Lee et al., 2020).

## IMPLICATIONS FOR THERAPEUTIC INTERVENTIONS

In view of the possible involvement of the APN paradox in linking neurodegeneration to metabolic disease, this may account for the pathological positioning of T2DM upstream of

AD in aging, suggesting that therapeutic targeting of APN might be a viable strategy.

## Targeting Adiponectin Expression

For this purpose, suppressing APN expression by various methods, such as antisense oligonucleotides against APN mRNA (Rinaldi and Wood, 2018) and immunotherapy against the APN protein (Lannfelt et al., 2014), might effectively decrease formation of APs protofibrils, leading to suppression of APN paradox and AD (Figure 2C). However, the majority of the previous studies describe that the potential of APN activity for therapeutic purposes based on the presumption that APN is protective. Therefore, it is necessary to bear in mind the possibility of a therapeutic “trade-off” by suppression of APN expression.

Notably, administration of D-ribose leads to an increase of visceral triglycerides in mice (Chen et al., 2019b); and since high levels of D-ribose (Su et al., 2013; Chen et al., 2019a) and high HbA1c (Chen et al., 2017) are associated with diabetes, this raises a possibility that D-ribose could be utilized as a biomarker to assess the therapeutic efficiency.

## Anti-Diabetes Mellitus and Metabolic Syndrome

It is expected that combining APN with treatment against T2DM and other related metabolic disorders might enhance the therapeutic efficiency of targeting of APN. Because of an increased risk of neurodegenerative disorders related to T2DM, previous studies have strongly suggested that treatment of T2DM might be beneficial for and repurposed to therapy of neurodegenerative disorders. Indeed, a recent phase II clinical trial of glucagon-like peptide-1 (GLP-1)/incretin for PD appeared promising (Hölscher, 2012; Athauda et al., 2017), prompting initiation of a subsequent clinical trial of GLP-1/incretin in AD (Gejl et al., 2016). Although metformin has long been used to treat T2DM, there is growing evidence for the benefits of metformin to counteract age-related diseases such as cancer, cardiovascular disease, and neurodegenerative diseases (Rotermund et al., 2018). Moreover, studies are in progress to assess the therapeutic potential of other anti-T2DM molecules, such as DPP-4 inhibitors (Kosaraju et al., 2017) and APN (Sekiyama et al., 2014; Waragai et al., 2018). In relation to the current state of neurodegenerative therapy in relation to T2DM, our current view regarding evolvability may offer several novel insights.

Recently, chronic hypertension has been suggested as one of the largest modifiable risk factors for developing AD (Marfany et al., 2018). Indeed, several epidemiological studies reveal that  $\beta$ -blocker treatment reduces the prevalence of AD in patients suffering from hypertension (Yu et al., 2011). Since it is possible that A $\beta$  evolvability might be promoted not only by amylin protofibrils but also by other molecules, such as cholesterol and catecholamines, it follows that disease-modifying therapies targeted against other metabolic syndrome disorders in addition to T2DM, especially anti-hypertension agents, might increase overall treatment efficacy.

## CONCLUDING REMARKS

In the present discussion, the concept of amylin evolvability was shown to provide novel insights into the T2DM and related diseases, which are currently elusive. First, we argue that T1DM and T2DM, etiologically distinct types of DM, might be linked through amylin evolvability. Furthermore, the comorbidity of AD and T2DM in aging might be an antagonistic pleiotropy phenomenon derived from evolvability regulated by AD-relevant APs, including A $\beta$ , tau, and amylin. Importantly, it was suggested that APN resistance might stimulate amylin protofibrils, leading to A $\beta$  protofibrillar formation in evolvability, which might manifest as an increased AD risk driven by T2DM through an antagonistic pleiotropy mechanism in aging. Taken together, a better understanding of the mechanism of evolvability may shed light on novel evolvability-based therapeutic strategies.

doi: 10.3389/fnagi.2020.527658

**Background:** Age-related cognitive decline begins in middle age and persists with age. Leukocyte telomere length (LTL) decreases with age and is enhanced by inflammation and oxidative stress. However, whether shorter LTL correlates with cognitive decline remains controversial.

**Aims:** We aimed to investigate the relationship between LTL and cognitive decline in the American elderly.

**Methods:** We used data from the 1999 to 2002 U.S. National Health and Nutrition Examination Survey (NHANES). We included participants aged 65–80 with available data on LTL and cognitive assessments. The cognitive function assessment used the digit symbol substitution test (DSST). We applied multivariate modeling to estimate the association between LTL and cognitive performance. Additionally, to ensure robust data analysis, we converted LTL into categorical variables through quartile and then calculated the *P* for trend.

**Results:** After adjusting for age, cardiovascular disease (CAD) score, gender, race, body mass index (BMI), and educational level, LTL showed a positive correlation with DSST score (odds ratio [OR] 3.47 [0.14, 6.79], *P* = 0.04). Additionally, to further quantify the LTL–DSST interaction, we found a similar trend when LTL was regarded as a categorical variable (quartile) (*P* for trend = 0.03).

**Conclusion:** LTL was associated with cognitive capabilities among the elderly, implying that LTL might be a biomarker of cognitive aging.

**Keywords:** aging, biomarker, telomere length, cognitive decline, elderly

## INTRODUCTION

The aging global population presents a threat of increased disease and disability (Vos et al., 2012). Age-related cognitive decline begins in middle age and continues over time (Li et al., 2001), but studies have found individual differences in the severity of age-related cognitive decline under the influence of genetic and environmental factors (Foster, 2006; Connors et al., 2015; van der Wardt et al., 2015; Heywood et al., 2017). Studies have also suggested that oxidative stress and inflammation might influence aging and age-related memory disorders, which may explain why cognitive decline is highly associated with the elderly (Anstey et al., 2005; Peila and Launer, 2006; Lau et al., 2007; Rafnsson et al., 2007). However, the exact mechanism of cognitive decline remains unknown. Thus, to help reduce the risk of dementia and promote overall health among the elderly, it is essential to identify the potential predictive biomarkers of cognitive dysfunction.

Telomeres, which are repetitive nucleoprotein regions located at the ends of eukaryotic chromosomes, maintain genomic integrity and stability by protecting the end of the chromosome from illegitimate degradation and recombination (Jiang et al., 2018). Successive somatic cell divisions gradually abrade telomere length (TL) during aging (Miu et al., 2019). This cumulative age-interrelated TL shortening conduces to cellular senescence, an attribute of aging (López et al., 2013; Xu et al., 2018). Cellular lifespan is influenced by the length and stability of telomeres to some degree. Therefore, TL has been proposed as a candidate biomarker of aging (Xu et al., 2018). The TL shortening process was reported to accelerate under oxidative stress and inflammatory response and could serve as a record of the cumulative burden of oxidative stress along with inflammation (von Zglinicki et al., 2000; Aviv et al., 2006). Judging from longer telomeres protect cells from cellular senescence and death, it is reasonable to expect that they would also protect neuronal cells against oxidative stress and neurodegeneration that are related with cognitive decline (Collado et al., 2007). Research has reported the implication of shortened leukocyte TL (LTL) in multiple age-related diseases including neurodegenerative ones (Serrano and Andrés, 2004; Valdes et al., 2007; Shammas, 2011; Willeit et al., 2014).

Previous research on LTL and cognitive ability, predominantly in the elderly, has yielded inconsistent results. Studies have noticed a correlation between shortened LTL and age-related cognitive decline among the elderly (Valdes et al., 2010; Yaffe et al., 2011), but other studies have found such an association to be relatively small or absent (Mather et al., 2010; Harris et al., 2012). Therefore, we used the U.S. National Health and Nutrition Examination Survey (NHANES) database to investigate the relationship between LTL and cognitive function in a cohort of elderly individuals.

## MATERIALS AND METHODS

### Data Source and Participant Selection

The NHANES is an ongoing cross-sectional survey of a nationally representative, non-institutionalized U.S. population conducted

by the U.S. National Center for Health Statistics (NCHS). To promote overall representativeness, the NHANES uses a complex multi-stage probability sampling design. Its dataset combines five major factors: socio-demographic characteristics, physical examinations, dietary information, laboratory investigations, and interview or questionnaire data—with raw data that are processed in 2-year cycles and made publicly available online (Cawthon, 2002; Mazidi et al., 2017). The NHANES protocol was approved by the NCHS Research Ethics Review Board, and all participants provided written informed consent. More NHANES data and detailed information on survey methods are available on the center's official website<sup>1</sup>.

In this study, we restricted our analysis to participants from 1999 to 2000 and from 2001 to 2002 cycles of the NHANES survey because only these cycles contained TL and cognitive testing information. Eligibility inclusion criteria required participants to be between ages 60 and 85 at the time of the survey, with high school education or above, and to have available data on both LTL and cognitive function examination.

### Telomere Measurements

With standardized procedures, purified DNA was acquired from whole blood and stored at  $-80^{\circ}\text{C}$  before the LTL assay. Using quantitative polymerase chain reaction, we measured LTL relative to standard-reference DNA (T/S ratio) (Cawthon, 2002; Lin et al., 2010; Needham et al., 2013). The LTL was calculated as the mean T/S ratio, which is an approximation of average TL across all the chromosome ends. More details regarding the LTL quantification procedure and analytical methods are on the NHANES website (see footnote 1).

### Cognitive Function Assessment

We evaluated cognitive function using the digit symbol substitution test (DSST), an executive function subtest of the Wechsler Adult Intelligence Scale, Third Edition (WAIS III) (Oberlin et al., 2013). In this test, participants were given a key that paired symbols and numbers. Then, they were given a train of numbers and had to draw symbols under the corresponding numbers using the substitution key in 120s. The DSST score represents the correct number of symbols drawn, with a maximum score of 133. It is considered a sensitive test for cognitive disorder because it could record the participants' response speed, associative learning, continuous attention, visual spatial skills, and memory abilities (Oberlin et al., 2013).

### Covariates

Multivariate models contain variables that might confound the link between LTL and cognitive ability. Educational level was coded as a level 2 categorical variable (high school and above). Cardiovascular disease (CAD) was also a potential confounder as it could affect both LTL and cognitive impairment. To avoid multicollinearity, we generated a comprehensive CAD variable that aggregated multiple risk factors. One score was assigned to each of the three current risk factors: history of hypertension,

<sup>1</sup><http://www.cdc.gov/nchs/nhanes.htm>

coronary heart disease, or stroke. Additionally, two points were added for diabetes. Scores ranged from 0 to 5 (Golub et al., 2019).

## Statistical Analysis

Statistical analysis was performed following CDC analytical reporting guidelines for complex NHANES data analysis<sup>2</sup>. We considered masked variance and used the recommended weighting scheme. Demographic characteristics among different TL groups (quartile) were compared using chi-square test or weighted linear regression model. To assess whether LTL is correlated with cognitive decline, our statistical analysis included three main steps. First, we employed weighted univariate and multivariate linear regression models. Multivariate models included model I (only gender, race, and educational level were adjusted) and model II [gender, race, educational level, age, CAD score, and body mass index (BMI) were adjusted]. Second, to account for non-linearity of cognitive decline and LTL, we conducted smooth curve fitting (penalized spline method) and weighted generalized additive model (GAM). Third, we performed subgroup analyses using weighted stratified linear regression models. For the continuous variable, we first converted it to a categorical variable according to the clinical cut point and then performed an interaction test.

To ensure that the data analysis is robust, we converted the TL into a categorical variable by quartile and calculated the P for trend. We did this to verify the TL results as a continuous variable and to observe the possibility of non-linearity.

All analyses were performed using the statistical software packages R<sup>3</sup> (The R Foundation) and EmpowerStats<sup>4</sup> (X&Y Solutions, Inc., Boston, MA, United States). *P*-values less than 0.05 (two-sided) were considered statistically significant.

## RESULTS

### Participants' Baseline Characteristics

**Table 1** shows the weighted distribution of socio-demographic characteristics and other covariates of the selected participants in the NHANES 1999–2002 population.

The participants in this sample averaged  $70.99 \pm 7.54$  years old, with women representing 51.1%. Among different TL groups (quartile, Q1–Q4), the following distributions were similar: educational level, BMI, CAD score, history of hypertension, diabetes, hyperlipidemia, and stroke. Compared with groups Q1 and Q2, groups Q3 and Q4 were younger and had a higher percentage of females. Regarding cognitive performance, DSST scores ranged from 0 to 117, with a mean of 44.56 (*SD* = 17.68). In addition, the maximum and minimum T/S ratio values were 3.00 and 0.39, respectively, with a mean of 0.91 (*SD* = 0.22).

### Univariate Linear Regression Analysis

We first assessed a univariate linear regression model to evaluate the relationship between LTL and DSST. The results found that

female gender, educational level, and LTL are positively correlated with DSST score, whereas male gender, age, and CAD score are negatively associated with DSST score (see **Supplementary Table S1** in the Appendix).

### Multivariate Linear Regression Analysis of the LTL–DSST Relationship

**Table 2** shows the coefficients of the association between LTL as continuous variable and DSST score. Our multivariate linear regression analysis showed a negative correlation between LTL and DSST score in the crude model (odds ratio [OR] 9.51 [5.82–13.19], *P* < 0.01) (see **Table 2**). In the adjusted model I (adjusted by gender, race, and educational level) and model II (adjusted by gender, race, educational level, age, CAD score, and BMI), the results remained stable (OR 10.27 [6.83, 13.72], *P* < 0.01; OR 3.47 [0.14, 6.79], *P* = 0.04).

Additionally, to further detect the correlation of LTL–DSST interaction, we stratified the participants into four groups by the 25th, 50th, and 75th LTLx percentiles (0.39–0.76, 0.76–0.88, 0.88–1.03, and 1.03–3.00, respectively). LTL was regarded as a categorical variable (quartile), and a similar trend was observed (*P* for trend = 0.03; see **Table 2**). On multivariable analysis, participants in quartile 4 had 139% higher odds of getting higher DSST score than those in quartile 1.

### Analyses of LTL–DSST Non-linear Relationship

It is essential to analyze non-linear relationships for continuous variables. A weighted GAM and smooth curve fitting (penalized spline method) were used to investigate the non-linear relationship between LTL and DSST scores. After adjusting for gender, age, educational level, race, CAD score, and BMI, we did not observe a non-linear relationship between LTL and DSST (see **Supplementary Figure S1** in the Appendix).

### Subgroup Analyses

**Table 3** shows our subgroup analysis results. We found that, after adjusting for potential confounders, the interaction test was not statistically significant for age, educational level, gender, race, CAD score, and BMI (*P* for interaction > 0.05). Thus, we do not detect any substantial evidence to prove that there are systematic differences in associations in different subgroups of the population, which means our main results are stable.

## DISCUSSION

This study's central finding suggests that cognitive decline correlated significantly with shorter LTL among elderly individuals, and the findings were found to be robust after adjusting for various potential confounders.

Previous studies have noted the role of LTL in a series of age-related chronic diseases including neurodegenerative and CAD (Panossiana et al., 2003; Benetos et al., 2004; Martin et al., 2006; Brouillette et al., 2007; van der Harst et al., 2007; Fitzpatrick et al., 2011). Consistent with our results, some previous studies

Model I adjusted for gender, race, and educational level; model II adjusted for gender, race, educational level, age, CAD score, and BMI.

found that compared with healthy individuals, patients with cognitive disorder [including mild cognitive impairment (MCI) and Alzheimer's disease (AD)] have truncated TLs in peripheral blood leukocytes (Honig et al., 2006; Grodstein et al., 2008; Mather et al., 2010; Valdes et al., 2010), mononuclear cell (Panossiana et al., 2003), and even in brain tissue (Thomas et al., 2008), while other studies did not observe a correlation between cognitive performance and LTL (Zekry et al., 2010; Hochstrasser et al., 2012; Movérare-Skrtic et al., 2012).

Furthermore, genetics might be a potential confounder in such a correlation in view of the heritable characteristics of LTL (Jeanclos et al., 2000; Nawrot et al., 2004). However, studies have

also found significant differences in cognitive scores between twins with inconsistent TL, and the results confirmed that the correlation observed between decreased cognitive ability and shortened TL is robust to age and possible confounding factors.

The precise mechanism underlying the correlation between shorter LTL and cognitive decline remains unclear. Regarding TL, apart from the erosion of telomeres with cell division, telomeres are highly sensitive to damage by oxidative stress and inflammation (Saretzki and Von Zglinicki, 2002; Aviv et al., 2006). Oxidative stress enhances telomere attrition with each cell division (Saretzki and Von Zglinicki, 2002), whereas inflammation entails increased leukocyte turnover

and subsequently heightens telomere attrition. An *in vitro* study reported that the telomere shortening process could be modulated by oxidative stress (Kawanishi and Oikawa, 2004), and many proinflammatory markers, such as interleukin (IL)-6, were negatively correlated with TL (O'Donovan et al., 2011). Evidence showed that short/dysfunctional telomeres in peripheral immune cells as well as in microglia could contribute to cellular senescence that are linked to higher secretion of proinflammatory mediators that play an important role in the etiopathogenesis and progression of cognitive impairment (Collado et al., 2007; Jurk et al., 2012; Weng, 2012; Boccardi et al., 2015). To some extent, LTL might hinge on the cumulative burden of inflammation and oxidative stress across the lifespan (Sultana et al., 2009). Therefore, oxidative stress and inflammation might be the potential thread linking TL shortening with cognitive dysfunction.

Several alternative pathways may underlie the pathogenesis of cognitive impairment. The hippocampus is closely associated with cognitive function and is regarded as a key area affected by aging. It has been reported that TL is independently associated with cortical epithelial marginal areas (including hippocampus and orbitofrontal cortex areas), which overlaps with brain regions related to cognitive impairment psychopathology. Previous animal research reported that telomerase-deficient mice models showed neuronal loss in the hippocampus and frontal cortex linked with short-term memory deficits (Rolyan et al., 2011), whereas telomerase reactivation could reverse aging-related cognitive deficits (Jaskelioff et al., 2011).

This study exhibits multiple strengths. The multi-ethnic, national representative data from NHANES allow our findings to be extrapolated to a broader population. LTL and cognitive assessment were measured in a large sample, offering high statistical power to explore their connection. Additionally, with the NHANES's rigorous methodology and comprehensive quality procedures, we adjusted for several potential confounders by capitalizing on its abundant data.

However, this study also has several limitations. First, its primary constraint is its cross-sectional design, precluding inferences about causation. Second, LTL comes from one measurement rather than assessed longitudinally, which may provide key insights into the aging process. The shortening rate of LTL may be a more relevant indicator of the wear and tear that results in accelerated biological aging than TL measured at one point in time. Third, because TL maintenance or loss is related to many environmental factors, TL is also controlled by genetics and varies widely between individuals (Graakjaer et al., 2004). Therefore, ideally, one must consider all these intermediate parameters before attributing the differences in TL to a particular phenomenon. Fourth, a potential limitation is the use of only one specific measure of cognitive ability rather than multiple ones, and the type of cognitive measurement might lead to different findings. Accompanying tests, such as the Mini Mental Status Examination (MMSE), could help to assess cognitive function more comprehensively. However, DSST performance seems to be sensitive in reflecting attention/concentration, visual discrimination, information processing speed, and working memory and is especially suitable for screening MCI in the elderly (Salhouse, 1996). Moreover, it was reported to be less sensitive to educational level (Hoyer et al., 2004). Thus, the DSST scale may represent a relatively comprehensive cognitive scale (Launer et al., 2011). Future studies are required to determine the relationship between LTL and cognitive decline, which may reveal new knowledge on the effect of oxidative stress and inflammation on health and longevity.

## CONCLUSION

Using the NHANES database, this study found a significant association between LTL and cognitive performance in the elderly after adjusting for potential confounding factors. Further high-quality studies need to be conducted to better understand the pathophysiology of such a correlation.

## DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. These data can be found here: <https://wwwn.cdc.gov/nchs/nhanes/tutorials/default.aspx>.

## ETHICS STATEMENT

The studies involving humans were reviewed and approved by the National Center for Health Statistics Research Ethics Review

Board. Patients/participants provided their written informed consent to participate in the study.

## AUTHOR CONTRIBUTIONS

DBR, DLH, and QS designed the study. DLH and QS drafted the manuscript. DLH, QS, and CC acquired the data. CC, DLH, and QS analyzed the data. DBR, CC, LXL, ZLX, and ZZL revised the manuscript critically for important intellectual content. All authors contributed to the article and approved the submitted version.

Bruchhage MMK, Correia S, Malloy P, Salloway S and Deoni S (2020) Machine Learning Classification Identifies Cerebellar Contributions to Early and Moderate Cognitive Decline in Alzheimer's Disease. *Front. Aging Neurosci.* 12:524024. doi: 10.3389/fnagi.2020.524024

Alzheimer's disease (AD) is one of the most common forms of dementia, marked by progressively degrading cognitive function. Although cerebellar changes occur throughout AD progression, its involvement and predictive contribution in its earliest stages, as well as gray or white matter components involved, remains unclear. We used MRI machine learning-based classification to assess the contribution of two tissue components [volume fraction myelin (VFM), and gray matter (GM) volume] within the whole brain, the neocortex, the whole cerebellum as well as its anterior and posterior parts and their predictive contribution to the first two stages of AD and typically aging controls. While classification accuracy increased with AD stages, VFM was the best predictor for all early stages of dementia when compared with typically aging controls. However, we document overall higher cerebellar prediction accuracy when compared to the whole brain with distinct structural signatures of higher anterior cerebellar contribution to mild cognitive impairment (MCI) and higher posterior cerebellar contribution to mild/moderate stages of AD for each tissue property. Based on these different cerebellar profiles and their unique contribution to early disease stages, we propose a refined model of cerebellar contribution to early AD development.

## INTRODUCTION

Alzheimer's disease (AD) is the most prevalent form of dementia in the developed world (Reitz et al., 2011) and is defined by a progressive decline of a variety of cognitive functions and motor abilities. Accumulating evidence suggests that AD has a lengthy preclinical phase, where brain pathology accumulates and patient function declines, but symptoms are insufficient to warrant a clinical diagnosis of dementia. AD neurodegeneration follows specific topographic patterns of gray and white matter atrophy that emerge during its early stages (Serra et al., 2010).

Although the pathobiological basis of these alterations remains unclear, there is increasing evidence that white matter and myelin alterations occur at the earliest stages of the disease and are associated with cognitive decline, potentially preceding gray matter (GM) volume changes and loss (Braak et al., 2000). This has been supported by emerging preclinical (Desai et al., 2010), histological (Zhan et al., 2014) and longitudinal studies documenting white matter changes to be of particular importance for AD stages (Frings et al., 2014), in turn stressing the need to better characterize white matter and myelin change in early stages of cognitive decline in AD.

While the traditionally focus has been placed on neocortical and hippocampal atrophies, recent evidence suggests that the cerebellum undergoes focal atrophy in concert with interconnected cerebral nodes in both AD and fronto-temporal dementia (Guo et al., 2016). Histopathology studies of AD have shown cerebellar amyloid- $\beta$  oligomers to be affected in a counter-clockwise pattern during disease progression, starting in the posterior cerebellar lobe, and paralleling cerebrum atrophy staging and associated symptom progression (Jacobs et al., 2018).

However, the functional decline is often present before an official AD diagnosis has been reached. For example, 60% of elderly patients with a cognitive decline also suffer from falls; twice more than those without impairment (Davis et al., 2011). In a functional MRI study, falling significantly more often in the elderly has implicated the right cerebellum as a potential region of interest in early cognitive decline and aging (Liu-Ambrose et al., 2008). While the cerebellum has long been associated with motor function, it is also involved in many non-motor functions, including working memory and executive functioning (Schmahmann et al., 2001; Bellebaum and Daum, 2007). Nevertheless, the role of cerebellar white and GM in disease progression and classifying stages of early cognitive decline from typical aging remain a challenge. To address these questions, we used machine learning-based classification on GM anatomical and volume fraction myelin images to investigate their contributions to predict the first two early stages of dementia [mild cognitive impairment (MCI) and mild and moderate AD] when compared with typically aging controls. We further calculate their predictive accuracy within the whole brain and neocortex and compare them with the anterior, posterior, and whole cerebellum to investigate the role of cerebellar white and GM in early AD progression.

## MATERIALS AND METHODS

### Participants

Forty-three age- and gender-matched participants (15 healthy controls; 17 MCI; and 11 Mild/Moderate AD) were included. Subject group demographics are shown in **Table 1**. A clinical interview, an assessment of cognitive decline using the Mini-Mental State Examination (MMSE), and clinical dementia rating (CDR) scores were used to assign the participants to the healthy (CDR = 0), MCI (CDR  $\leq$  0.5), and Mild/Moderate

AD ( $0.5 \leq$  CDR  $\leq$  1.0) groups. The CDR is a reliable and valid measure to assess AD stages (Morris, 1993; Nyunt et al., 2013) and its scores have been shown to usefully predict functional decline and incident dementia (Woolf et al., 2016). The MMSE is a 30-point questionnaire that is routinely used to assess cognitive impairment in clinical and research settings (Pangman et al., 2000). MANOVAs revealed no significant group differences in mean age or gender ratio between groups ( $p > 0.10$ , **Table 1**). Genetic screening was performed on individuals with AD and APOE (Apolipoprotein E) status was determined.

### MRI Acquisition

All participants were imaged on a Siemens Tim Trio 3T scanner (Siemens Healthcare GmbH) with a 32-channel head RF array. A multimodal protocol was performed that included mcDESPOT myelin water imaging (Deoni et al., 2008), T1-weighted MP-RAGE anatomical, and diffusion tensor imaging. The mcDESPOT acquisition consists of eight variable flip angle T1-weighted spoiled gradient echo (SPGR) images and two sets of eight variable flip angle T1/T2-weighted fully-balanced steady-state free precession (bSSFP) images, with each set acquired with 0 or 180-degree RF phase cycling pattern (Deoni, 2011). In addition, an inversion-prepared (IR)-SPGR image was also acquired to correct for flip angle ( $B_1$  field) inhomogeneities (Deoni, 2011).

### MRI Analysis

Following the acquisition, data were visually checked for motion-related artifacts and then a standardized processing pipe-line was performed that included: (1) Skull stripping using the brain extraction tool (Smith, 2002) from the FSL software library (Smith et al., 2004); (2) Linear registration to account for subtle inter-scan motion using FSL's linear image registration tool (Jenkinson et al., 2002; Zhang et al., 2004); (3) Calculation of the main and transmit magnetic field ( $B_0$  and  $B_1$ ) calibration maps (Deoni, 2011); and (4) Estimation of the VFM at each brain voxel using a stochastic region contraction approach to fit a 3-pool model to the acquired SPGR and bSSFP data (Deoni and Kolind, 2015).

All anatomical and VFM images were first loaded to the SPM12's SUIT toolbox (Diedrichsen et al., 2009) to isolate structures of interest. For the whole brain and neocortex, we used the following steps for analysis: gray and white matter tissue class segmentation, DARTEL registration (Ashburner, 2007) to a common inter-subject space, a DARTEL utility to create Jacobian images. For the cerebellum, we used the following steps for analysis: SPM12's SUIT toolbox (Diedrichsen et al., 2009) to isolate the structure, DARTEL registration to SUIT space, a DARTEL utility to create Jacobian images. Jacobian determinant images have previously shown promise in discriminating neurodegeneration by allowing a comparison of the expansion and contraction of voxels across and within subjects (Studholme et al., 2004a,b; Hua et al., 2009, 2010; Anderson et al., 2012; Aksman et al., 2016). After applying a thresholded mask created in Matlab to fit the whole brain, cerebrum or whole/anterior/posterior cerebellum to exclude

**TABLE 1** | Participant demographics.

	Healthy aging	Mild cognitive impairment	Mild to moderate AD	ANOVA <i>p</i> -value
Male:Female	3:12	8:9	2:9	0.24
Age	74.7 (5.2)	74.3 (7.7)	78.4 (8.6)	0.12
CDR	0	0.48 (0.2)	0.6 (0.2)	
MMSE	29.4 (1)	27.8 (1.7)	22 (1.6)	
APOE Not tested	15	3	0	
APOE ε2ε2		0	0	
APOE ε2ε3		1	0	
APOE ε3ε3		6	4	
APOE ε2ε4		0	0	
APOE ε3ε4		5	5	
APOE ε4ε4		2	2	

Mean values are given for male to female ratios, age in years, CDR and MMSE values as well as APOE status for all participants. Standard deviations are noted in brackets and *p* values on the right show non-significant differences between groups. Abbreviations: AD, Alzheimer's Disease; CDR, Clinical Dementia Rating; MMSE, Mini-Mental State Examination; APOE, Apolipoprotein E.

extracerebral or extracerebellar voxels, we used a two-class linear support vector machine learning algorithm, implementing the C cost support vector classifier at a fixed value of  $C = 1$  throughout all classifications. Within the full dataset, we defined a set that is split into a training set  $N$  of subjects used to train the classifier, and a set  $T$  of subjects that are used to test the classifier's prediction ability. Specifically, we used leave-one-out cross-validation to learn a function from the data that can accurately predict the labels of unseen or new patterns and thus evaluate the classifier's performance. The model parameters learned in the training phase are represented as weights (weighted images are displayed in **Supplementary Figure 1**) and demonstrate the relative contribution of each feature to the predictive task.

Using freely available Matlab code<sup>1</sup>, we created Jacobian weighted images, forward maps, as well as  $p$  and  $t$  thresholded maps at  $p \leq 0.005$ . Cerebellar masks were created by using the SUIT atlas (Diedrichsen et al., 2009) by combining vermis, left and right cerebellar lobules I–V to create the anterior cerebellar mask, and vermis, left and right cerebellar lobules VI–X to create the posterior cerebellar mask. The cerebrum mask consisted of the whole brain mask but excluding the cerebellum and brainstem. Jacobian weighted GM volume will be referred to as GM volume throughout the manuscript.

## RESULTS

As expected, cognitive decline increased with increasing dementia stages (**Table 1**). The cerebellum as a region of interest displayed up to 28% higher classification accuracy when compared with the neocortex and up to 18% higher classification accuracy when compared with the whole brain, with the highest prediction accuracy of 75% of cerebellar VFM for mild/moderate dementia (all results thresholded at  $p \leq 0.005$ , **Figure 1**). Clusters with the highest cerebellar effects were localized in the lateral cerebellum (x/y/z: 33/26/29 and 37/58/38 in SUIT space).

Weighted images are shown in **Supplementary Figure 1**. While classification accuracy increased with AD stages, GM volume was the best predictor for the earliest stage of dementia (MCI), while VFM demonstrated the highest prediction

accuracy for the mild/moderate stage of dementia when compared with typically aging controls. Similarly, the cerebellar GM showed the highest prediction accuracy for CDR score (66.8%; **Supplementary Figure 2**), and consistently higher prediction accuracy when compared with the neocortex (**Supplementary Figure 2**). When dividing the cerebellum into its anterior and posterior lobe, the posterior cerebellar contribution increased in both GM volume and VFM (**Figure 2**). These changes were strongest in the Crus I/II (**Figure 2**).

## DISCUSSION

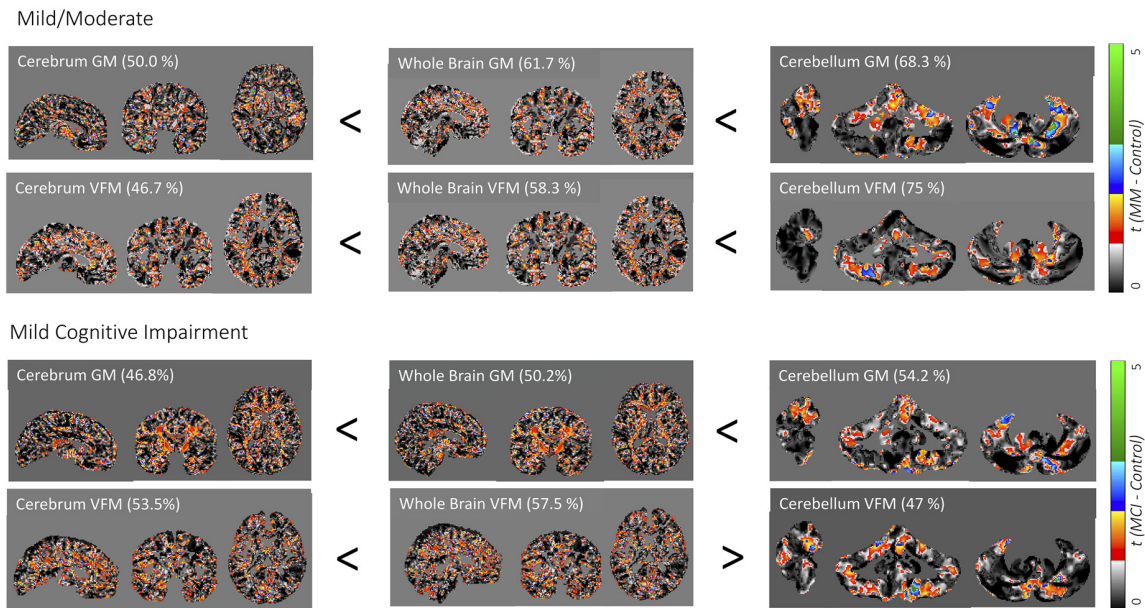

In this study, we investigated the contribution of cerebellar GM volume and VFM to predict the first two early stages of AD (MCI and mild/moderate AD) when compared with the whole brain and cerebrum gray matter volume and volume fraction myelin.

Our findings suggest VFM and GM volume loss occur in the early stages of AD, with distinct patterns of anterior and posterior cerebellar contributions (**Figure 2**). Specifically, disease classification was driven by differences in the posterior cerebellum with its prediction accuracy increasing with symptom severity, paralleling histopathological findings of cerebellar  $\beta$  in the posterior cerebellar lobe (Jacobs et al., 2018).

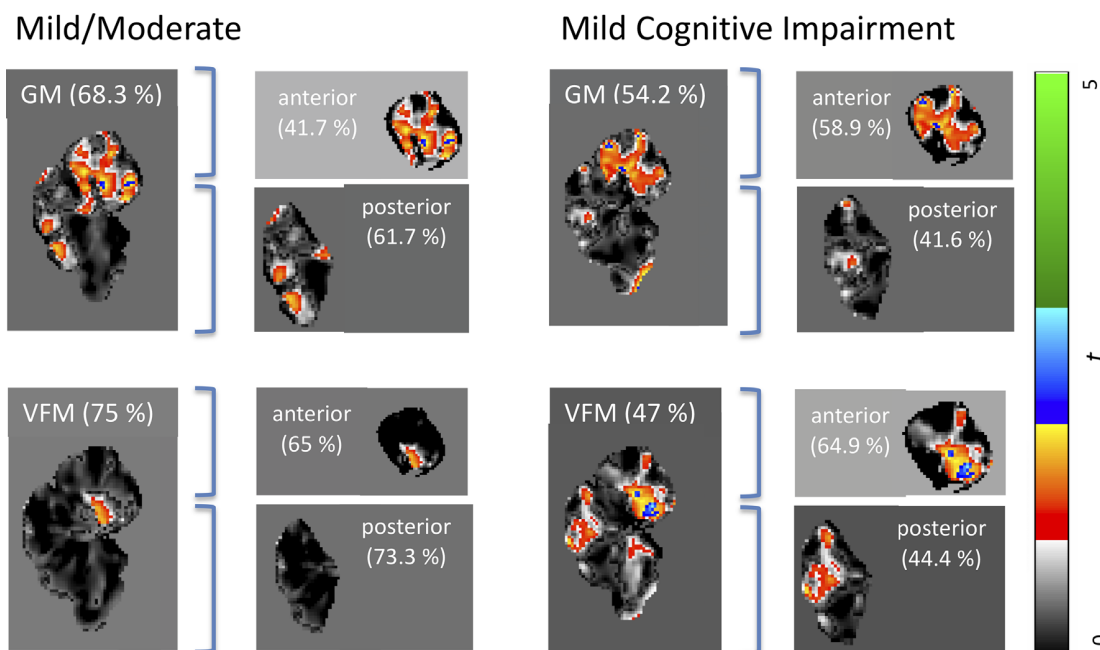

The cerebellum can be divided functionally into the motor and sensorimotor functions processed in the anterior- posterior lobe and cognitive functions in posterior cerebellar regions, enabled by its distinct neuroanatomic (Middleton and Strick, 2001; Kelly and Strick, 2003) and functional connectivity (Buckner et al., 2011) connections. During the development of AD, cerebellar GM volume appears to follow a predictable pattern, affecting the vermis and posterior lobe in the early stages of the disease, continuing to evolve to the anterior lobe with disease progression (Jacobs et al., 2018). Indeed, lower GM cerebellar anterior volume has been shown in patients with early-onset AD carriers compared to non-carriers (Reiman et al., 2012) as well as in patients with MCI, although the direct nature of its contribution remains unclear possibly because of the diffuse nature of the disease (for a review, Jacobs et al., 2018). In contrast, cerebellar white matter volume declines more

**FIGURE 1 |** Weighted prediction  $t$ -maps for the whole brain and cerebellum. Jacobian gray matter (GM) volume and volume fraction myelin (VFM) prediction  $t$ -maps for the cerebrum, whole brain, and whole cerebellum for mild/moderate Alzheimer's disease (AD; above) and mild cognitive impairment (MCI; below). Prediction accuracy percentage is noted in brackets and  $t$ -values ranging from 0 to 5 are indicated with a color bar on the right, with the lowest  $t$ -value in black to the highest  $t$ -value in green. x/y/z coordinates for the neocortex and whole-brain are 64/78/58 in DARTEL space, and 70/47/43 for the cerebellum in SUIT space.

**FIGURE 2 |** Weighted prediction  $t$ -maps for the whole, anterior, and posterior cerebellum. Jacobian GM volume and VFM prediction  $t$ -maps for the whole, anterior, and posterior cerebellum for mild/moderate AD (left), and MCI (right). Prediction accuracy percentage is noted in brackets and  $t$ -values ranging from 0 to 5 are indicated with a color bar on the right, with the lowest  $t$ -value in black to the highest  $t$ -value in green. All  $x$  coordinates are  $x = 70$  in SUIT space.

rapidly than GM volume, a pattern similar to that observed in the cerebral hemispheres (Jernigan et al., 2001). This pattern of different white and GM volume decline was supported by

our study results, where myelin water fraction demonstrated the highest prediction accuracy, underlining the role of white matter alterations at the earliest stages of dementia.

These early developments of AD are also reflected microstructurally, as more diffuse amyloid-beta deposits in early-onset patients showed cerebellar pathology 30 years earlier than sporadic patients (Cole et al., 1993). Here, the degree of cerebellar amyloid-beta was negatively correlated with the age of onset, indicating cerebellar atrophy as a possible biomarker for the early stages of AD. This cerebellar pathology in early-onset AD is further accompanied by cerebellar motor phenomena such as ataxia, especially in PSEN1 mutations (Bateman et al., 2011). Motor phenomena precede the loss of cognitive functions and are associated with early detectable cognitive impairments of MCI and incident AD (Camicioli, 2010). This is in line with our results where the anterior cerebellar contribution to AD was strongest in the early stages followed by increasing posterior cerebellar contribution with cognitive function loss as indicated by decreasing CDR values and prediction (**Table 1, Figure 2, Supplementary Figure 2**). Our results are further paralleled by histological findings, where the concentration of cerebellar soluble fibrillar amyloid oligomers was inversely correlated with MMSE AD classification performance but positively with the presence of cerebral plaques and tangles, suggesting that AD molecular changes possibly already occur in the cerebellum in the preclinical stages and may contribute to the symptomatology and pathophysiology of the disorder (Mann et al., 1990). While our cerebellar findings seem to mirror these histopathological findings, it remains unclear whether this pattern corresponds to microtissue changes and should be followed up by combining VFM and GM volume MRI scans and histopathology of the cerebellum on tissue from early AD stages.

Cerebellar amyloid- $\beta$  oligomers have been documented to be affected in a counter-clockwise manner starting in the posterior cerebellar lobe, thus paralleling cerebrum atrophy staging and associated symptom progression (Jankowsky et al., 2004; Gentier et al., 2015), has led to an AD stage model of cerebellar atrophy starting from the posterior to the anterior lobe with disease progression (Jacobs et al., 2018). Based on our findings, we propose a refined model of cerebellar contribution to AD development. We suggest that early AD disease stages are driven by both the anterior and posterior cerebellum, but an initially higher anterior cerebellar lobe contribution to the classification of the earliest stages of the disease and posterior cerebellar lobe contribution increasing with symptom severity. This parallels cerebellar functionality and AD symptom disease progression, as motor phenomena that are classically associated with anterior cerebellar dysfunction, such as ataxia, are early AD symptoms preceding cognitive symptoms that have been associated with posterior cerebellar dysfunction.

While high prediction accuracies of up to 75% could indicate an important contribution of the cerebellum to the earliest stage of AD (mild/ moderate), it decreases for MCI to around 50%. This discrepancy might suggest a less substantial contribution of the cerebellum to MCI development. However, when investigating cerebellar sub-regions, a pattern of higher anterior cerebellar contribution to MCI classification appears (64.9% prediction accuracy; **Figure 2**), which could be linked to its essential role in motor function and dysfunction.

Our findings support the role of cerebellar contribution to the early stages of AD pathology and define its unique contribution to early disease development prediction as well as subregions driving this classification. However, the cerebellum is often regarded as being spared in AD pathology and is consequently usually used as a control area or reference region in PET imaging studies over total brain volume to control for differences (for example, Dukart et al., 2010). Nevertheless, when a study compared regional glucose metabolism normalization methods using either total cerebral or cerebellar volume, cerebellar normalization was determined superior in identifying dementia patients in comparison to control subjects (Dukart et al., 2010). Together with our findings, it can be suggested to rather chose global brain measures than cerebellar volume for normalization methods to avoid bias towards early AD stages.

The disease biology of frontotemporal lobe dementia (FTD) is complex and not fully understood, with limited translational value appreciated from animal models to date. Human cellular systems that can recapitulate phenotypic features of disease offer promise as translational tools to not only increase our understanding of disease processes but also increase the probability of success of translating novel treatment options to patients. However not all researchers may necessarily have access to well-characterized induced pluripotent stem cell (iPSC)-derived human neurons. As an example, we therefore comprehensively profiled phenotypic features over time in one commercially-available iPSC-derived human neuron cell line. This included systems-level assessments of neurite outgrowth dynamics, neuronal network function, and genome-wide gene expression. By investigating progranulin biology as an example we then demonstrated the utility of these cells as a tool to investigate human disease biology. For example, by using the siRNA-mediated knockdown of the progranulin (*GRN*) gene, we demonstrated the establishment of an isogenic human cellular model to facilitate translational FTD research. We reproduced findings from rodent neurons by demonstrating that recombinant progranulin (rPGRN) mediated neuroprotection. Contrary to previous rodent data, in our human cellular models, growth factor treatment showed no consistent sensitivity to modulate neurite outgrowth dynamics. Our study further provides the first evidence that rPGRN modulated neuronal firing and

synchrony in human neurons. Taken together, our datasets are a valuable systems-level resource demonstrating the utility of the tested commercially-available human iPSC neurons for investigating basic human neurobiology, translational neuroscience, and drug discovery applications in neurodegenerative and other CNS diseases.

**Keywords:** progranulin (PGRN), frontotemporal lobe dementia (FTD), neurodegeneration, translational neuroscience, MEA, RNA-Seq, live-cell imaging

## INTRODUCTION

While most basic biological studies utilize animal-based models to investigate disease mechanisms and biology, suitable models that allow translation of these findings to human biology are often missing. This is especially true in the neuroscience field, which lacks broadly available well-characterized human neuronal models. Variability in pharmacological responsiveness between animal and human cells is particularly rate-limiting for quantitative drug discovery applications and the identification of potential therapeutic molecules. Therefore, novel human cell-based model systems could offer key advantages for translational biology. Induced pluripotent stem cells (iPSCs) can be differentiated into a host of cell types, including neurons (Takahashi et al., 2007) and consequently, have been implemented to model common and rare neurological diseases (Park et al., 2008; Ross and Akimov, 2014), including Alzheimer's disease (AD; Israel et al., 2012) and frontotemporal lobe dementia (FTD; Almeida et al., 2012; Raitano et al., 2015). Such iPSC-derived neuronal models from normal donors and patients are useful but have certain disadvantages. The creation of these cells is time-consuming and requires extensive characterization (Xu and Zhong, 2013); moreover, results have been shown to vary substantially between labs (Volpato et al., 2018).

Commercially-available iPSC-derived neurons are already differentiated and subjected to quality control, thus making this technology available to the broader research community that would otherwise need expertise in iPSC reprogramming and differentiation procedures. Well-characterized commercially-available cells would be a useful alternative to enhance the availability and reproducibility of iPSC models. iPSC-derived neurons representing distinct brain regions are commercially-available, including the iCell® line from FUJIFILM Cellular Dynamics, Inc. (FCDI). iCell® GlutaNeurons (GNs), for example, express predominantly glutamatergic markers and according to the manufacturer have been previously used to study electrophysiology, cell survival, and neurite outgrowth and the neuronal identity of GNs has been confirmed by flow cytometry and by assessment of gene expression in individual cells, while neuronal function has been assayed by multi-electrode array and calcium influx analyses (Fujifilm, 2018). Therefore, our objective was to perform an independent and longitudinal assessment of key phenotypic features in human iPSC-derived GNs Using live-cell imaging, RNA-Sequencing (RNA-Seq), and multi-well multi-electrode array (mwMEA) technologies, we present comprehensive data characterizing: (1) neuronal morphology and outgrowth; (2) neuronal network

activity and synchrony; and (3) genome-wide gene expression profiles in GNs over a culture period of 3 weeks.

Next, we used the cells to study progranulin (PGRN) as proof-of-principle that these human neuronal cells are applicable to better understand translational disease biology in the context of neurodegenerative disease. FTD is a cluster of neurological disorders associated with behavioral and speech abnormalities and the most common pre-senile dementia (Bang et al., 2015). Gene linkage studies identified that heterozygous mutations in the *GRN* gene lead to haploinsufficiency of the encoded PGRN protein and cause FTD characterized by prominent deterioration of frontal and temporal cortical lobes (Baker et al., 2006; Cruts et al., 2006). We developed a siRNA-mediated knockdown protocol to study how the loss of endogenous *GRN* expression in human iPSC neurons relates to *GRN* haploinsufficiency in human FTD patients and studied how the treatment of the used human iPSC neuronal cultures with recombinant PGRN impacts neuronal outgrowth dynamics, resilience towards neurotoxic stress and neuronal function. This work aimed to explore the feasibility of using commercially-available human iPSC glutamatergic neurons as a tool to investigate neuronal structure and function concerning disease with direct application to understanding the influence of progranulin, a common causal genetic risk factor for FTD (Baker et al., 2006; Cruts et al., 2006) on relevant phenotypic endpoints.

## MATERIALS AND METHODS

### Culture of iPSC-Derived Neurons

iCell® GlutaNeurons (GNs; FUJIFILM Cellular Dynamics Inc., FCDI) are human cells differentiated from a master bank of stably induced pluripotent stem (iPS) cells from normal donors (stemcell.com). The iPS cell lines were generated from human peripheral blood through ectopic expression of reprogramming factors (i.e., Oct4, Sox2, Nanog, Lin28, Klf4, L-Myc, and SV40LT) by episomal transfection. The iPS cell clones were then engineered using nuclease-mediated methodologies to exhibit neomycin resistance under the control of a neuronal-specific promoter. GNs were cultured according to the manufacturer's protocol. Clear, flat-bottom 96-well plates (Corning) were coated with 0.01% poly-L-ornithine (PLO, Sigma-Aldrich) for a minimum of 1 h at room temperature. After three washes with PBS (Thermo Fisher Scientific, Waltham, MA, USA), the wells were coated with 0.028 mg/ml Growth Factor Reduced Matrigel (Corning) for at least 1 h in a 37°C incubator. Cells were thawed for 2 min in a 37°C water bath, then slowly equilibrated by the dropwise addition of room-temperature

complete medium [BrainPhys Neuronal Medium (STEMCELL Technologies) containing iCell<sup>®</sup> supplements (CDI), N-2 Supplement (Thermo Fisher Scientific, Waltham, MA, USA), laminin (1  $\mu\text{g/ml}$ , Sigma-Aldrich), and penicillin-streptomycin (Thermo Fisher Scientific, Waltham, MA, USA)]. The cells were then plated and allowed to recover overnight at 37°C.

For culturing GNs for multielectrode array (MEA) experiments, 48- and 96-well MEA plates (Axion Biosystem, Atlanta, GA, USA) were coated with 80  $\mu\text{l}$  of 0.07% polyethyleneimine (Sigma-Aldrich) diluted in borate buffer for 1 h at room temperature. The plates were then washed four times with sterile water and air-dried overnight in a sterile biological safety cabinet. GNs were thawed as described above and were resuspended in dotting medium (Complete BrainPhys Medium with 11  $\mu\text{g/ml}$  laminin) to reach a concentration of 10 million cells/ml and 7 million cells/ml for 48- (M768-KAP-48) and 96-well plates (M768-KAP-96), respectively. A 10  $\mu\text{l}$  droplet of the cell suspension was then manually dispensed directly over the recording electrode area of each well. Plates were kept for 1 h in the incubator at 37°C before gently adding 300  $\mu\text{l}$  of fresh complete BrainPhys Medium in each well. A 50% medium change was performed 1-day post-plating and then every other day.

### IncuCyte<sup>™</sup> ZOOM Analysis

We utilized the IncuCyte<sup>™</sup> ZOOM Live-Cell Analysis System (Essen BioScience) to perform live imaging assays for neurite outgrowth and cellular toxicity. This system consists of an incubator housing a microscope for the acquisition of phase as well as red/green fluorescent images over a user-defined time range. By leveraging the systems software modules and algorithms, we performed rapid, long-term, and unbiased high-throughput analyses of multiple morphological features in real-time. Using the NeuroTrack<sup>™</sup> module (Essen BioScience), a set of criteria (called a “processing definition”) defining cell bodies and neurites was optimized for GNs to quantify neuronal morphology metrics, including neurite length, the number of neurite branch points, and the number of cell body clusters.

For neurite outgrowth analysis, the following parameters were used for the NeuroTrack<sup>™</sup> software: Cell-Body Cluster Parameters = Segmentation Mode (Brightness), Segmentation Adjustment (0.2); Cleanup = Hole Fill (0  $\mu\text{m}^2$ ), Adjust Size (0 pixels), Min Cell Width (9  $\mu\text{m}$ ); Cell-Body Cluster Filters = Area (min = 290  $\mu\text{m}^2$ ); Neurite Parameters = Filtering (None), Neurite Sensitivity (0.55), Neurite Width (1  $\mu\text{m}$ ). For monitoring cellular morphology during siRNA treatment, the following parameters were used for the NeuroTrack<sup>™</sup> software: Cell-Body Cluster Parameters = Segmentation Mode (Brightness), Segmentation Adjustment (0.9); Cleanup = Hole Fill (0  $\mu\text{m}^2$ ), Adjust Size (0 pixels), Min Cell Width (7  $\mu\text{m}$ ); Cell-Body Cluster Filters = None; Neurite Parameters = Filtering (None), Neurite Sensitivity (0.5), Neurite Width (1  $\mu\text{m}$ ).

For Annexin V analysis, the following parameters were used for the Basic Analyzer<sup>™</sup> software: Phase parameters = Segmentation Adjustment (0.4), Cleanup = Hole Fill (0  $\mu\text{m}^2$ ), Adjust Size (0 pixels), Min Area (40  $\mu\text{m}^2$ ); Green

Channel (Annexin V) parameters = Top hat Radius (60  $\mu\text{m}$ ), Top hat Threshold (2 GCU), Edge split on, Edge split sensitivity (0), Cleanup = Hole Fill (0  $\mu\text{m}^2$ ), Adjust Size (0 pixels).

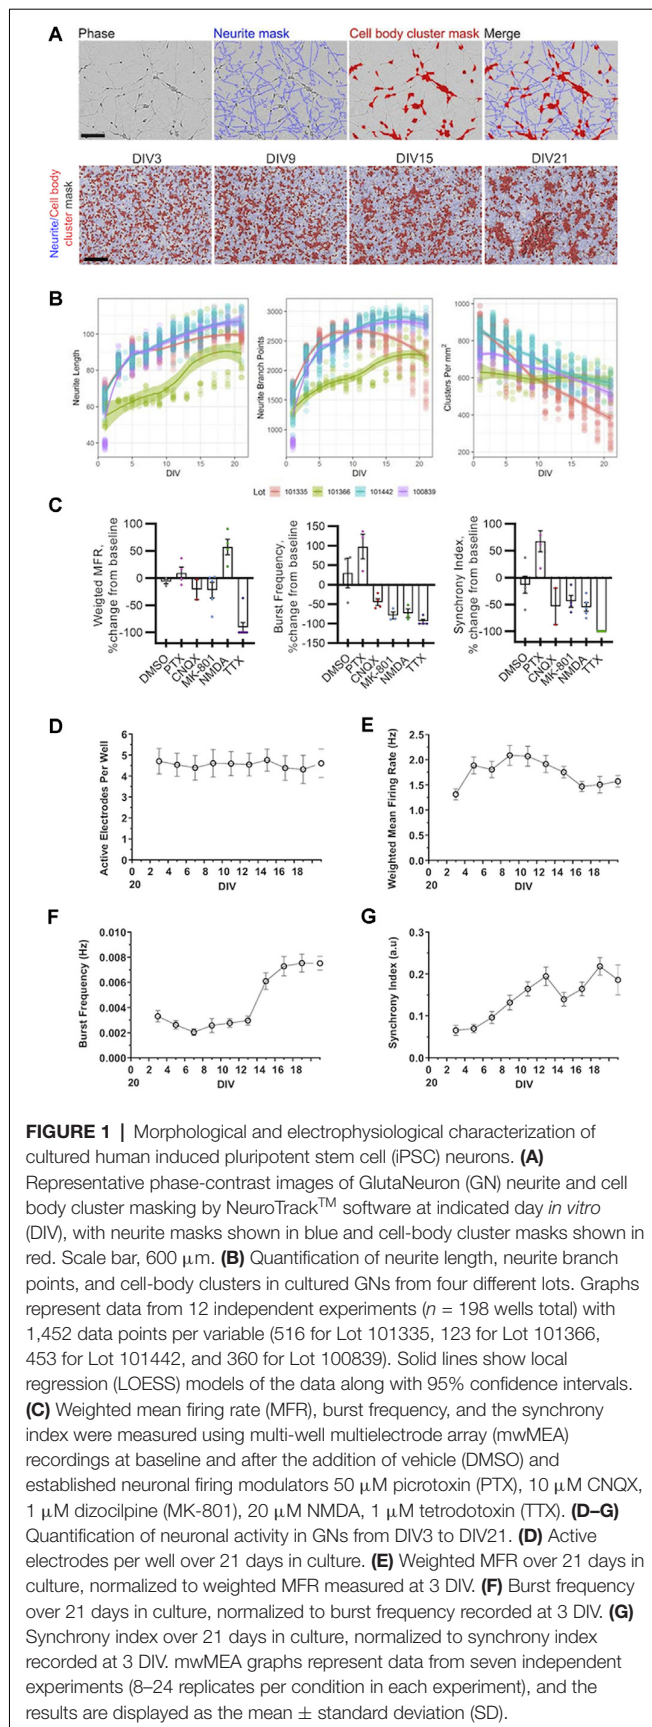

### Neurite Outgrowth Assay

One day after plating (7,000 cells/well), GNs were treated with either PBS (vehicle), 7.41 nM BDNF (PeproTech), 7.41 nM NGF (R&D Systems), concentrations that in previous studies were sensitive to increase neurite outgrowth (Van Damme et al., 2008) or (Thermo Fisher Scientific, Waltham, MA, USA). For all samples, the amount of the vehicle was kept the same. After 50% of the complete medium was removed from the cells, the aforementioned treatments (prepared as 2 $\times$  concentrations) were diluted 1:1 in the remaining medium. Every other day, half of the medium in each well was exchanged with fresh medium containing the appropriate treatments. The cells were imaged using the IncuCyte<sup>™</sup> ZOOM Live-Cell Analysis System (beginning approximately 1 h after the initial treatment); neurite morphology was assessed on the 10th day of treatment. Representative images show that an optimized NeuroTrack<sup>™</sup> processing definition accurately masked neurites for quantification and analysis (Figure 4E). Both neurite length and the number of branch points increased over the 10-day assay, as represented by GNs treated with vehicle (PBS; Figure 4F); this is consistent with the increased neurite growth over time seen in GNs plated at a higher density in previous experiments (Figures 1B,C). To determine the fold-change in the neurite metrics, all measurements at day 10 of treatment were normalized to those of the first imaging time point (i.e., 1 h after the first treatment).

### Neurotoxicity Assay

GNs plated at 25,000 cells/well were treated at DIV14 with IncuCyte<sup>®</sup> Annexin V Green (4642, Essen BioScience Inc.,) at a final dilution of 1:200. Annexin V, a  $\text{Ca}^{2+}$ -dependent phospholipid-binding protein, has a high affinity for membrane phosphatidylserine, which translocates from the inner side of the plasma membrane to the cell surface during the early stages of apoptosis (Andree et al., 1990; Koopman et al., 1994). Neuronal toxicity was induced by treating the cells with staurosporine, a nonselective protein kinase inhibitor (STS, Enzo Life Sciences) at 0.1  $\mu\text{M}$ . Vehicle (PBS, Thermo Fisher Scientific, Waltham, MA, USA), 2.2 nM recombinant NGF (Human  $\beta$ -NGF, R&D Systems), 3.7 nM recombinant BDNF (R&D Systems) or a concentration range of PGRN Recombinant Human Progranulin/PGRN (R&D Systems, Thermo Fisher Scientific, Waltham, MA, USA) was co-added to the STS treatment as indicated. For all samples, the amount of the vehicle was kept the same. After 50% of the complete medium was removed from the cells, the treatments mentioned above (prepared as 2 $\times$  concentrations) were diluted 1:1 in the remaining medium. Every other day, half of the medium in each well was exchanged with fresh medium containing the appropriate treatments. The cells were imaged using the IncuCyte<sup>™</sup> ZOOM Live-Cell Analysis System

(Essen BioScience; beginning approximately 1 h after the initial treatment).

## siRNA-Mediated Gene Knockdown

The Accell Human *GRN* siRNA SMARTpool (E-009285-00-0050) and Accell Non-targeting Pool (D-001910-10-50) were purchased from Dharmacon. The target sequences of the *GRN* SMARTpool are GUGCUGUGUUAUGGUCGAU, GAGAUGUCCCCUGUGAUAA, UUGUCCAGCUCGGUCAUGU, and GUGUUUCAAUAAAGUUU. The target sequences of the Non-targeting Pool are UGGUUUACAUGUCGACUAA, UGGUUUACAUGUUUCUGA, UGGUUUACAUGUUUC CUA, and UGGUUUACAUGUUGUGUGA. The siRNA was reconstituted to 100  $\mu$ M with 1 $\times$  Dharmacon siRNA Buffer (B-002000-UB-100) and added directly to the GN media immediately before use. All experiments using siRNA were done with 70,000 GNs per well in 96-well plates. The first 50% media change on the day *in vitro* (DIV) three was done with 2 $\times$  concentrated siRNA to achieve the desired concentration of siRNA in each well. All subsequent 50% of media changes were done with freshly added 1 $\times$  siRNA to maintain the desired siRNA concentration during the culture.

## RNA-Sequencing (RNA-Seq)

Plates containing GNs were washed with PBS and then frozen at  $-80^{\circ}\text{C}$  until they were thawed for RNA purification using the RNEasy UCP Micro Kit (Qiagen #73934). Four independent experiments were performed (two using lot 100839 and two using lot 101442), and there were five to six technical replicate wells per condition per experiment. The lysates from technical replicate wells were combined before RNA purification to yield sufficient quantities of RNA for RNA-Seq. PolyA RNA was isolated using the NEBNext® Poly(A) mRNA Magnetic Isolation Module, and barcoded libraries were made using the NEBNext® Ultra II™ Directional RNA Library Prep Kit for Illumina® (NEB, Ipswich, MA, USA). Libraries were pooled and single-end sequenced ( $1 \times 75$ ) on the Illumina NextSeq 500 using the High output V2 kit (Illumina Inc., San Diego, CA, USA). Transcript level quantification was generated using *Salmon* (v0.8.2; Patro et al., 2017), and an index was built using cDNA sequences from the human genome assembly GRCh38 ([ftp://ftp.ensembl.org/pub/release-92/fasta/homo\\_sapiens/cdna/Homosapiens.GRCh38.cdna.all.fa.gz](ftp://ftp.ensembl.org/pub/release-92/fasta/homo_sapiens/cdna/Homosapiens.GRCh38.cdna.all.fa.gz)). Gene abundance estimates were created with *Tximport* (v1.8.0; Soneson et al., 2015) using a tx2gene file containing Ensembl transcript IDs and their associated HGNC symbols. Samples were assigned to one of fifteen possible groups based on treatment type and day *in vitro* (DIV; Untreated\_DIV7, *GRN*\_siRNA\_DIV7, Control\_siRNA\_DIV7, et cetera), and a DESeqDataSet was constructed using a design formula of ~group in *DESeq2* (Love et al., 2014). Genes with count means of less than five were removed before principal component analysis (PCA) and pairwise comparisons. Differential expression was determined using the *DESeq2* default of a Benjamini–Hochberg adjusted  $p$ -value cutoff of 0.10. Gene ontology (GO) analysis was performed using the Overrepresentation Enrichment Analysis method of WebGestalt (Wang et al., 2017) with

“geneontology” selected as the functional database. Note that the RT-PCR presented in **Figure 7B** is from the same samples we used for RNA-Seq. The RT-PCR data shows reduced GRN expression in treated samples. This validation our RNA-Seq data, which similarly demonstrated reduced GRN expression through an orthogonal method. RNA-Seq data are publicly accessible at the Gene Expression Omnibus under Accession GSE157573.

## Quantitative Reverse Transcription PCR

Gene expression in siRNA dose-response experiments was determined using the TaqMan™ Gene Expression Cells-to-CT™ Kit (Invitrogen #AM1728). For the RNA-Seq samples, cDNA was synthesized from 10 ng of total RNA using Superscript III (Invitrogen #18080), and gene expression were analyzed using the standard TaqMan protocol. The TaqMan assays used were: *GRN* (Hs00963707\_g1), *PPIB* (Hs00168719\_m1), *ACTB* (Hs99999903\_m1), and *GAPDH* (Hs99999905\_m1). The fold change of *GRN* relative to reference genes (*ACTB* for dose-response experiments or the mean of *ACTB*, *PPIB*, and *GAPDH* for the RNA-Seq samples) was determined using the comparative Ct method. The R package *drc* was used for dose-response modeling (Ritz et al., 2015).

## Multi-well Multielectrode Array (mwMEA)

The neuronal electrical activity of cultured GNs was acquired using the Maestro MEA system (Axion Biosystem) according to the manufacturer’s guidelines. Briefly, 48- or 96-well plates were inserted in the Maestro machine (set up at 37°C and 5% CO<sub>2</sub> without perfusion) and were recorded using AxIS software (Axion Integrated Studio, Axion Biosystem, version 2.4.2.13). mwMEA plates were composed of 48 wells or 96 wells, with each well containing an array of 16 or 8, respectively, individual embedded nano-textured gold microelectrodes (~40–50 μm diameter; 350 μm center-to-center spacing) with four integrated ground electrodes (Axion Biosystems). Treatment with the control compounds was performed at DIV18–23 with 20 min baseline recording followed by 20 min recording after the addition of 55 μl of a 7× concentration of either 50 μM picrotoxin (PTX, Tocris), 10 μM 6-cyano-7-nitroquinoxaline-2, 3-dione (CNQX, Sigma–Aldrich), 1 μM dizocilpine (MK-801, Sigma–Aldrich), 30 μM *N*-methyl-D-aspartic acid (NMDA, Sigma–Aldrich) or 1 μM tetrodotoxin (TTX, Tocris). For the acute addition of PGRN experiments, GNs were recorded from DIV18 to DIV24 depending on the network maturation, which can be quantified by a synchrony index of ~0.2 (see “Results” section below). To start, a 20 min baseline recording was performed on the 48-well mwMEA plate followed by the addition of 55 μl of a 7× concentration of PGRN (ranging from 0.0014 to 11.4 nM) or PBS. Another 20 min recording was made in the presence of the compound. Then, the compounds were washed out with four 50% media changes. This was followed by a 20 min post-wash recording. Finally, plates were recorded 2 days post-treatment.

For the *GRN* haploinsufficiency experiments, *GRN* or NT siRNA (30 nM) was added 3 days post-plating by replacing 50%

of the medium with 2× siRNA, and a first mwMEA recording was performed the same day for 20 min. From there, neuronal activity of the treated cells was measured for 20 min every other day until DIV21.

The channels of the mwMEA were sampled simultaneously with a gain of 1,200× and a sampling rate of 12.5 kHz/channel. For all recordings, a Butterworth band-pass filter (200 Hz – 3 kHz) was applied along with an adaptive threshold spike detector set at 6× standard deviation. Data from the recordings were saved to two different file types simultaneously: a raw data file (\*.raw file) that included all data, and an AxIS spike file (\*.spk file) that included the spikes per electrode with a 1 s bin time. The Axis spike data file was then analyzed using Neural Metric tool software (Axion Biosystem, version 2.2.4) with an active electrode criterion of 5 spikes per min. For a single electrode burst, the Poisson Surprise algorithm was selected with a setting of 10. For the network burst, the Envelope statistic was chosen with a threshold factor of 3, a minimum inter-burst interval of 2,000 ms, a minimum electrode percentage of 50%, and a burst inclusion of 75%.

## RESULTS

### Quantifying the Morphology and Neurite Dynamics of Human iPSC Neurons

First, we characterized key morphological processes in cultured GNs neurons starting at the time of plating. We tracked neurite dynamics in GNs from four separate cell lots over 3 weeks in culture using live-cell imaging. Representative images in **Figure 1A** illustrate the precision of the automatic capture of neurite metrics by our optimized algorithms and the typical morphological progression of the cultures over time from DIV3 to DIV21. As expected, we were able to track and quantify the outgrowth and branching of neurites over time. Additionally, we were able to identify small, discrete groups of cell bodies in younger cultures that over time tended to form larger continuous cell cluster organizations. In general, across multiple lots, we found that neurite length and branching rapidly increased during the first few days in culture and then began to plateau after around DIV7 (**Figure 1B**). The number of defined groups of cells (named cell-body clusters), on the other hand, tended to decrease over time (**Figure 1B**), indicating that the cells and their soma were surprisingly mobile and tended to organize into larger groups as the cultures aged. Notably, we found that, although all lots of GNs showed robust outgrowth of neurites, there was considerable within-lot variation in the overall performance of the GNs in our morphological assays. For example, one lot consistently showed inferior performance across metrics as compared to the three others (**Figure 1**). Taken together, our unbiased live-cell imaging approach allowed us to quantify morphological parameters in commercially-available human iPSC-derived GNs and demonstrated that these cells are a useful tool to study neurite dynamics and the quantitative pharmacology of molecules that potentially modulate this process.

## Quantifying Neural Network Activity in Human iPSC Neurons

Outgrowth and branching of cultured GNs suggest that individual neurons connect into networks. We thus expected that—once neurons extended neurites and connect with each other—spontaneous electrical activity would emerge in the cultures. To capture and quantify dynamics in extracellular membrane potentials in plated excitable GNs (Obien et al., 2015) longitudinally, we plated them on mwMEA.

First, we validated qualitatively that GNs are electrophysiologically active and sensitive to established chemical modulators using our standard plating and cell culture conditions. Our results demonstrate that in GN cultures treatment with the sodium channel blocker TTX, the glutamate receptor antagonist dizocilpine (MK-801), or the AMPA/kainate receptor antagonist CNQX abolished network bursting and reduced synchronization of neuronal firing. Conversely, the addition of the GABA antagonist PTX to GN cultures increased the number of bursts and synchronization of neuronal firing as expected, while treatment with NMDA increased the mean firing rate (MFR; **Figure 1C**).

We then longitudinally measured and analyzed the mwMEA data of cultured GNs without pharmacological treatments. Over 3 weeks in culture, the total number of active electrodes did not change significantly (**Figure 1D**) suggesting that neuronal activity and, thus, neuronal connections between iPSC neurons appeared to be equally distributed across the entire well. However, over time and in particular, during the first few days in culture, an increase in the weighted MFR was evident (**Figure 1E**) concomitantly to the increased neurite growth in the first week after plating, followed by a plateau period afterward (compare timing to that in **Figure 1B**). Therefore, the initial increase in growth of GN neurites and branch points appeared proportional to the increased neuronal connectivity and spontaneous firing as measured by electrical network activity.

Burst frequency sharply increased after approximately 2 weeks in culture (**Figure 1F**). This is consistent with the literature (Tukker et al., 2018) and suggests that synchronized electrical network activity emerges delayed after a sufficient amount of neuronal connections has been established across an *in vitro* neuronal network. The synchrony index is another metric to quantify neuronal synchronization. This metric is based on measuring spike firing events between electrode pairs and comparing them across all electrodes throughout the mwMEA well (Paiva et al., 2010). In the commercially-available human iPSC neurons used in this study, the synchrony index steadily increased over time (**Figure 1G**) suggesting that firing progressively increased during the first 2 weeks and that neural networks mature over time. Thus, after approximately DIV14, relatively mature networks are established that are characterized by synchronous neuronal network burst activity. Taken together, our assessments demonstrate that for at least 3 weeks in culture, commercially-available GNs exhibit spontaneous neuronal activity and bursting behavior that can be leveraged

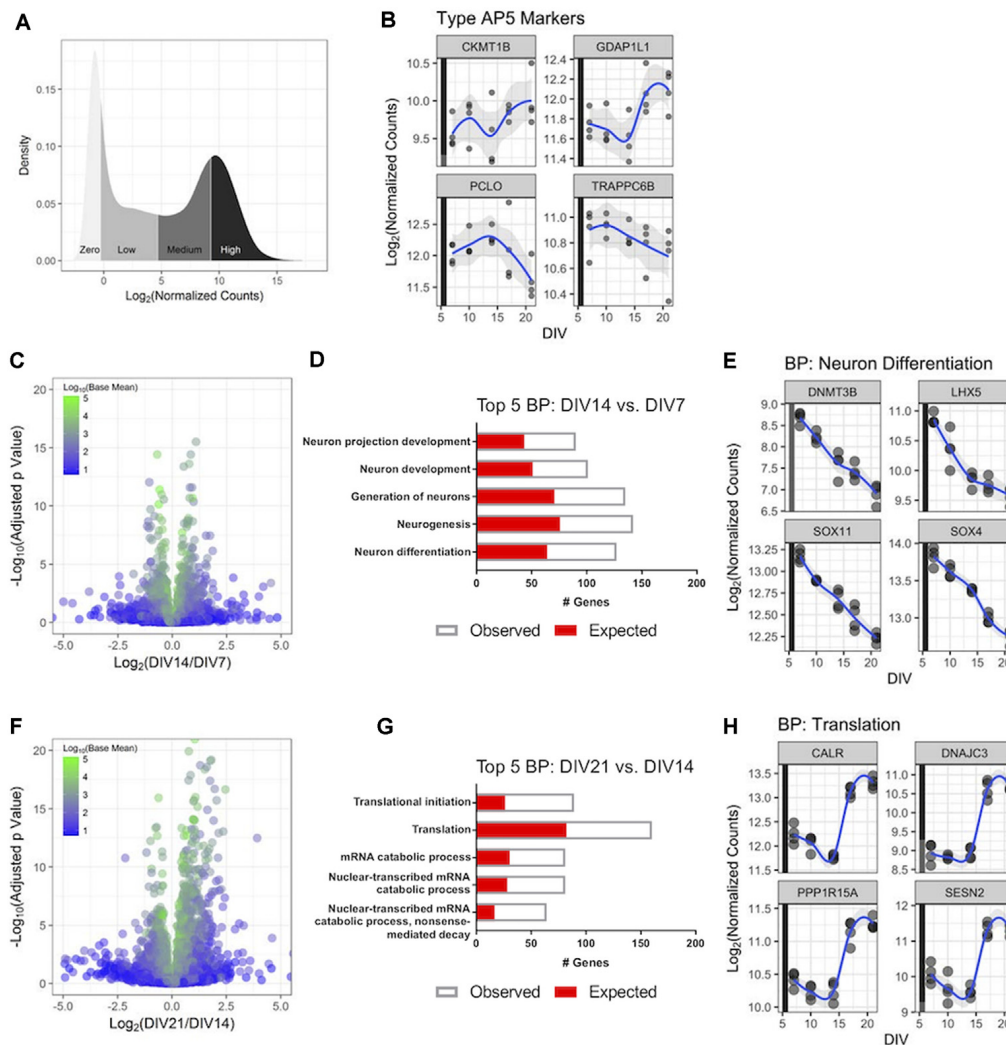

to model human neuronal network development and function using mwMEA.

## Genome-Wide Gene Expression Dynamics in Cultured Human iPSC Neurons

We then aimed to better understand gene expression in cultured GN longitudinally on a genome-wide scale to investigate how GNs transcriptionally mature over time and to validate that GNs express genes relevant to the phenotypic readouts we are interested in, such as neurite dynamics and neuronal firing mentioned above. We monitored and compared the GN transcriptome *via* RNA-Seq after DIV7, DIV10, DIV14, DIV18, and DIV21. We first investigated the distribution of the genome-wide count data for all of the genes in the human transcriptome, broken down into quartiles (**Figure 2A**), and refer to genes within quartiles as having high, medium, and low levels of expression, respectively. Genes with no or very low expression (mean counts <5) were excluded.

Gene expression signatures of GN were compared to published postmitotic iPSC-derived neuron datasets which suggested a classification of iPSC-derived human neurons into less vs. highly mature and active types based on gene expression and electrophysiological features (Bardy et al., 2016). We determined expression levels of the top four genes specifically expressed in the highly functional AP5 human neuron type—*CKMT1B*, *GDAP1L1*, *PCLO*, and *TRAPPC6B*—longitudinally in GNs. All four genes were present in the highest gene expression quartile of all transcribed GN genes (**Figure 2B**) throughout the assayed 3-weeks-long cell culture period revealing that GN are postmitotic and properly differentiated human neurons and transcriptionally similar to highly functional AP5 type neurons. This is consistent with our mwMEA recordings (**Figures 1E–H**) and highlights the utility of GNs for electrophysiology studies in mature human neuronal cultures.

Next, to better understand how cultured GNs transcriptionally mature over time-periods which complement our longitudinal neurite dynamics and mwMEA datasets, genome-wide gene expression dynamics were compared between three key time points (DIV7, DIV14, and DIV21). Around DIV7 a plateau in neurite outgrowth becomes apparent and after ~DIV14 highly synchronous network activity is established, we terminated most experiments for this study at DIV21. Over 1,000 genes were differentially expressed when comparing DIV14 to DIV7 RNA-Seq datasets (536 upregulated, 526 downregulated; **Figure 2C**). An unbiased GO analysis further showed that differentially expressed genes were significantly enriched in the biological processes (BP) neuron differentiation and neuron projection development (**Figure 2D**). For example, the expression of key neuron differentiation genes steadily decreased over time (**Figure 2E**), which is consistent with our neurite dynamics data. The combined results suggest a shift to a morphologically and structurally mature state at DIV14 compared to DIV7. Between DIV21 and DIV14, almost 3,000 genes were differentially expressed (1,678 upregulated, 1,143 downregulated; **Figure 2F**). In particular, the genes involved in mRNA catabolism and translation were significantly

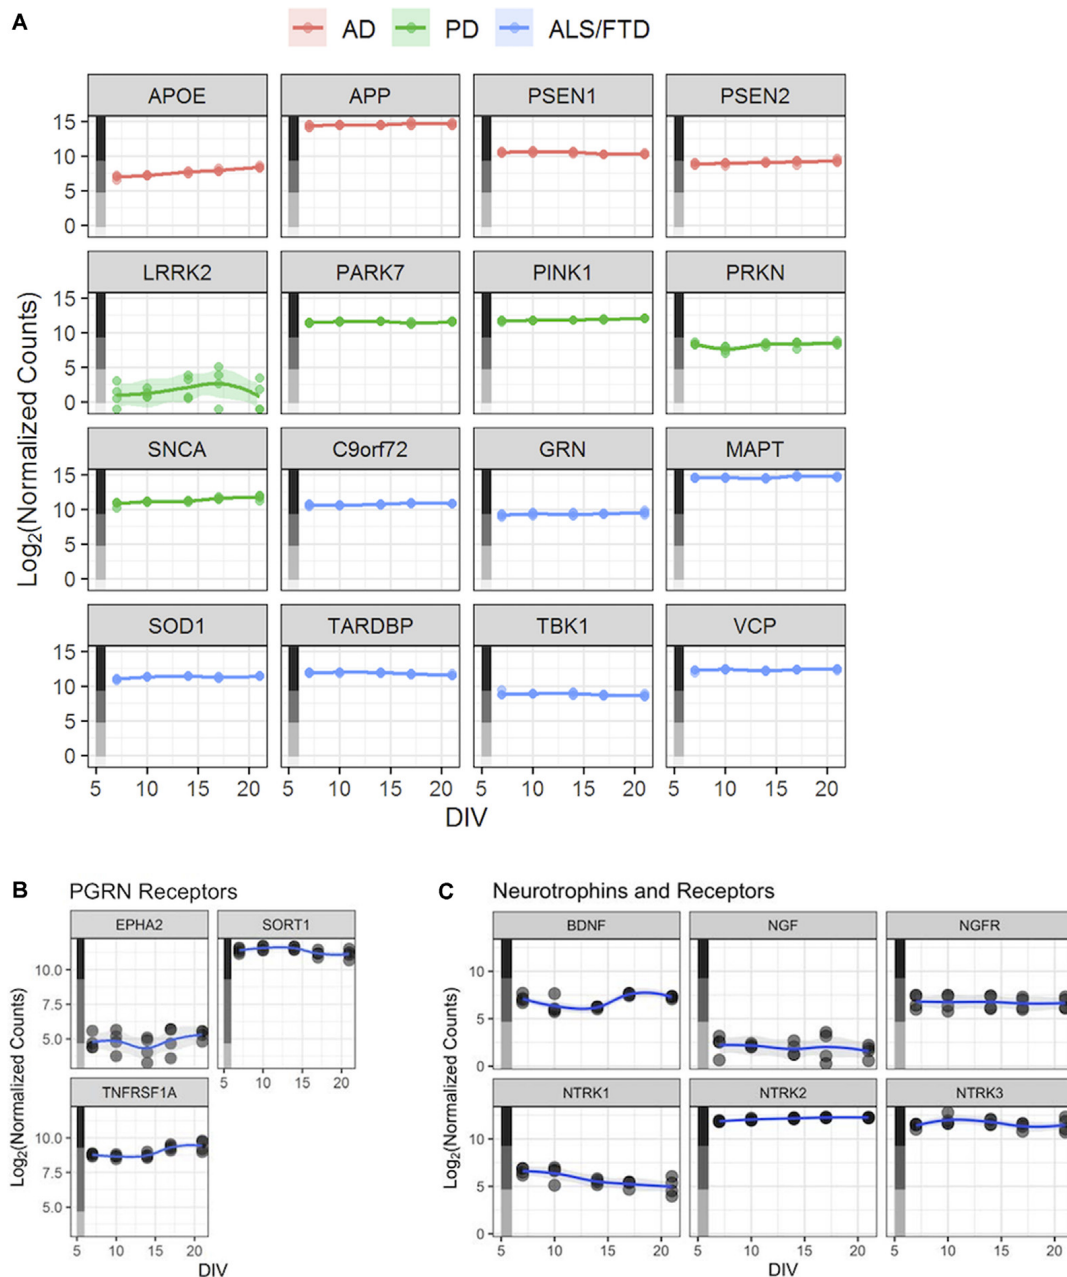

**FIGURE 2 |** RNA-Sequencing (RNA-Seq) profiling of human iPSC neurons during 3 weeks in culture. Untreated GN cultures were collected over 3 weeks in culture, and global gene expression was determined with RNA-Seq. **(A)** Distribution of the RNA-Seq count data for the 27,882 genes measured in the experiment. The y-axis displays the kernel density estimate, and the x-axis displays the normalized count data with each quartile shaded. **(B)** Expression of four genes associated with highly functional (Type AP5) iPSC-derived neurons over time. Each point represents an independent replicate ( $n = 4$  independent replicates per time point), and the blue line shows a LOESS model of the data. The colored stripe on the y-axis indicates the quartile of count values shown in panel **(A)**. **(C)** Volcano plot displaying RNA-Seq data comparing gene expression at DIV14 relative to DIV7. The plot displays 16,591 genes colored according to the mean of their normalized count values across all samples ( $n = 4$  independent replicates per time point). **(D)** The top five biological processes (BPs)—identified by gene ontology (GO) analysis—that were significantly enriched with differentially expressed genes at DIV14 vs. DIV7. The number of genes observed as differentially expressed and the number expected by chance are superimposed. **(E)** Expression values over time for the four most statistically significant genes in the neuron differentiation BP at DIV14 compared to DIV7. Data are displayed as in panel **(B)**. **(F)** Volcano plot of RNA-Seq data comparing gene expression at DIV21 and DIV14 displayed as in panel **(C)**. **(G)** The top five BPs that were significantly enriched with differentially expressed genes at DIV21 compared to DIV14. **(H)** Expression values over time for the four most statistically significant genes in the translation BP at DIV21 compared to DIV14. Data are displayed as in panel **(B)**.

enriched in the GO analysis (Figure 2G), demonstrating that during this time interval the human iPSC neurons are becoming functionally active as evidenced by the sharply increasing expression level of genes representative for the “Translation” group after DIV14 (Figure 2H), which once again mirrored the increased neuronal activity and synchrony we identified using mwMEA (Figure 1G). In all, these transcriptional dynamics highlight relevant developmental stage changes that occur as the GNs progress through 3 weeks *in vitro*.

## Human iPSC Neurons Express Key Neurodegenerative Disease-Linked Genes

A potential utility of these cells could be to facilitate the study of aberrant cellular functions in cellular models of human disease. Our RNA-Seq datasets revealed that expression levels of AD-associated genes *APOE*, *APP*, *PSEN1*, and *PSEN2* were expressed consistently in the medium-to-high quartiles (Figure 3A), with *APP* being the most highly expressed disease gene. Relevant Parkinson’s Disease (PD)-associated genes

**FIGURE 3 |** Human iPSC neurons as a potential tool to study neurodegenerative and other CNS diseases. **(A)** Expression profiles—based on the RNA-Seq dataset described in **Figure 2**—for genes linked to selected neurodegenerative diseases. Each point represents an independent replicate ( $n = 4$  independent replicates per time point), and the line for each graph shows a LOESS model of the data. The colored stripe on the y-axis indicates the quartile of count values shown in **Figure 2A**. Alzheimer's Disease (AD), Parkinson's Disease (PD), amyotrophic lateral sclerosis (ALS), frontotemporal lobe dementia (FTD). **(B)** Expression of three PGRN receptor genes—*EPHA2*, *SORT1*, and *TNFRSF1A*—in untreated GNs. **(C)** Expression of *BDNF*, *NGF*, and their receptors—*NGFR* (NGF receptor gene) and *NTRK1–3* (BDNF receptor genes) in untreated GNs. Data in panels **(B,C)** are displayed as in **Figure 2B**.

*PARK7*, *PINK1*, *SNCA*, and *PRKN* are expressed at medium-to-high levels, while *LRRK2* is expressed at overall lower levels (**Figure 3A**). Finally, amyotrophic lateral sclerosis (ALS)-linked gene, including *SOD1*, and genes causing FTD, including *GRN*, are also robustly expressed in GNs at all assayed time points (**Figure 3A**).

## Progranulin Mediates Neuroprotection in Human iPSC Neurons

Next, we used GNs to understand the quantitative pharmacology of genes with an established role in neurodegenerative diseases in humans. PGRN is a pleiotropic growth factor that modulates diverse BP including neuronal survival and neurite outgrowth,

PGRN mutations cause FTD (Van Damme et al., 2008; Gao et al., 2010; Gass et al., 2012). We analyzed the expression of the putative PGRN receptors (Figure 3B; Hu et al., 2010; Tang et al., 2011; Neill et al., 2016) in GNs. While the expression of *EPHA2* was relatively low, both *SORT1* and *TNFRSF1A* were highly expressed in GNs through the assayed 3 weeks in culture (Figure 3B). To qualify them as potential reference molecules and controls for our phenotypic assays, we verified that the expression of growth factors that have been shown to mediate neuroprotection (Nguyen et al., 2009, 2010) and enhance neurite outgrowths (Drubin et al., 1985; Iwasaki et al., 1998), such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF), BDNF and NGF and their signaling receptors (NTRK1, NTRK2, NTRK3, and NGFR), are robustly expressed in GNs (Figure 3C).

Cortical neurons from an FTD patient carrying mutated *GRN* show increased vulnerability to the neurotoxin staurosporine (Almeida et al., 2012), while the affected growth of iPSC-derived cortical neurons in a separate PGRN-FTD model is rescued by the reinstatement of *GRN* expression (Raitano et al., 2015). *in vitro* rodent studies have established that recombinant PGRN may promote neuronal survival (Van Damme et al., 2008; Ryan et al., 2009; Gao et al., 2010; Guo et al., 2010; Kleinberger et al., 2010; Xu et al., 2011). To complement rodent-derived data, we next quantified the responsiveness of human iPSC-derived GNs to recombinant PGRN in a neurotoxicity assay. GNs were grown uninterrupted for 2 weeks before being treated with 0.1  $\mu$ M staurosporine (STS), an established non-selective protein kinase inhibitor and potent neurotoxin (Rüegg and Burgess, 1989), to trigger apoptotic neuronal death (Koh et al., 1995). To assess neuroprotection, cells were co-treated with either vehicle (PBS), positive controls (recombinant NGF or BDNF; Ichim et al., 2012), or a range of recombinant PGRN concentrations (Figure 4A) while cells were continuously monitored the fluorescence of the added annexin V dye to quantify apoptosis in our live-cell imaging platform. There were considerably more annexin V-labeled cells and annexin V-labeled area after 48-h STS treatment compared to treatment with medium alone, thus confirming STS cytotoxicity and validating the annexin V reagent to track cell death longitudinally (Figure 4B). Co-treatment of cells with either BDNF or NGF significantly lowered STS-induced neuronal death. Similarly, co-treatment experiments with PGRN concentrations of 0.114 nM or higher lead to a significant reduction in cell death compared to treatment with STS alone (Figures 4B,C). Our data complement evidence derived from rodent neurons and demonstrate a neuroprotective role for PGRN also in human GNs.

## No Sensitivity to Growth Factor-Mediated Neurite Dynamics in Human iPSC Neurons

We established a live-cell imaging neurite outgrowth assay using BDNF and NGF as positive controls (Figure 4D; Huang and Reichardt, 2001) to test if recombinant PGRN promotes neurite outgrowth in human GNs, as previously found in rodent neurons (Van Damme et al., 2008; Gao et al., 2010; Wang et al., 2010; Gass et al., 2012; De Muynck et al., 2013). Cells were incubated with recombinant growth factors or PGRN for 10 days,

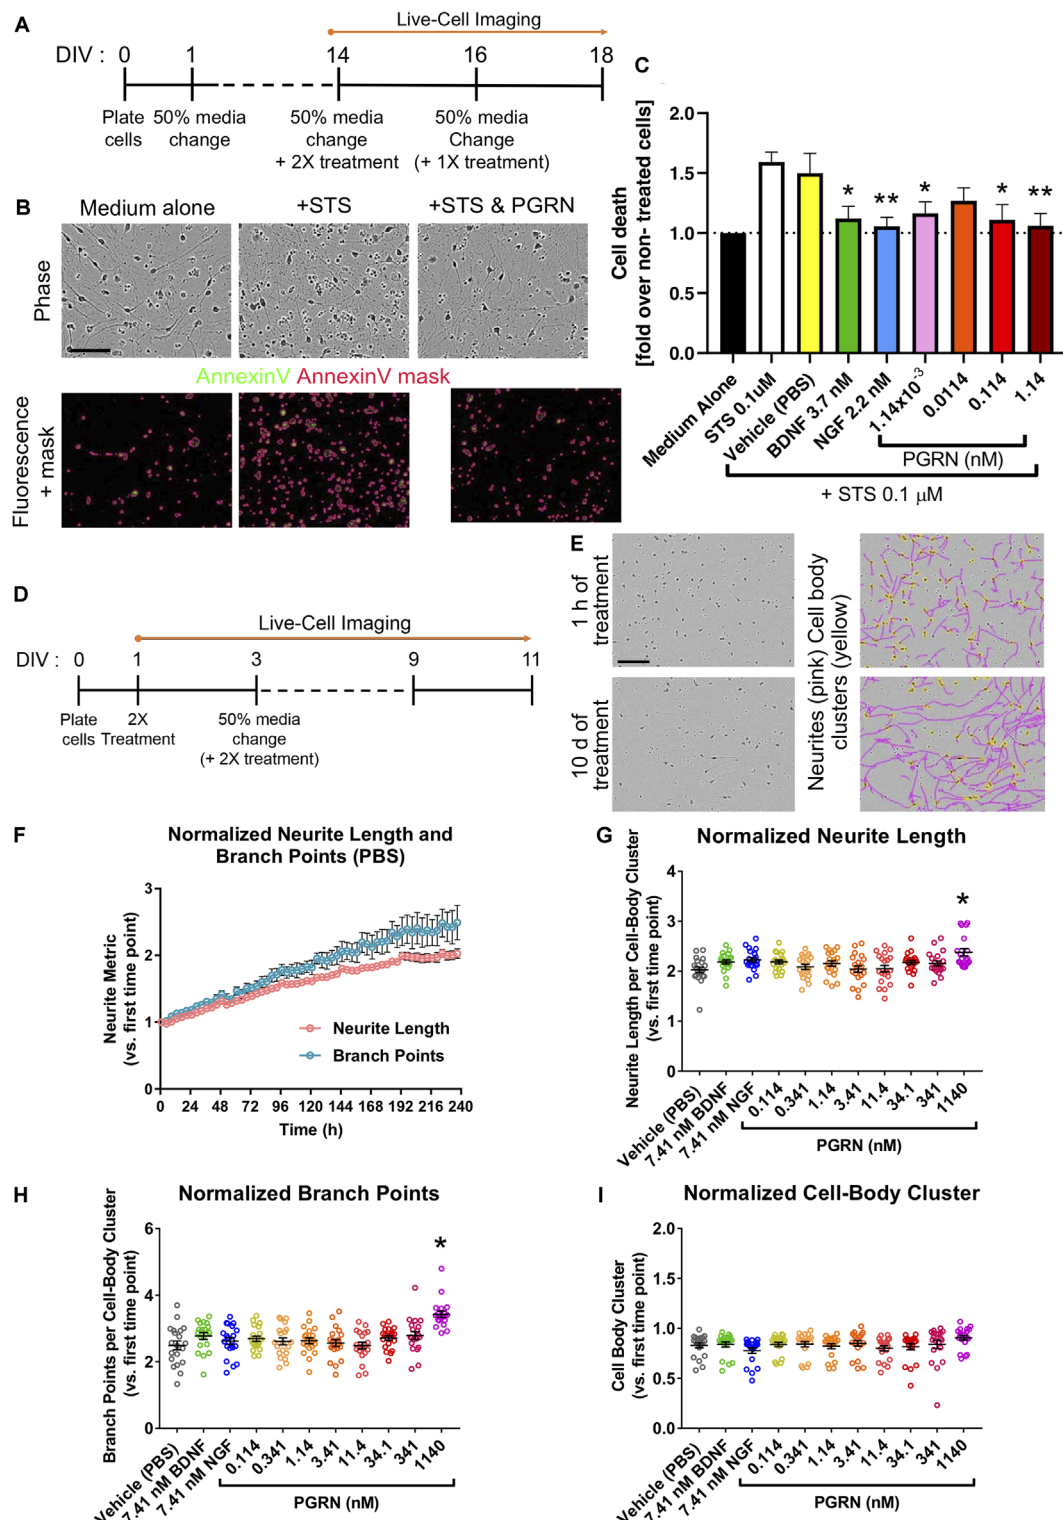

then morphological neurite metrics were analyzed (Figure 4D). BDNF, NGF (Iwasaki et al., 1998; Colombo et al., 2014), and PGRN (Van Damme et al., 2008; Gao et al., 2010; Wang et al., 2010; De Muynck et al., 2013) treatments using concentrations that have been previously shown to increase neurite outgrowth did not affect GNs (Figures 4C,G,H). Only 1,140 nM PGRN, which is  $\sim$ 16,000 times higher than the normal PGRN levels in human CSF (Nguyen et al., 2013), significantly enhanced neurite length in GN cultures. Cell-body cluster number was overall unchanged (Figure 4I), suggesting that captured effect sizes were not masked by variations in plating density, and thus neurite outgrowth in GNs may not be sensitive to physiologically-relevant concentrations of exogenous growth factor proteins.

## Acute PGRN Treatment Increases Neuronal Activity in Human iPSC Neurons

PGRN plays a role in synaptic plasticity (Tapia et al., 2011; Lui et al., 2016), PGRN treatment in murine cortical neurons can modulate aspects of spine maturation and synaptic transmission (Zhang et al., 2017). However, electrophysiological data in human iPSC neurons is lacking. To address this, we cultured GNs on mwMEA plates and exposed them to recombinant PGRN. mwMEA recordings were performed before, during, and immediately after treatment of functionally mature DIV19 GNs, followed by a final recording session 2 days after treatment (Figure 5A). Acute, one-time addition of 0.114 nM PGRN induced a significant increase in the overall firing activity of the cells, measured by the weighted MFR compared to the vehicle (Figures 5B,C). Surprisingly, 2 days after treatment, cells treated with either 0.00114, 0.114, or 11.4 nM PGRN also exhibited an enhanced firing rate compared to vehicle-treated cells (Figure 5C). Burst frequency was not modulated by the addition of PGRN either before or immediately after the washes, but 2 days after treatment a significant increase was observed for GNs that were exposed to 0.114 nM PGRN (Figure 5D). The network burst percentage, a measure of the spontaneous synchronization of burst activity across the network in the well, did not immediately respond to treatments but exhibited a significantly higher burst percentage after the washes up until 2 days after treatment (Figure 5E). The synchrony index (an alternative metric of neuronal synchronization) was not changed significantly, but 0.114 nM PGRN addition showed a trend towards increases network synchrony (Figure 5F). These results suggest that recombinant PGRN can enhance network activity in human iPSC neurons in a sustained manner.

## Using Human iPSC Neurons to Model Frontotemporal Lobe Dementia

To complement our approaches utilizing increased levels of (recombinant) PGRN, we next aimed to develop human cellular assays with decreased PGRN expression using siRNA (Baker et al., 2006; Cruts et al., 2006). First, we tested three different pools of self-delivering siRNAs in GNs, and found that in each tested pool we produced nearly complete knockdown of their target at 72 h (Figures 6A–D). To assess possible off-target effects of long-term siRNA exposure on neuronal health, morphology, and outgrowth, GNs were treated with a

Scale bar, 400  $\mu\text{m}$ . **(C)** Measured by annexin V staining-covered area, graph shows the fold change of cell death and toxicity concerning untreated wells. Cells were untreated (medium alone) or co-treated with STS and recombinant PGRN, BDNF, or NGF. The graph represents data from 4 or 10 independent experiments (three replicates per condition in each experiment). Results are displayed as mean  $\pm$  SD. For all graphs,  $*p < 0.05$ ;  $**p < 0.01$  (one-way ANOVA with Dunnett's *post hoc* test, all conditions compared to STS treated wells). **(D)** Schematic of the neurite outgrowth assay. Dashes represent 50% media changes (containing treatments in double concentration: 2 $\times$ ) every other day. **(E)** Representative phase-contrast images and the masking of neurites utilizing the NeuroTrack™ software in the IncuCyte™ system. Images and masks were used to quantify neurite length and neurite branch points. Example images show PBS vehicle-treated GNs; images show masked neurites (pink) and cell body clusters (yellow) after 1 h and after 10 days of treatment. Scale bar, 600  $\mu\text{m}$ . **(F)** Quantification of neurite length and neurite branch point measurements for vehicle-treated GNs. Each data point represents the mean  $\pm$  SEM for four to five independent experiments (four replicates per experiment). **(G–I)** Quantification of neurite metrics after 10 days of treatment with either vehicle (PBS), 7.41 nM BDNF, 7.41 nM NGF, or a range of PGRN concentrations. All graphs represent data from five independent experiments (four replicates per condition in each experiment). Results are displayed as mean  $\pm$  SEM. For all graphs,  $*p < 0.0001$  (one-way ANOVA with Dunnett's *post hoc* test, all conditions compared to vehicle). **(G)** Neurite length per cell-body cluster (normalized to the measurement at the first imaging time point). **(H)** Neurite branch point number per cell-body cluster (normalized to the measurement at the first imaging time point). **(I)** Cell-body cluster number (normalized to the measurement at the first imaging time point).

range of non-targeting (NT) siRNA concentrations, and their morphology was quantified. The highest concentration of NT siRNA tested (1,000 nM) caused extensive clustering of GNs at DIV21 (**Figures 6E,H**) and impeded neurite growth, but the tested lower concentrations of NT siRNA were well tolerated (**Figures 6F–H**).

We then studied the impact of various levels of GRN siRNA on GRN mRNA expression at DIV21 (**Figure 7A**). GRN mRNA was nearly undetectable in cells treated with 300 nM siRNA. A log-logistic dose-response model was fit to the GRN siRNA data (top =  $1.073 \pm 0.034$ , slope =  $0.941 \pm 0.111$ ,  $ED_{50} = 10.45 \pm 1.43$  nM). This model indicated that 10 nM siRNA produced  $\sim 50\%$  knockdown at DIV21, further experiments showed that 30 nM siRNA produced  $\sim 50\%$  knockdown at DIV10 (**Figure 7B**). As expected in our approach to continuously replenish siRNA, the effects of 30 nM siRNA were more pronounced at the endpoint ( $71 \pm 5.8\%$  knockdown). We chose to continue using 30 nM siRNA for our experiments because it produced an approximated GRN haploinsufficiency in the time window that was most-relevant for our phenotypic assays (between  $\sim$ DIV10 and  $\sim$ DIV15) without noticeable off-target effects (**Figures 6F–H**).

## GRN Knockdown Does Not Impact the Transcriptome in GNs

Global gene expression abnormalities are present in human post mortem GRN-FTD brain samples (Chen-Plotkin et al., 2008). Next, we used RNA-Seq to determine if additional genes were changed in the GNs treated with 30 nM GRN siRNA or NT siRNA for up to DIV21 (**Figure 7B**). A PCA was used to reveal factors that modulate gene expression variance among samples.

The first identified principal component was DIV, which accounted for 26% of the variance in the data (**Figure 7C**). This is not surprising given the expected developmental changes in gene expression (**Figures 2C,F**). The second principal component was the lot of GNs, which accounted for 8% of the variance (**Figure 7D**). The very little variance was due to the presence of either siRNA itself, as data from NT siRNA-treated cells were grouped with that from untreated cells. Surprisingly, knockdown of GRN also had little impact in the PCA (**Figure 7C**), which suggests that reduced GRN expression did not significantly affect the GN transcriptome. This was confirmed by pairwise analyses of the NT siRNA and GRN siRNA sample groups at DIV7, DIV14, and DIV21 (**Figures 7E–G**). This unbiased analysis detected significant decreases in GRN mRNA at DIV 14 and 21, which validated the RT-PCR data shown in **Figure 7B** and demonstrated that the study was powered to detect similar changes in other genes if they existed. We conclude that siRNA-mediated GRN knockdown in GNs under the current culture conditions did not affect global gene transcription signatures.

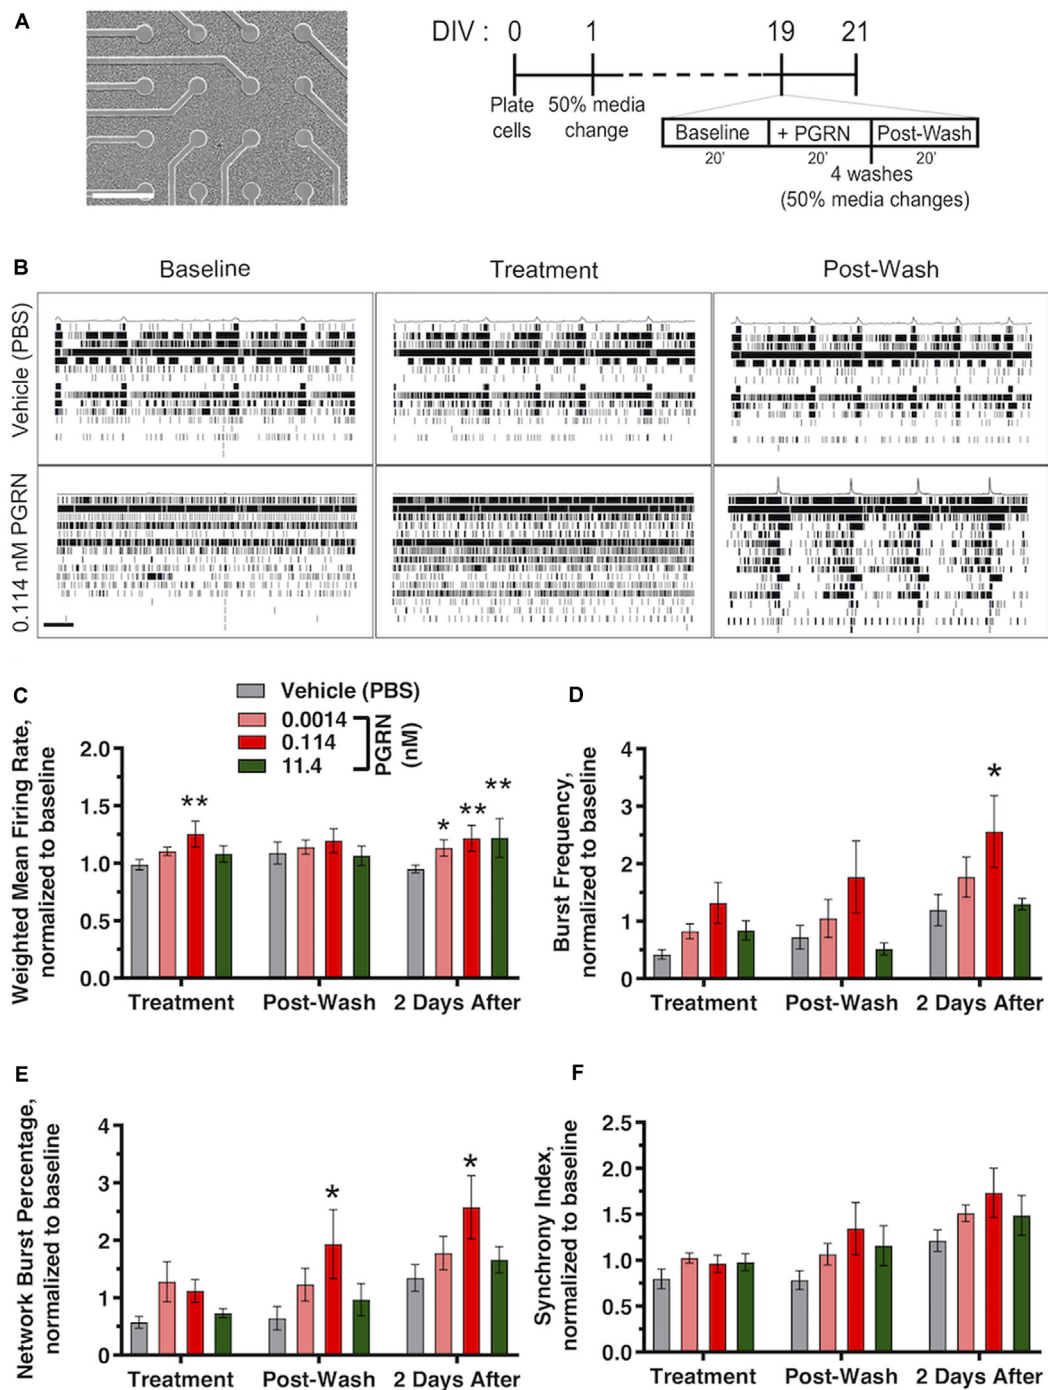

## GRN Knockdown Does Not Affect Neurite Dynamics in Human Neurons

Full GRN knockout rodent cortical and spinal cord neurons have decreased outgrowth and neurite complexity *in vitro* (Van Damme et al., 2008; Gao et al., 2010; Wang et al., 2010; De Muynck et al., 2013). Some neurons, including in the amygdala, may also show reduced neurite complexity in 6–9-month-old heterozygous GRN knockout mice *in vivo* (Arrant et al., 2016). We investigated next if the neurite dynamics are affected in cultured iPSC-derived human GNs with reduced PGRN expression. Automated and unbiased quantitative assessment of morphological features (illustrated by the schematic in **Figure 8A**) revealed that treatment of GNs with 30 nM of GRN siRNA had no significant effect on neurite length, neurite branch points, and density or movement of cell body clusters, compared to NT siRNA or untreated control cells (**Figures 8B–D**). GRN knockdown results mirror those from the recombinant PGRN treatment experiments described earlier (**Figures 4G–I**) and suggest that neurite dynamics in human iPSC-derived GNs under the probed conditions are not sensitive to bi-directional manipulations of progranulin levels.

## GRN Knockdown Does Not Consistently Affect Neuronal Network Activity in Human Neurons

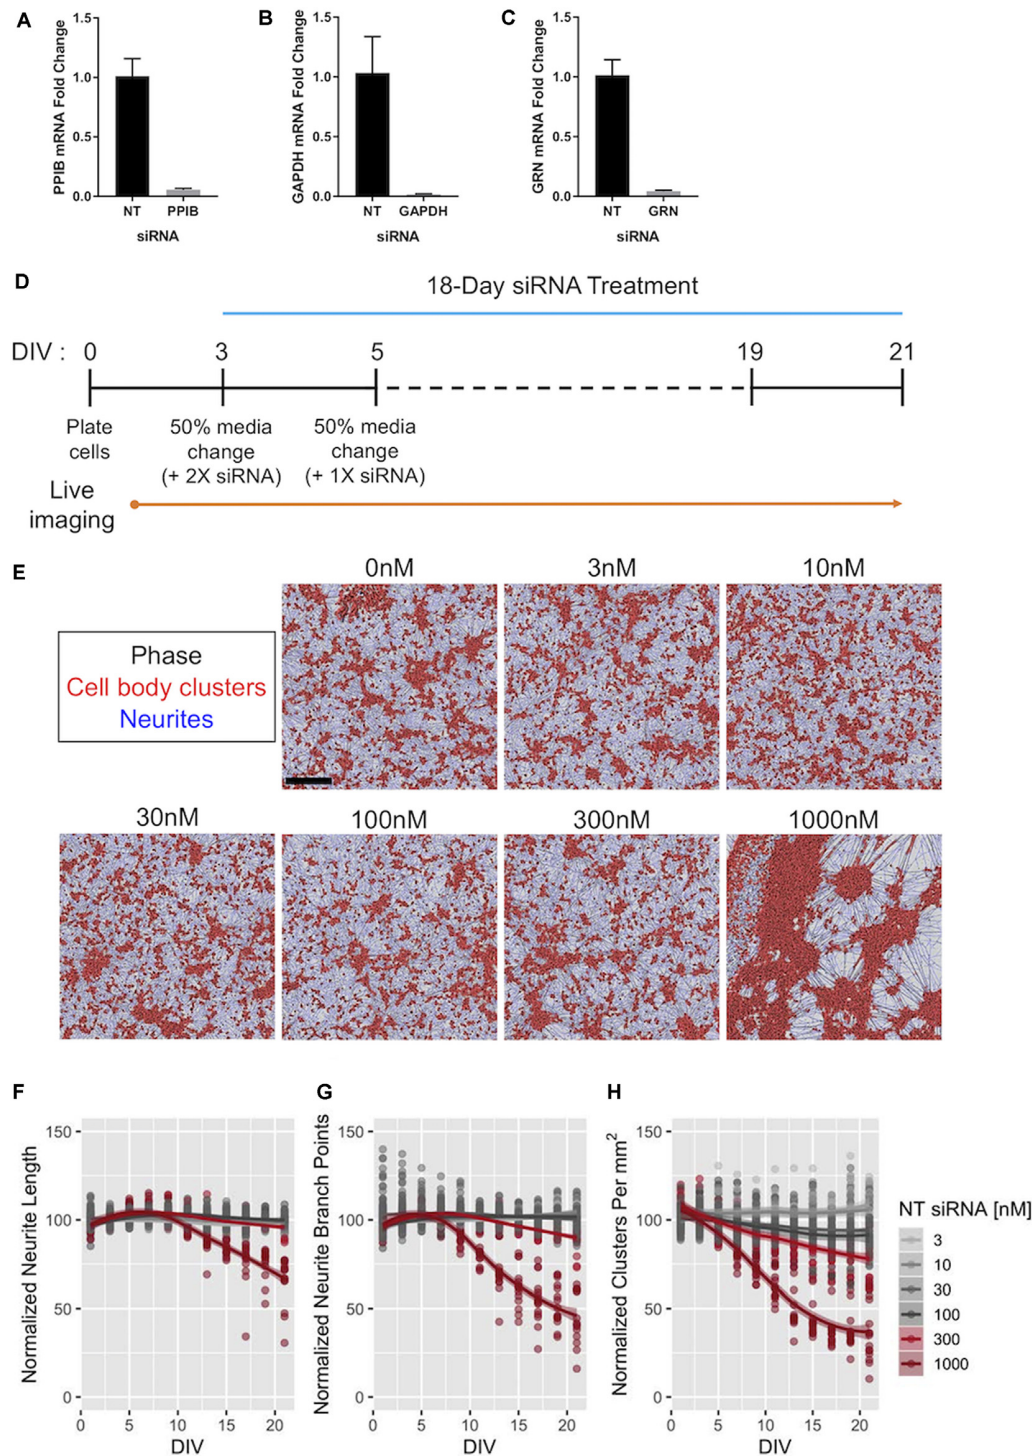

By utilizing mwMEA recordings, we now explored if siRNA-mediated GRN haploinsufficiency in human GNs neurons modulates electrophysiological properties. The mwMEA activity of NT siRNA- and GRN siRNA-treated cells was longitudinally measured every second day starting at DIV3 (the first day of siRNA treatment) up to DIV21 (**Figure 8A**). Throughout the experiments, the number of active electrodes remained relatively constant. Although GRN siRNA-treated measurements trended lower, there was no significant difference between GRN siRNA- and NT siRNA-treated cells (**Figure 8E**). The weighted MFR in GRN siRNA-treated human iPSC neurons showed a consistent trend toward lower neuronal activity over 21 days that only

**FIGURE 5 |** Recombinant PGRN enhances firing and synchronization in cultured human iPSC neurons. **(A)** Representative images of GNs at 19 DIV growing on top of the electrodes of a 48-well mwMEA plate and schematic of the experiment and mwMEA recording. Dashes represent 50% of media changes every other day. Recordings were made before, during, and after PGRN treatment on DIV19; then, an additional recording was performed 2 days later. **(B)** Representative raster plots for neuronal firing before, during, and after exposure to the vehicle (PBS) or 0.114 nM PGRN in DIV19 cells. Each row of the raster plot represents an electrode within a well (16 total), and each black line within the row represents a neuronal spike. Averages of spikes are shown at the top of each raster plot. Scale bar, 20 s. **(C–F)** Quantification of neuronal activity relative to baseline activity in cells during treatment, directly after washes, and 2 days after treatment/washed. All graphs represent data from six independent experiments (two to six replicates per condition in each experiment). Results are displayed as mean  $\pm$  standard error of the mean (SEM). For all graphs, \* $p < 0.05$ ; \*\* $p < 0.01$  (one-way ANOVA with Dunnett's *post hoc* test, all conditions compared to vehicle). **(C)** Weighted mean firing rate (MFR), normalized to baseline weighted MFR recorded before treatments. **(D)** Burst frequency, normalized to baseline burst frequency recorded before treatments. **(E)** Network burst percentage, normalized to baseline network burst percentage recorded before treatments. **(F)** Synchrony index, normalized to baseline synchrony index recorded before treatments.

The data were collected for nine independent (Continued)

**FIGURE 6 |** Continued

experiments ( $n = 183$  untreated wells,  $n = 120$  wells treated with 30 nM, and  $n = 15$  wells for remaining concentrations). All measurements were normalized to the mean of the untreated cells per recording for each experiment. Solid lines show a LOESS fit of the data, and the shaded area represents the 95% confidence intervals of the model (when large enough to display). The concentrations displayed in red were significantly different than untreated cells at DIV21 [ $p_{\text{adj}} < 0.05$ , Tukey's Honest Significant Difference (HSD) test].

reached statistical significance at DIV15 (**Figure 8F**). Consistent to previous experiments (**Figure 1**), the network burst frequency and synchrony index as a measure of neuronal synchrony increased over time in both NT siRNA- and GRN siRNA-treated cells, but no group difference was evident (**Figures 8G,H**). Our assessments of human iPSC neurons with reduced PGRN levels demonstrated no effect on global gene transcription or neuronal morphology and only modest modulation of neuronal firing. In all, our study describes a longitudinal systems-level characterization of GNs and highlights the diversity of phenotypic screening assays and manipulations of target genes that can be performed using these particular commercially-available human iPSC neurons.

## DISCUSSION

Animal-based cellular models drive our understanding of disease biology, but often these tools do not have sufficient translational value for more clinically-relevant human biology. Therefore, in this study, we focused our attention on iPSC-derived neuronal cells as a key technology that is commercially available and, thus, would allow independent validation and wide distribution of the presented tools among the science community to open up this technology also to researchers that are not proficient in iPSC reprogramming. Since comprehensive and longitudinal profiling of human iPSC GNs is lacking, we have characterized systems-level phenotypic neuronal features (neurite outgrowth dynamics, neuronal network function, genome-wide gene expression).

Our longitudinal morphological dataset as a proof-of-principle demonstrates that live-cell imaging of GNs qualifies assay conditions and time points that are appropriate for investigating a given biological question. Furthermore, quantitative pharmacology of compounds that potentially modulate a cellular process can be performed using the assays and conditions outlined in this study. For example, since neurite outgrowth reaches a plateau around  $\sim$ DIV10, GN experiments that focus on studying these neurite dynamics during the phase of strongest growth should be performed before DIV10.

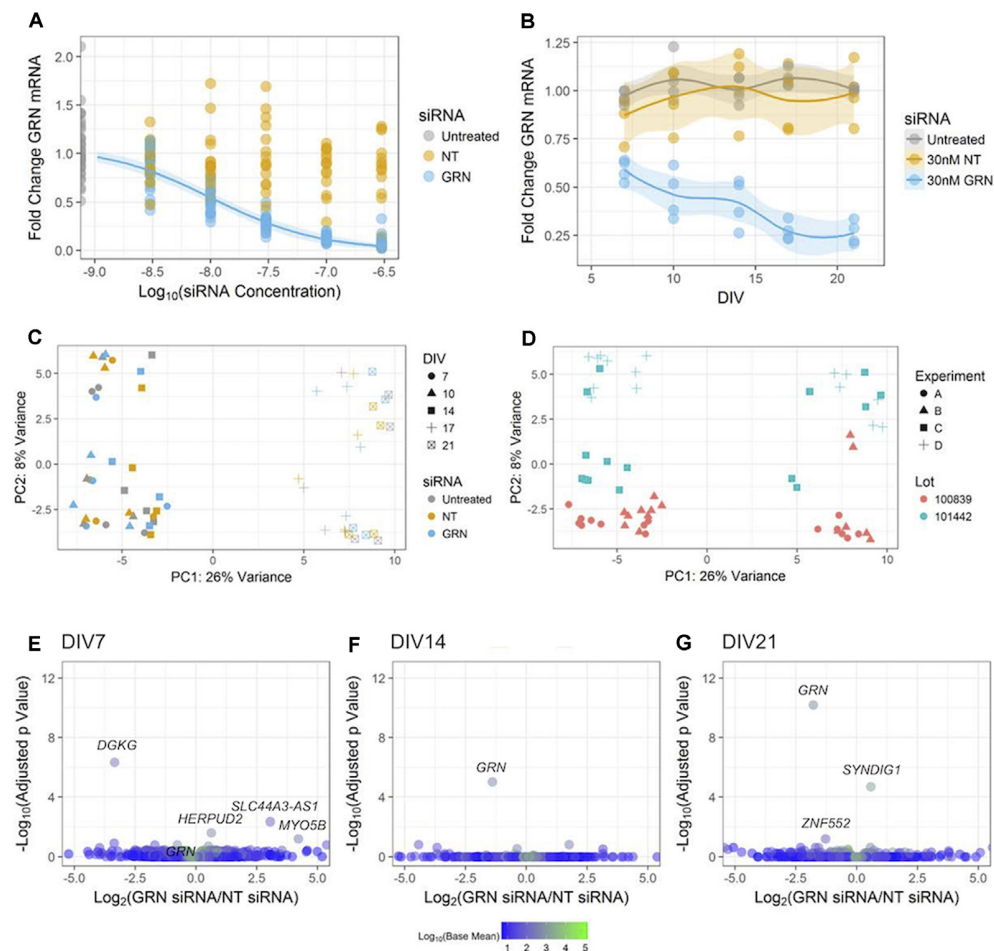

To complement the quantification of morphological features in GNs, we established a long term mwMEA platform that enabled us to quantify the formation and synchronization of functional neuronal network activity in human iPSC neurons. Our results are consistent with previous studies in both rodent and human neurons (Tukker et al., 2018; Odawara et al., 2016; Tukker et al., 2016) and demonstrate that, as neurons grow *in vitro*, they spontaneously form networks that are characterized by electrical activity. Our data further revealed

that GNs need approximately 2 weeks in culture before a robust synchronization of neuronal firing develops across the well (**Figure 1**). Therefore, human iPSC GNs are a valuable tool to study a variety of electrophysiological features and offer ways to robustly quantify (either acutely or over time) how neuronal firing and synchrony may be modulated by genetic or pharmacological manipulations.

The third major arm of longitudinal phenotypic characterization that we performed in GNs was a comprehensive genome-wide gene expression characterization spanning 3 weeks in culture. Our data validate that GNs are of a postmitotic neuronal phenotype and that intrinsic global gene expression is fluid during the *in vitro* culture period. While the first week of culture (growth phase) is characterized by genes that are typically expressed during neuronal development, the second week (maturation and refinement phase) is dominated by neuronal differentiation gene networks. The third week of culture (synchronous and steady-state phase) shows highly expressed gene networks typical for very mature neuronal homeostasis and activity (**Figure 2**). These changes in the gene expression profile over time are consistent and overlap with the developmental progression of the previously quantified morphological and functional features in GNs (**Figure 1**). Besides, our RNA-Seq data also can be utilized for data mining in the context of identifying molecular targets and genes that are associated with neuronal diseases. We show, for example, that GNs express relevant genes that are important for studying growth factors or neurodegenerative diseases including Alzheimer's, Parkinson's, ALS, and FTD (**Figure 3**). To allow additional analyses of our data, data sharing, and combination with other published datasets, our RNA-Seq datasets will be made publicly available at the Gene Expression Omnibus as a resource to study and better understand the longitudinal expression of any gene(s) of interest in GN cultures.

To provide a practical demonstration, we have leveraged our GN datasets to investigate relevant human neurobiology questions in phenotypic assays. For example, we have investigated if growth factor treatment during the initial neuronal outgrowth phase impacts the dynamics of neurite outgrowth; in separate assays, we have quantified if such treatment can mediate neuroprotection and lower apoptotic cell death. One of the key findings of our study is that recombinant progranulin is neuroprotective in human neurons (**Figure 4**). This is noteworthy for at least two reasons: (1) revealing that the potency of PGRN to protect human neurons against apoptosis caused by STS (Almeida et al., 2012) is comparable to that of BDNF and NGF (Aloe et al., 2012; Allen et al., 2013; Kowiański et al., 2018); and (2) this result builds a translational bridge from previous rodent neuronal data (Van Damme et al., 2008; Gao et al., 2010; Gass et al., 2012; Wang et al., 2010; De Muynck et al., 2013) to human neuronal data.

Some involvement of PGRN in synapse biology is prominent in the literature (Tapia et al., 2011; Petoukhov et al., 2013; Yuan et al., 2015; Lui et al., 2016; Meeter et al., 2016; Zhang et al., 2017; Uesaka et al., 2018), but not much was known about the role of PGRN in regulating neuronal firing. Our mwMEA experiments provide evidence that a one-time acute

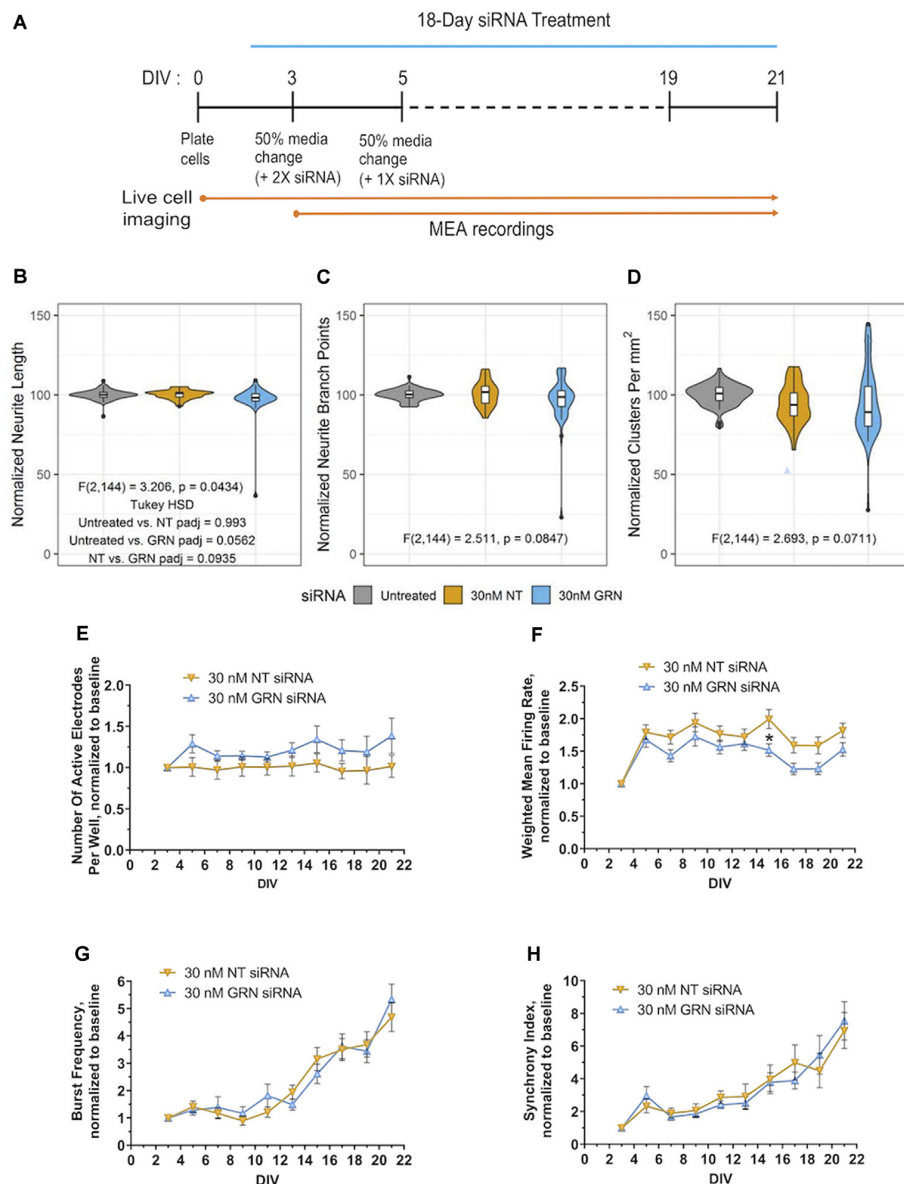

**FIGURE 7 |** Reducing *GRN* expression in human iPSC neurons to model FTD. **(A)** *GRN* mRNA levels were determined using qPCR (with *ACTB* as a reference gene) following 18 days of treatment with the indicated siRNA concentrations. A three-parameter log-logistic model, with a bottom set to zero, was fit to the *GRN* siRNA data and is displayed as a blue line along with 95% confidence intervals. No model converged for the NT siRNA data. Untreated and *GRN* siRNA data come from seven independent experiments ( $n = 36$  untreated wells and 105 *GRN* siRNA wells), while the NT siRNA data come from five independent experiments ( $n = 75$  wells). Gene expression data are not displayed for the highest dose of siRNA used in **Figures 5E–H** due to toxicity. **(B)** *GRN* mRNA expression levels measured using qPCR in GNs treated with 30 nM siRNA and collected at DIV7, 10, 14, 17, and 21 ( $n = 4$  independent replicates per time point for each treatment). The solid line shows a LOESS model of the data, with the 95% confidence intervals displayed in the shaded areas. The mean of *ACTB*, *PPIB*, and *GAPDH* expression was used for the reference. **(C,D)** Principle component analysis of RNA-Seq data from the cells treated with siRNA and collected at DIV7, 10, 14, 17, and 21 ( $n = 60$  samples). The data are displayed according to shape (indicating the DIV) and color (indicating the siRNA) in **(C)**, while **(D)** shows the data with the shape indicating the experiment and the color indicating the cell lot number. **(E–G)** Volcano plots of RNA-Seq data comparing 30 nM of either NT or *GRN* siRNA at DIV7, 14, and 21. Each plot displays 16,591 genes colored according to the mean of their normalized count values across all samples ( $n = 4$  independent replicates per siRNA). The labeled points were statistically significant ( $p_{adj} < 0.1$ ), except for the *GRN* point labeled in the DIV7 plot.

treatment with recombinant PGRN can increase neuronal firing and synchrony in human iPSC neurons (**Figure 5**). Surprisingly, we further found that this effect appears to be long-lasting for at least up to 2 days after treatment. While we currently do not understand which mechanism mediates this activity, future studies that investigate the role of PGRN are warranted including for example to complement our existing data with PGRN overexpression or *GRN* gene editing using e, g, CRISPR technologies.

Our proof of principle approach to model FTD in human neurons *in vitro* using siRNA-mediated *GRN* knockdown demonstrated that GNs combined with other off-the-shelf

reagents can be used to elucidate the functions of disease-associated genes in highly customized isogenic models and assays of human disease (**Figure 6**). At this stage, our analyses of this model are still preliminary and suggest that siRNA-mediated *GRN* knockdown in GNs under the current culture conditions seemingly did not modulate global gene transcription signatures (**Figure 7**), although gene expression defects have been reported in *GRN*-deficient post mortem brains (Chen-Plotkin et al., 2008). We speculate that a *GRN* knockdown of longer than 2–3 weeks could be needed to influence the genome-wide transcriptional landscape more robustly in cultured GNs. It is further difficult to directly

**FIGURE 8 |** Morphological and electrophysiological features in human iPSC neurons with reduced *GRN* expression. **(A)** Schematic shows the repeated siRNA treatment protocol for knocking down *GRN* mRNA in GNs and the time course of the 21 DIVs with live cell imaging and mwMEA recordings. **(B–D)** Violin plots of GN neurite length **(B)**, branch points **(C)**, and cell-body clusters **(D)** at DIV21 following repeated treatment with the indicated concentrations of siRNA for 18 days. The white box plots display the median, with whiskers displayed using the Tukey method. Outliers are shown as black dots. The colored violin plots display the distribution of the data collected from 11 independent experiments ( $n = 69$  untreated wells,  $n = 36$  NT siRNA wells, and  $n = 42$  GRN siRNA wells). The results of ANOVA are displayed in the graph along with the results of Tukey's HSD test when the ANOVA results were significant. **(E–H)** Quantification of neuronal activity in GNs treated with either NT or *GRN* siRNA 30 nM from DIV3 to DIV21. **(E)** Graph showing active electrodes per well over 21 days in culture. **(F)** Plotted weighted MFR over 21 days in culture, normalized to weighted MFR measured at 3 DIV. **(G)** Graphed burst frequency over 21 days in culture, normalized to burst frequency recorded at DIV3. **(H)** Synchrony index over 21 days in culture, normalized to synchrony index recorded at 3 DIV. mwMEA graphs represent data from seven independent experiments (8–24 replicates per condition in each experiment). mwMEA graphs represent data from six independent experiments (two to six replicates per condition in each experiment), results are displayed as mean  $\pm$  standard deviation (SD) \* $p < 0.05$ ; (one-way ANOVA with Dunnett's *post hoc* test, all conditions compared to NT siRNA).

compare our human GN knockdown model, which was designed to mimic haploinsufficiency and have a  $\sim 50\%$  reduction in PGRN levels to previous studies utilizing PGRN-deficient mice. Virtually all phenotypes described previously in rodent neurons were derived from analyzing full PGRN knockout

tissues or cells, which do not express PGRN at all. Additional experiments are needed to more deeply investigate PGRN biology in human cellular models, our study provides a validation of available siRNA tools and a roadmap to demonstrate how our isogenic and scalable knockdown protocol

can be leveraged to manipulate the expression of virtually any gene in the genome in commercially-available human iPSC GNs. In conclusion, we have deeply characterized one commercially-available human iPSC-derived neuronal cell line as a potential translatable tool for fundamental and translational neuroscience research.

## DATA AVAILABILITY STATEMENT

RNA-Seq data are publicly accessible at the Gene Expression Omnibus under Accession GSE157573.

## AUTHOR CONTRIBUTIONS

GR, JE, and DH performed research, analyzed data, and wrote the article. PW designed research and wrote the article. AZ designed research, analyzed data, and wrote the article. All authors contributed to the article and approved the submitted version.

A reliable disease model is critical to the study of specific disease mechanisms as well as for the discovery and development of new drugs. Despite providing crucial insights into the mechanisms of neurodegenerative diseases, translation of this information to develop therapeutics in clinical trials have been unsuccessful. Reprogramming technology to convert adult somatic cells to induced Pluripotent Stem Cells (iPSCs) or directly reprogramming adult somatic cells to induced Neurons (iN), has allowed for the creation of better models to understand the molecular mechanisms and design of new drugs. In recent times, iPSC technology has been commonly used for modeling neurodegenerative diseases and drug discovery. However, several technological challenges have limited the application of iN. As evidence suggests, iN for the modeling of neurodegenerative disorders is advantageous compared to those derived from iPSCs. In this review, we will compare iPSCs and iN models for neurodegenerative diseases and their potential applications in the future.

## INTRODUCTION

Neurodegenerative diseases comprised of a group of complicated disorders of the central nervous system among the aged population. To design effective treatment strategies to cure these diseases, scientists are in desperate need of convenient and reliable disease models. Previous neurodegenerative disease models based on genetic manipulations include transgene integration or gene knockout systems. These systems can only be utilized partially to understand disease mechanisms, pathology, and progression (Hargus et al., 2014; Heilker et al., 2014; Imaizumi and Okano, 2014; Zhao et al., 2014). These current models cannot be used as accurate models for neurodegenerative diseases especially due to specific limitations. First, although the fibroblasts or disease-associated mutation transformed cell lines of patients have enabled detailed mechanistic studies to be carried out, the biology of cell lines does not resemble the biology of primary neurons (Hargus et al., 2014). Thus it is often unclear whether the mechanisms studied are directly comparable to patients' pathology. Second, animal models—such as dogs, flies, monkeys, and especially rodents (Zhao et al., 2014), is another method of studying neurodegenerative diseases (Gitler et al., 2017). However, these models often cannot accurately recapitulate human disease and animal models of the sporadic forms of neurodegenerative diseases due to species-specific differences. In addition, it is difficult to manipulate affected cell types in neurodegenerative disorders *in vitro*. Due to these limitations, a number of preclinical trials that aimed to identify drugs have failed to successfully translate into therapeutics in clinical settings (Kraljevic et al., 2004; Ledford, 2011; Ke et al., 2016). In summary, it is important to develop accurate and predictive disease models as they are essential to providing key insights to understanding disease mechanisms and the development of drugs to cure neurodegenerative diseases.

Innovations in cellular reprogramming technology have provided us with a promising tool to solve this problem. Takahashi and Yamanaka (2006) established a unique method of reprogramming somatic cells to iPSCs, which can be differentiated into cell types of all the three germ layers including non-proliferating neurons. The neurons derived from iPSCs would have the same genetic information as the individual patient and can be differentiated from iPSCs. This technology has been utilized by other investigators for neurodegenerative disease modeling (Table 1; Wan et al., 2015; Haston and Finkbeiner, 2016; Liu and Deng, 2016; Csobonyeiova et al., 2017). Moreover, in recent years, the discovery of direct reprogramming technology has enabled the reprogramming of somatic cells to neurons, bypassing the iPSC stage (Vierbuchen et al., 2010; Ambasudhan et al., 2011; Li et al., 2015, 2017; Karow et al., 2018; Tanabe et al., 2018; Xiao et al., 2018). With the advancement of these technologies, scientists have been able to create highly efficient and lineage-specific neurons through the reprogramming of somatic cells (Marro et al., 2011; Xu Z. et al., 2015; Black et al., 2016; Mall et al., 2017). Altogether, these technologies can be used for modeling neurodegenerative diseases (Shi et al., 2017; Sun et al., 2017; Han et al., 2018; Farkhondeh et al., 2019).

Even though, the mechanisms of iPSCs or iN reprogramming are still unclear (Xu J. et al., 2015; Omole and Fakoya, 2018), there are some obvious differences between iPSCs-derived neurons and iN. Among them, recent studies have indicated that the application of iN for aging-related neurodegenerative diseases would be a better choice, as it does not reset aging information (Mertens et al., 2015, 2018; Tang et al., 2017; Bohnke et al., 2018; Traxler et al., 2019). In this review, we summarize recent studies involving iPSCs and in neurodegenerative disease modeling and its advantages and limitations.

## REPROGRAMMING SOMATIC CELLS TO NEURON CELLS

### iPSC Technology

In 2006, a phenomenal study conducted in Yamanaka lab demonstrated that viral vectors carrying a combination of pluripotent transcription factors, including Oct4, Sox2, Klf4, and c-Myc (OSKM), were sufficient to effectively reprogram mouse fibroblasts cells to iPSCs (Takahashi and Yamanaka, 2006; Okano and Yamanaka, 2014). In 2007, their laboratory also demonstrated that OSKM could reprogram human fibroblasts to iPSCs by the retroviral system (Takahashi et al., 2007). The generated iPSCs had the potential to be differentiated into all three germ layers of cell type with the unlimited ability of self-renewal. Besides OSKM, the combination of other transcription factors, including Oct4, Sox2, Nanog, and LIN28, has also been demonstrated to be able to convert human somatic cells into iPSCs with a lentiviral system (Yu et al., 2007). In addition, this technology has been successfully used for translating into other somatic cell types, such as neural stem cells (Eminli et al., 2008; Kim et al., 2008), stomach and liver cells (Aoi et al., 2008), mature  $\beta$  lymphocytes (Hanna et al., 2008), melanocytes (Utikal et al., 2009), adipose stem cells (Sun et al., 2009), and keratinocytes (Maherali et al., 2008). iPSC technology provides a platform that can be used as a model system for neurodegenerative diseases to design new therapeutics. However, the current iPSC technology still has some limitations, including low efficiency and a long reprogramming process, which are primarily due to the existence of several roadblocks (Ebrahimi, 2015; Haridhasapavalan et al., 2020). Another problem is that iPSCs may cause cancerous tumor formation due to an undifferentiated pluripotent stem cell after transplantation (Choi and Hong, 2017). In recent years, researchers put tremendous efforts into refining and optimizing approaches to improve reprogramming efficiency and safety (O'Malley et al., 2009; Sommer and Mostoslavsky, 2010, 2013; Gonzalez et al., 2011; Morris and Daley, 2013; Omole and Fakoya, 2018; Borgohain et al., 2019; Haridhasapavalan et al., 2019). Maherali et al. (2008) created a doxycycline-inducible lentiviral system including OSKM, which had a higher frequency of converting primary fibroblasts into iPSCs. This system could even reprogram keratinocytes into iPSCs within 10 days (Maherali et al., 2008). In addition, using lentivirus or retrovirus to deliver OSKM may cause insertional mutagenesis when integrating gene sequences in the genomic DNA of the cells. To improve technical safety, other delivery methods, including

non-viral or non-integrating viral vectors, have been attempted, such as protein transduction, the transfection of modified mRNA transcripts, small molecules, sendai virus, and episomal vectors (Sommer and Mostoslavsky, 2010, 2013; Gonzalez et al., 2011; Morris and Daley, 2013; Omole and Fakoya, 2018; Borgohain et al., 2019; Haridhasapavalan et al., 2019). However, compared to the traditional viral gene delivery method, these alternative methods had poorer outcomes.

## iN Technology

After the establishment of iPSC reprogramming technology, researchers are continuously seeking effective ways to improve the reprogramming condition. The main challenge is to rapidly and efficiently change cell fate by reprogramming using minimal transcription factors. In 2010, Vierbuchen and his group succeeded in directly reprogramming mouse fibroblasts to functional neurons by overexpression of three transcription factors, including *Ascl1*, *Brn2*, and *Myt1l* (Vierbuchen et al., 2010). Subsequently, several studies showed some other transcription factors (*Ngn2*, *Ascl1*, and *Dlx2*) also could convert mouse postnatal astrocytes into both GABAergic and cholinergic neurons (Berninger et al., 2007; Heinrich et al., 2011; Xiao et al., 2018; Huang et al., 2019; Wazan et al., 2019). Moreover, only one transcription factor *NGN2*, when supplemented with chemicals including dorsomorphin and forskolin, could directly reprogram human fibroblasts (MRC5) to neurons (Liu et al., 2013) with high efficiency. The neurons generated are functional and mostly cholinergic neurons (Liu et al., 2013). Only epigenetic chemicals without transcription factors have been demonstrated to directly reprogram human and mouse fibroblasts into functional neuron

cells (Hu et al., 2015; Li et al., 2015, 2017; Smith et al., 2016; Qin et al., 2017). Other studies have shown that some defined tissue-specific transcription factors (TFs), such as *Sox2*, *Zfp521* (a single zinc-finger TF), and *Ptf1a*, directly reprogram human fibroblasts into a neural stem cell (Maucksch et al., 2013; Shahbazi et al., 2016; Xiao et al., 2018). In addition, in Rubio et al. (2016) used the CRISPR/Cas9 platform to inactivate two neurological disorder genes, *TSC2* and *KCNQ2* and subsequently combined with a multicistronic lentivirus expressing the *Ascl1*, *Lmx1a*, and *Nurr1* genes to directly convert fibroblasts into neuropathological-resistant neuronal cells. Although several other cell types can also be reprogrammed into neurons, like hepatocytes and pericytes cells (Marro et al., 2011; Karow et al., 2012), fibroblasts are still the most popular original cell type for reprogramming. Together these findings supported that iN can be directly derived from different cell types by certain combinations of transcription factors (Table 2). This technology for the generation of iN from other cell types could be useful for the development of neurological disease models (Ruggieri et al., 2014; Gascon et al., 2017; Gao et al., 2019; Pereira et al., 2019).

## DIRECT REPROGRAMMING TO GENERATE SPECIFIC NEURONAL SUBTYPES

During the early stages, just after the discovery of direct reprogramming technology, investigators paid more attention to the efficacy of reprogramming and whether the neurons generated are physiologically functional. Subsequently,

**TABLE 2 |** Neurons derived from direct reprogramming technology.

Transcription factors	Cell type	Techniques	Neurons type	<i>In vitro/ in vivo</i>	Efficiency	Functional or not	References
ASCL1, NGN2, SOX2, NURR1 and PITX3	human fibroblasts	lentivirus	iN (mostly dopaminergic neurons)	<i>in vivo</i>	~80%	functional electrophysiology	Liu et al., 2011

NGN2 with (Forskolin and dorsomorphin)	human fetal lung fibroblasts	retrovirus	cholinergic neurons	<i>in vitro</i>	>90%	characteristic electrophysiological properties	Liu et al., 2013
LDN193189, SB431542, TTNPB, Tzv, CHIR99021, VPA, DAPT, SAG, Purmo	Human astrocytes	with medium	Functional neurons (mainly glutamatergic neurons)	<i>in vitro</i>	>90%	functional	Zhang et al., 2015
Forskolin, ISX9, CHIR99021 and SB431542	mouse fibroblasts	with medium	iN	<i>in vitro</i>	>90%	functional electrophysiology	Li et al., 2015

investigators tried to control the reprogramming process to convert somatic cells to specific neuronal subtypes. Reprogramming somatic cells into defined neuronal subtypes is a crucial step for the application of iN reprogramming technology into clinical trials. In recent years, technical improvements in this field have made substantial progress, which would dramatically increase the applications of iN technology.

## Dopaminergic Neurons

Parkinson's disease is a neurodegenerative disorder with progressive loss of dopaminergic neurons in the midbrain (Alexander, 2004). Thus, using reprogramming technology for the generation of defined dopaminergic neurons could be an interesting approach for the treatment of Parkinson's disease. According to neuronal system development, several transcription factors play a critical role in the generation and specification of dopaminergic neurons, including Otx2, FoxA1/2 Lmx1a/b, Ascl1, Ngn2, Pitx3, and Nurr1 (Nr4a2) (Arenas et al., 2015). Several studies have reported the successful reprogramming of fibroblasts or astrocytes into induced dopaminergic (iDA) neurons. Among them, the minimal combination is Ascl1, Nurr1, and Lmx1a (Kim et al., 2011; Pfisterer et al., 2011; Torper et al., 2013; Caiazzo et al., 2015). The iDA neurons

that are generated are functional, can produce dopamine, and have firing of action potentials and functional D2 auto receptors (Caiazzo et al., 2011). Moreover, transplantation of these functional iDA neurons could improve the behavior deficit caused by the loss of endogenous DA neurons (Dell'Anno et al., 2014). De Gregorio et al. (2018) found that, when combined with transcription factors ASCL1 and NURR1, miR-34b/c could double the yield of transdifferentiated fibroblasts into dopaminergic neurons. The iDA neurons that are generated synthesize dopamine and showed spontaneous electrical activity and are reversibly blocked by tetrodotoxin, which is consistent with the electrophysiological properties featured by brain dopaminergic neurons (De Gregorio et al., 2018).

## Spinal Motor Neurons

Genetic disorders like Amyotrophic Lateral Sclerosis (ALS) result in the loss of motor neurons (Robberecht and Philips, 2013). Regeneration of new motor neurons is important for potential therapy and disease models for ALS. Studies on mouse models have demonstrated that reprogramming of mouse embryonic fibroblasts into induced motor neurons (iMN) could be achieved by combined overexpression of common transcription factors [Ascl1, Neurog2, Myt1l, and Brn2 (Pou3f2)] with some specific

TFs (Lhx3, Isl1, and Hb9) for spinal cord motor neurons (Lee et al., 2009; Son et al., 2011; Tang et al., 2017; Zhang et al., 2017). These iMN could survive after being transplanted into the spinal cord and are capable of forming a neuromuscular junction with myotube cells *in vitro* (Son et al., 2011). To optimize the reprogramming condition, four TFs (Neurog2, Sox11, LHX3, and Isl1), when supplemented with forskolin, dorsomorphin, and FGF2 could directly reprogram human fibroblasts into motor neurons, which are HB9 and ChAT-positive, have action potentials and can form a neuromuscular junction with extremely high efficiency (>80%) (Liu et al., 2016).

### GABAergic Neurons (Interneurons)

The GABAergic neurons are inhibitory interneurons located in the cortex, which play crucial roles in regulating the excitation and inhibition of nervous system activation (Tremblay et al., 2016). The loss or malfunction of GABAergic neurons would also result in neurological diseases, such as epilepsies, cognitive disorders, autism, schizophrenia, and intellectual disabilities (Woo and Lu, 2006; Brooks-Kayal, 2010; Marin, 2012). Colasante et al. (2015) demonstrated the use of five TFs (Foxg1, Ascl1, Sox2, Dlx5, and Lhx6) for reprogramming human and mouse fibroblasts into induced GABA (iGABA) interneurons. The generated iGABA interneurons could survive and mature after being transplanted into the hippocampus (Colasante et al., 2015). The new iGABA interneurons can form functional synapses, and release GABA (Colasante et al., 2015). Importantly, the transplanted iGABA interneurons can integrate into host circuitry and play inhibitory functions (Colasante et al., 2015). A great part of the GABAergic neurons also showed Parvalbumin (PV) protein and gene expression. Soon after, another research group obtained induced PV (iPV) neurons by *Ascl1* from mouse fibroblasts (Shi et al., 2016). These reports showed that the controlled reprogramming process by some specific regional TFs would lead to lineage reprogramming of neuronal subtypes (Masserdotti et al., 2016).

## iPSCs APPLICATION FOR NEURODEGENERATIVE DISEASES MODELING AND DRUG DISCOVERY

Neurodegenerative diseases including Alzheimer's Disease (AD), Parkinson's Disease (PD) and Amyotrophic Lateral Sclerosis (ALS) are aging-related disorders in which several genetic mutations have been identified before the onset of the diseases. However, even with a clearer understanding of the mechanisms of neurodegenerative diseases, the progression of designing therapy is going slow (Finkbeiner, 2010; Mason et al., 2014; Wyss-Coray, 2016). Based on these genetic mutations, different animal models have been established to study the underlying disease mechanisms and explore the potential drugs for treatment. Unfortunately, due to the variations among different species and the irreproducibility of human disease pathology, current animal models cannot ideally model neurodegenerative diseases as the data generated from these models cannot be successfully translated into clinical applications (Jucker,

2010; Imaizumi and Okano, 2014; Mitumoto et al., 2014). In this scenario, iPSC technology brought new hope for neurodegenerative disease modeling and drug discovery *in vitro*. Nowadays, iPSC technology has been widely applied for disease modeling, mechanism study, and the screening of drugs for neurodegenerative diseases (Figure 1).

### Alzheimer's Disease (AD)

Alzheimer's Disease is the most common chronic progressive neurodegenerative disease. In recent decades, researchers have focused on the study of the pathogenesis of AD. Several genetic mutations have been identified in genes namely, APP, presenilin 1/2 (PS1/2), and APOE, to cause Familial Alzheimer's disease (Armstrong, 2013; Karch et al., 2014; Shen, 2014; Moreno et al., 2018; Wang et al., 2018). However, the mechanisms of the neurons and synapse damage in AD remain unclear. The new iPSC technology from AD patients can provide sufficient quantity or quality neurons for the discovery of potential therapeutics (Byrne, 2014; Tcw, 2019).

In recent years, researchers have been successful in reprogramming fibroblasts carrying with different genetic mutations to iPSCs. Yagi et al. (2011) pioneered the use of iPSC technology to establish an *in vitro* model for AD, which was derived from iPSCs with PS1/2 mutation. The expression of A $\beta$ 42 was dramatically increased in neurons derived from iPSCs (Yagi et al., 2011). In addition to this, the APP gene mutation has also been investigated by Israel et al. (2012). They demonstrated that the levels of A $\beta$ 42 and tau are significantly increased in neurons derived from iPSCs (Israel et al., 2012; Ochalek et al., 2017). Subsequently, studies conducted by several groups of investigators used iPSCs to produce neurons derived to model AD where the properties of pathogenic A $\beta$ 42 and tau were reserved (Shi et al., 2012; Duan et al., 2014; Muratore et al., 2014; Sproul et al., 2014; Chang et al., 2015; Moore et al., 2015; Rowland et al., 2018; Tcw, 2019). In summary, the novel iPSCs *in vitro* model can be utilized as an excellent tool to study AD.

### Parkinson's Disease (PD)

The loss of dopaminergic neurons in the neuropathology of PD, which causes motor problems, including bradykinesia, resting tremor, rigidity, flexed posture, "freezing" and loss of postural reflexes (Seibler et al., 2011; Postuma et al., 2015). Similar to AD, the deficit of reliable *in vitro* models has limited the progression of drug discovery for PD. Several groups obtained iPSCs from patient somatic cells with different genetic mutations including LRRK2, SNCA, PARK2, or PINK1, which are related to familial PD, and the DA neurons derived from iPSCs has been used to investigate the molecular mechanisms (Ke et al., 2019). The dopaminergic neurons derived from LRRK2 iPSCs have some important PD features, including ( $\alpha$ -Syn aggregates, overexpression of oxidative stress genes, lower number of neurites, and caspase-3 activation (Nguyen et al., 2011; Sanchez-Danes et al., 2012). Importantly, after correction of LRRK2 mutation in iPSCs, they can rescue the pathogenic phenotypes of neurite shortening and mitochondrial DNA damage (Reinhardt et al., 2013; Sanders et al., 2014). iPSCs derived from PD patients, who received triplication of the SNCA gene, have also been

shown to have PD pathogenic neuron properties (Oliveira et al., 2015). PARK2 gene mutation has been shown to play a critical role in neuron morphology by iPSCs-derived neuron model (Imaizumi et al., 2012; Ren et al., 2015). In addition, (Seibler et al., 2011) also reported that iPSCs reprogrammed from PD patients' fibroblasts with PINK1 mutations can generate DA neurons. The new DA neurons showed properties of upregulation of PGC-1 $\alpha$ , which can be reversed after overexpression of wild-type PINK1 in new DA neurons. Together, all these studies demonstrated that iPSCs is a better *in vitro* model for PD with genetic mutations.

## Amyotrophic Lateral Sclerosis (ALS)

Induced Pluripotent Stem Cells technology also has been widely applied for ALS. The pathology of ALS includes the progressive loss of motor neurons in the brain and spinal cord. Several genes have been identified to be associated with ALS, such as SOD1, C9orf2, and TDP-43 (Rosen et al., 1993; Sreedharan et al., 2008; DeJesus-Hernandez et al., 2011). Among them, the SOD1 gene mutation is the most studied genetic alteration in ALS. Compare to wild type SOD1, motor neurons (MN) derived from SOD1 mutated patients' iPSCs showed the features of decreased survival rate, smaller soma size, and shorter neurite (Chen et al., 2014; Kiskinis et al., 2014). In addition, MN derived from SOD1 mutated iPSCs showed impaired mitochondrial function and increased oxidative stress (Chen et al., 2014). Importantly, the correction of the SOD1 mutation could rescue these phenotypes in iPSCs (Chen et al., 2014;

Kiskinis et al., 2014). iPSC-derived motor neurons retaining the patients' full genetic information, therefore, scientists established a large number of *in vitro* cellular models for sporadic ALS. The sufficient utility of sporadic ALS models is useful for elucidating the pathological characteristics of specific cases and identifying novel candidate drugs (Fujimori et al., 2018). On the other hand, many investigators have studied the phenotypes of MN derived from C9orf2 mutant iPSCs (Donnelly et al., 2013; Sareen et al., 2013; Devlin et al., 2015; Dafinca et al., 2016). Abnormalities of electrophysiology, calcium homeostasis, ER stress, and mitochondrial membrane potential have been identified in MN from iPSCs carrying C9orf2 mutation (Devlin et al., 2015; Dafinca et al., 2016). In addition, the C9orf2 mutant has been demonstrated to cause oxidative and neurotoxicity in MN from iPSCs (Donnelly et al., 2013; Sareen et al., 2013; Birger et al., 2019).

## iN FOR NEURODEGENERATIVE DISEASE MODELING AND DRUG DISCOVERY

With a specific combination of reprogramming factors, somatic cells can be directly converted into neurons bypassing the iPSC stage. Along with the advancement of direct reprogramming technology, the new generation of iN has also been applied for modeling neurodegenerative diseases and drug discovery (Figure 1). Liu et al. (2016) have used direct reprogramming technology through using a combination of TFs and small

molecules and efficiently reprogrammed ALS patients' fibroblasts to motor neurons with FUS gene mutation. The new iMN from ALS patients was unable to form neuromuscular junctions with muscle cells. Moreover, after the chemical screening, they found the chemical kenpaullone can rescue the disease phenotype. Recently, (Chang et al., 2018) utilized the mesoporous silica nanoparticles (MSNs) as a non-viral delivery system for the transduction of the three key factors to achieve the conversion of mouse fibroblasts (MFs) into functional dopaminergic neuron-like cells. These recent studies are the beginning of developments that will enable us to apply iN for neurodegenerative disease modeling and drug discovery. Before applying this technique for large scale drug screening, the problems associated with efficiency and the homogeneity of direct reprogramming needs to be further improved.

### COMPARISON OF iPSCs-DERIVED NEURONS TO iN

In contrast to the application of iPSC technology, the application of the iN approach is new and emerging in the field of neurodegenerative diseases. Like any technique, iN technology has some obvious advantages and disadvantages (Table 3). Because direct reprogramming does not involve the iPSC stage and the differentiation step, which saves a lot of time, iPSC technology may take several months, depending on the protocol. In addition, the technical challenges of iN are less compared to iPSCs culture technology. The most important difference between iPSCs and iN is epigenetic reset.

As we know, a healthy and diseased person not only differs in genomic levels but also has different epigenetics. Epigenetic information is crucial for disease onset, especially for aging-related diseases. A recent study conducted by Tang et al. (2017) found iPSCs derived motor neurons did not show age-related differences, while iN, in contrast, age-equivalent induced motor neurons showed nuclear envelope defects. Mertens et al. (2015) provided interesting evidence for iN

as it can reserve aging signatures of the original patient, which is not observed in iPSCs. Furthermore, they have also found downregulation of RanBP1 in aged fibroblasts and iN derived from aged fibroblasts, and when RanBP1 was knocked down, the transcriptional markers shifted from young to aged (Mertens et al., 2015). Therefore, iN is a more reliable model for neurodegenerative diseases and drug discovery, which could model natural disease progression, especially age-related information. On the other hand, iPSCs can maintain self-renewal but not iN, which is required for maintenance and stock. Due to the unlimited self-renewal of iPSCs, the neurons derived from iPSCs can be unlimited. Thus, without an iPSC stage, investigators might need to acquire a larger quantity of original cells from a patient to obtain enough iN. In addition, identification of the right combination of transcription factors, the inclusion of chemical compounds (small molecules), and the efficiency of reprogramming are also very important. However, to realize the application of iN in neurodegenerative diseases, the underlying mechanisms of direct reprogramming need to be further addressed.

### CONCLUSION AND PERSPECTIVE

In conclusion, this review has discussed recent iPSCs and iN technology and their application for neurodegenerative disease modeling. Compared them to traditional disease models, both iPSCs and iN are more accurate models for studying diseases and drug discovery. For iPSCs and iN disease models, there are still some challenges that need to be further investigated to optimize reprogramming conditions, especially the efficiency of direct reprogramming and lineage-specific reprogramming. For the modeling of neurodegenerative diseases, iN could be a better model for disease and the development of drugs, without epigenetic reset. In the coming years, we expect there to be extensive improvements in reprogramming technology for the application of iPSCs and iN for disease modeling and drug discovery.

### AUTHOR CONTRIBUTIONS

YZ, XX, and JY performed the literature research and wrote the manuscript. C-LZ and QZ proposed the framework. JH and KA critically revised the manuscript. QZ and JY provided the funding support. All authors read and approved the manuscript.

### FUNDING

This study was partly supported by the National Natural Science Foundation of China (No. 81771262), the Zhejiang Health Science and Technology Project (2016RCA022), Zhejiang Key Research and Development Project (2017C03027), and Zhejiang Provincial Natural Science Foundation of China (LQ20H090005).

TABLE 3 | The different features between iN and iPSCs-derived neurons.

Features	iN	iPSCs-derived neurons
Epigenetics reset	The generation of iN will not reset epigenetic information	Neuron derived from iPSCs will reset epigenetic information
Cell number and maintain	iN cell number is limited by original cell number and reprogramming efficiency, which are uneasy to maintain.	After acquisition of iPSCs, the production of neurons can be unlimited, which are easy to maintain.
Time for acquiring mature neurons	Directly reprogramming somatic cells to neurons only takes several weeks	Obtaining neurons derived from iPSCs will takes several months depending on protocol
Technical Challenges	Generation of iN using direct reprogramming technology is much simpler	iPSC technology of generation iN is complicated
Original cell types	Based on technology, the source for iN is limited (fibroblasts ect.)	The source for iPSCs is variable (fibroblasts, adipose stromal cells ect.)

Shu Z, Pang P, Wu X, Cui S, Xu Y and Zhang M (2020) An Integrative Nomogram for Identifying Early-Stage Parkinson's Disease Using Non-motor Symptoms and White Matter-Based Radiomics Biomarkers From Whole-Brain MRI. *Front. Aging Neurosci.* 12:548616. doi: 10.3389/fnagi.2020.548616

**Purpose:** To develop and validate an integrative nomogram based on white matter (WM) radiomics biomarkers and nonmotor symptoms for the identification of early-stage Parkinson's disease (PD).

**Methods:** The brain magnetic resonance imaging (MRI) and clinical characteristics of 336 subjects, including 168 patients with PD, were collected from the Parkinson's Progress Markers Initiative (PPMI) database. All subjects were randomly divided into training and test sets. According to the baseline MRI scans of patients in the training set, the WM was segmented to extract the radiomic features of each patient and develop radiomics biomarkers, which were then combined with nonmotor symptoms to build an integrative nomogram using machine learning. Finally, the diagnostic accuracy and reliability of the nomogram were evaluated using a receiver operating characteristic curve and test data, respectively. In addition, we investigated 58 patients with atypical PD who had imaging scans without evidence of dopaminergic deficit (SWEDD) to verify whether the nomogram was able to distinguish patients with typical PD from patients with SWEDD. A decision curve analysis was also performed to validate the clinical practicality of the nomogram.

**Results:** The area under the curve values of the integrative nomogram for the training, testing and verification sets were 0.937, 0.922, and 0.836, respectively; the specificity values were 83.8, 88.2, and 91.38%, respectively; and the sensitivity values were 84.6, 82.4, and 70.69%, respectively. A significant difference in the number of patients with PD was observed between the high-risk group and the low-risk group based on the nomogram ( $P < 0.05$ ).

**Conclusion:** This integrative nomogram is a new potential method to identify patients with early-stage PD.

## INTRODUCTION

Parkinson's disease (PD) is a common age-related progressive neurodegenerative disease (Dorsey et al., 2007). PD begins subtly and progresses slowly; thus, when the diagnosis is clear, most patients are in the middle or late stages of the disease. As the use of neuroprotective drugs by these patients has little effect on the speed of PD progression (LeWitt, 2015), an early diagnosis is of paramount importance for identifying disease onset and developing effective treatment plans. Currently, the diagnosis of PD mainly depends on the patient's medical history and clinical symptoms; however, the early stages of PD can include many atypical symptoms such as sleep disorders, decreased olfactory function and cognitive disturbances, and these non-motor symptoms often precede clinical motor signs (Mielke and Maetzler, 2014). Unfortunately, the cardinal and defining nonmotor symptoms used for the early diagnosis of PD in the clinic, particularly the symptoms that are typical of the early stages, also occur in patients with other disorders (Trojano and Papagno, 2018; De Pablo-Fernández et al., 2019), and the diagnostic error rate is as high as 25% among practitioners with limited clinical experience in diagnosing early-stage of PD (Miller and O'Callaghan, 2015). Thus, it is very challenging to diagnose early-stage PD based on current diagnostic standards.

In recent years, progress has been achieved in magnetic resonance imaging (MRI) technology in the field of neuroimaging (Agosta et al., 2017), such as structural MRI (Tzarouchi et al., 2010), diffusion tensor imaging (Schwarz et al., 2013), and blood oxygen level-dependent functional MRI (Benzagmout et al., 2019). These different techniques represent effective methods for non-invasively studying changes in brain morphology and function associated with PD. However, given the high cost of long functional imaging sessions and a general lack of standard imaging protocols, as represented by differences between MRI systems, scanning protocols and magnetic field strength (Frederick and Meijer, 2014), these complex scanning techniques cannot become widespread in clinical practice. Therefore, the identification of a simple, noninvasive measure to preclinically identify patients with early-stage PD is important.

Radiomics is a recently emerged field of radiology that quantifies imaging data with the aid of advanced image processing techniques, including high-throughput analysis and feature selection, to build biomarkers for the complete characterization of tumors (Liu et al., 2019). At this stage, the new quantitative imaging technology of radiomics has already been used to diagnose neurodegenerative diseases, including PD (Shinde et al., 2019). Nevertheless, most PD studies using radiomics examine only the substantia nigra (SN), where iron accumulation is spatially heterogeneous, allowing clinicians to easily distinguish patients with PD from healthy people (Guan et al., 2017). While the SN provides robust disease biomarkers, the concern is that radiomic analysis of the SN depends on the use of a special sequence, such as quantitative susceptibility mapping or neuromelanin-sensitive imaging, to display the contours of the SN. Understandably, the complexity of this technology has limited its clinical application.

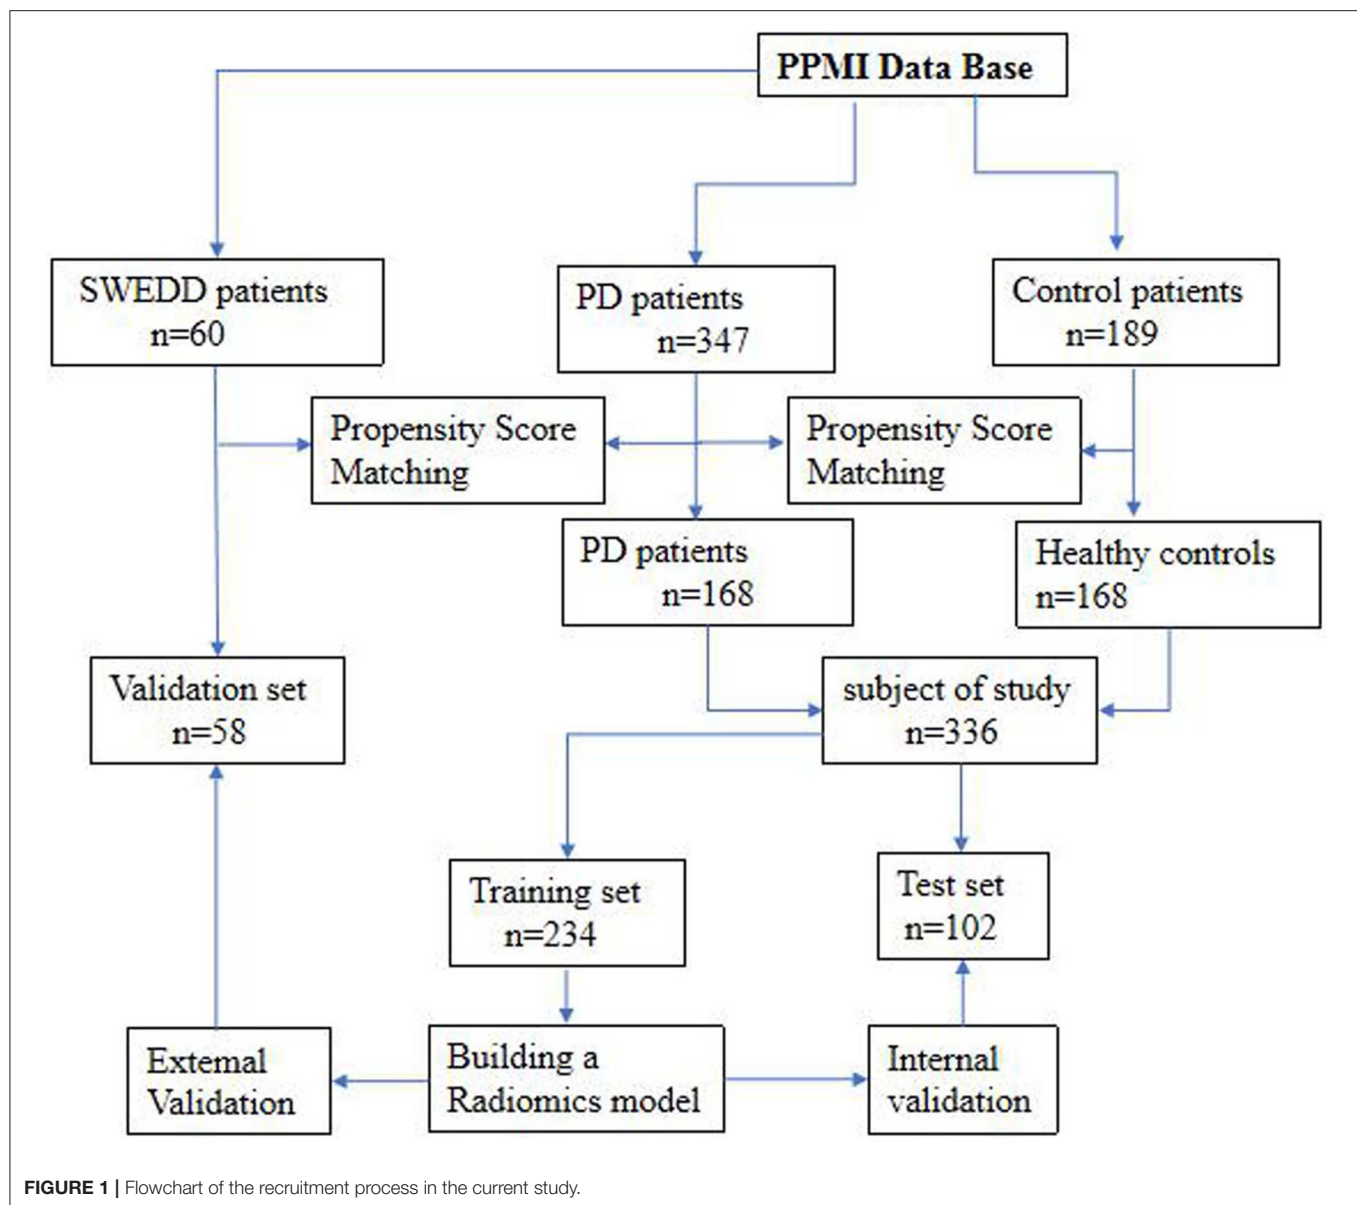

However, the SN of patients with PD is not the only area exhibiting obvious disease-related tissue changes. White matter (WM) has also been reported to exhibit widespread microstructural alterations in patients with early-stage PD in the absence of gray matter atrophy and cognitive impairment (Pelizzari et al., 2020). In addition, several studies have shown widespread WM and gray matter changes in individuals with PD (Muthuraman et al., 2017; Koirala et al., 2019). Hence, an investigation of WM microstructural integrity in patients with PD may enable more successful exploration of early biomarkers of PD. Previous studies based on diffusion tensor imaging have shown that patients with PD present a greater decrease in WM integrity (Pozorski et al., 2018) than healthy people and often display extensive changes in the microstructure of WM in the early stage of PD even before the onset of cortical neuron loss (Rektor et al., 2018). Based on this evidence, structural changes occur earlier than physiological changes in the early stage of PD. Moreover, a three-dimensional radiomic analysis of WM throughout the brain was recently shown to reflect microstructural changes based on conventional T1-weighted imaging sequences (Shu et al., 2020), which may be more suitable than diffusion tensor imaging sequences for clinical application based on cost alone. Accordingly, we hypothesized that the structural changes in WM in patients with early-stage PD would also be detected by a radiomic analysis and would be of potential use for exploring new imaging-based disease biomarkers. To the best of our knowledge, this type of analysis has not yet been performed.

PD is a complex neurodegenerative disorder in which many different pathophysiological processes have been identified in different brain regions. Furthermore, a single WM biomarker will not be able to accurately diagnose and monitor disease progression; rather, a combination of different biomarkers should be used to provide a more comprehensive approach. As shown in previous studies, early diagnosis has been accomplished by the detection of multiple factors including impaired olfaction, depression, rapid eye movement sleep behavior disorder (RBD), excessive daytime sleepiness (EDS) and cognitive decline (CD) (Kalia and Lang, 2015), which usually occur in the prodromal stage of PD (Filippi et al., 2018). Accordingly, the purpose of this study was to explore the possibility of developing novel imaging biomarkers of PD from WM using radiomics and combining them with prodromal nonmotor symptoms to generate an integrative nomogram for disease classification. Overall, we hope to propose a low-cost and highly accurate method for identifying patients with early-stage PD.

## MATERIALS AND METHODS

### Patients

The datasets used to build the model were all obtained from the Parkinson's Progress Markers Initiative (PPMI) database (<http://www.ppmi-info.org>), which is the first global and comprehensive international Parkinson's research database (Parkinson Progression Marker Initiative, 2011). The PPMI is a landmark observational clinical study designed to comprehensively evaluate cohorts of significant interest

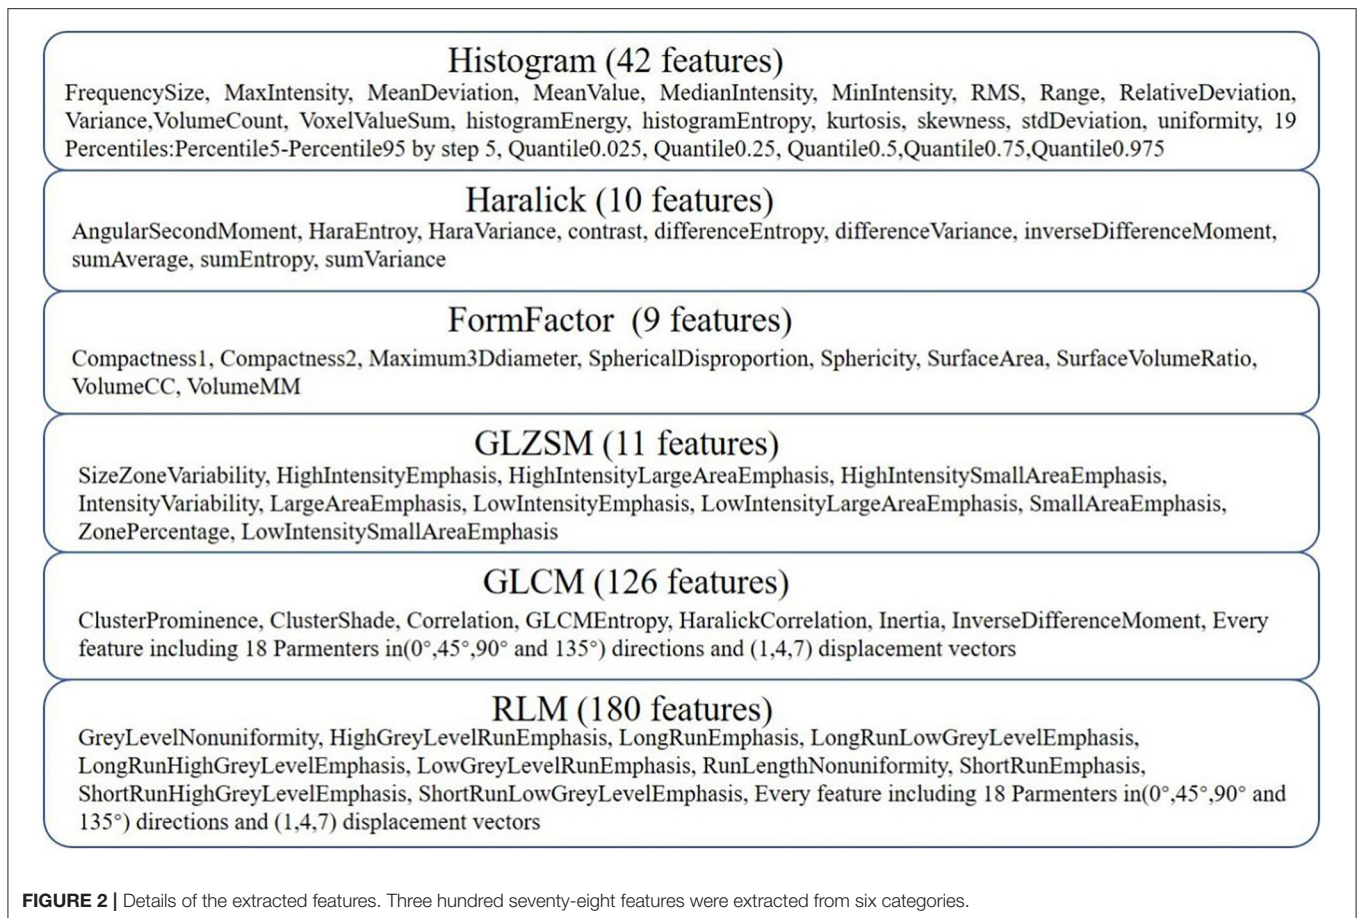

using advanced imaging, biological, clinical and behavioral assessments to identify biomarkers of PD progression. Because the PPMI is a longitudinal study, we chose to use the baseline data to study early-stage PD. Importantly, all subjects were in the first or second stage of the disease according to the Hoehn-Yahr scale, and none of them had received drug treatment. The average interval between the development of clinical symptoms and the diagnosis of PD in these patients was  $16.5 \pm 14.9$  months. Therefore, we defined the disease stage of these subjects as the early stage of PD. The detailed characteristics of the patients and the disease duration are provided in the **Supplementary Materials**. After age and sex matching, 168 healthy controls (HCs) and 168 patients with PD were selected from the database. These 336 subjects were then randomly divided into a training set ( $n = 234$ ) and a test set ( $n = 102$ ).

The training set was used to build the diagnostic model, and the test set was used to verify the reliability of the model. We also investigated 58 age- and sex-matched patients with atypical PD from the PPMI who had imaging scans without evidence of dopaminergic deficit (SWEDD) to determine whether the model was able to distinguish patients with typical PD from patients with SWEDD. The matching details are provided in the supporting materials. **Figure 1** shows the recruitment process for the research study.

### Whole-Brain White Matter Segmentation and Image Preprocessing

We obtained T1-weighted MRI data from the PPMI database. The PPMI diffusion MRI data were acquired using Siemens Tim Trio and Siemens Verio 3 Tesla MRI scanners at 32

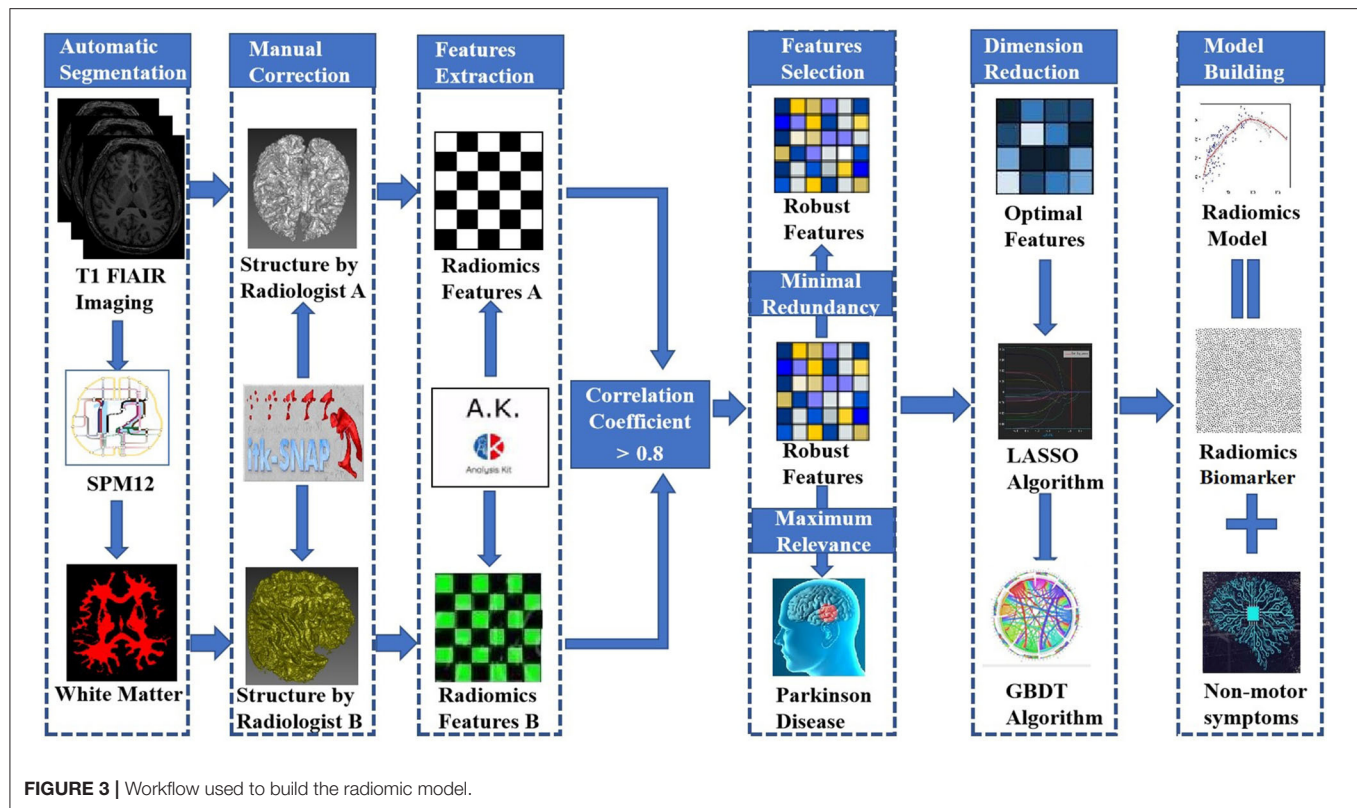

different international sites based on a standardized protocol. T1-weighted MRI data were obtained using the following parameters: TR = 2300 ms, TE = 2.98 ms, TI = 900 ms, image matrix =  $240 \times 256 \times 176$ , and voxel resolution =  $1 \times 1 \times 1 \text{ mm}^3$ . All images were automatically segmented into whole-brain gray matter, WM and cerebrospinal fluid volumes using the spm12 software package (<https://www.fil.ion.ucl.ac.uk/spm/software/spm12/>). The WM boundaries were manually adjusted using ITK-SNAP software (<http://www.itksnap.org>) by two experienced neuroradiologists (radiologist A and radiologist B, with 5 and 10 years of neuroimaging experience, respectively) who were blinded to the clinical data. This modification was accomplished using the following steps: (1) removal of nonbrain tissue, brainstem, and cerebellum and (2) modification of WM segmentation. Then, the WM volumes were imported into AK software (Quantitative Analysis Kit, version 1.2, GE Healthcare) for image preprocessing. First, all images were resampled to  $1 \times 1 \times 1 \text{ mm}^3$  resolution through linear interpolation to eliminate the effect of anisotropy on the features. A Gaussian filter was then applied to reduce noise, and the magnetic field inhomogeneity was corrected, which also assisted with reducing the effects of external interference factors. Finally, the intensity was standardized to limit the grayscale values of all images to a range of 0-32 and ensure that they would be compared without bias (Sun et al., 2018).

## Radiomic Feature Extraction

AK software was used to extract 378 radiomic features based on the WM images, including histogram (42 features), Haralick (10 features), form factor (9 features), gray-level co-occurrence matrix (126 features, GLCM), run-length matrix (180 features, RLM) and gray-level size-zone Matrix (11 features, GLSZM) features. A detailed description of the features is provided in **Figure 2**. These features have been shown to characterize cancer heterogeneity and potentially reflect changes in the image structure (Mayerhoefer et al., 2020). In addition, we used the features that were most robust to manual correction by different radiologists (Shu et al., 2019) to ensure the stability and repeatability of the radiomics features. The Spearman rank correlation test was used to calculate the correlation coefficient (CC) of each feature between feature set A (from radiologist A) and feature set B (from radiologist B). Features with a  $CC > 0.8$  were considered robust features (Wu et al., 2016). The quantitative value of robust features is the average of the two features.

## Establishment of an Overarching Radiomic Biomarker

Not every single feature is equally relevant to the diagnosis of PD. Furthermore, data reduction or feature selection is

necessary to obtain meaningful results from pattern recognition analysis (Ashburner, 2009). In the present study, the minimum redundancy maximum relevance (mRMR) algorithm was used to extract robust features from the training set (Mukaka, 2012). The aim of the maximum relevance procedure was to select features with the maximal correlation with the actual PD diagnosis. At the same time, the minimum redundancy process ensured that the selected features had minimal redundancy among the other features, and we defined features with CCs greater than 0.1 and 0.8 as high-correlation and low-redundancy features, respectively. Then, the mRMR method was used to obtain an optimal feature set with a high correlation and low redundancy. Second, the least absolute shrinkage and selection operator (LASSO) algorithm was then applied to reduce the dimensionality of the optimal feature set. Finally, a gradient boosting decision tree (GBDT) algorithm was utilized to select radiomic features and build the composite radiomic biomarker. In order to quantify the radiomics biomarker discriminability, a score was calculated using the biomarker model from each patient in the training set. This result reflected the possibility of PD and was defined as the rad-score. The training set biomarker formula was employed to calculate the scores for the test set. Finally, the accuracy of the radiomic biomarker obtained from the training and test sets was evaluated by constructing a receiver operating characteristic (ROC) curve. To further verify the clinical efficacy of the radiomics biomarker, we conducted a stratified analysis of the rad-scores for patients with different nonmotor symptoms.

Detailed information on dimensionality reduction is provided in the **Supplementary Materials**.

### Construction of the Integrative Nomogram

Stepwise logistic regression analysis was performed to select independent predictors of PD for each potential predictive variable: demographic characteristics (i.e., family history of PD, age, and sex), nonmotor symptoms (i.e., impaired olfaction, depression, RBD, EDS, and CD) and radiomic biomarkers in the training set. In addition, machine learning, an important part of radiomics, improves the accuracy, performance, and predictive ability of the model (Chen et al., 2018; Watson et al., 2019). Accordingly, five machine learning classifiers were used to construct the predictive model and included support vector machine (SVM), Bayes, logistic regression, random forest, and decision tree classifiers. All models were examined using 5-fold cross-validation, in which 20% of the data were used to test the biomarker that was created with the other 80% of data. Different test and training set data were used for every 5-fold cross-validation, and the average classification accuracy was calculated based on 10 iterations of 5-fold cross-validation. The accuracy of the model using different machine learning classifiers was evaluated with an ROC curve and the DeLong test. Finally, the best machine learning method was applied to develop a predictive model for PD based on independent predictors, and an integrative nomogram was constructed. **Figure 3** shows the workflow for creating the radiomics model. Detailed information

about the machine learning techniques used in the present study is provided in the **Supplementary Materials**.

## Assessment of the Integrative Nomogram

Based on the nomogram, the risk score of PD was calculated for each patient. The accuracy of the nomogram obtained from the training and test sets was then evaluated with an ROC curve. A calibration curve was generated to evaluate the calibration performance, and the Hosmer-Lemeshow test was performed to analyze the goodness-of-fit of the nomogram. We attempted to distinguish the patients with PD in the SWEDD dataset to further evaluate the performance of the integrative nomogram. A dataset of age- and sex-matched patients with SWEDD and PD was collected from the PPMI, and the probability of PD was defined from the model score and was calculated for each patient using the integrative nomogram. Taking the threshold of the Youden index of the ROC curve as the classification point, we divided all cases into a low-risk and a high-risk group according to the model score. Based on the actual PD patients in different risk groups, the clinical effect of the nomogram was determined. Finally, the net benefit of the model was evaluated using decision curve analysis (DCA) (O'Brien, 2007).

## Statistical Analyses

Statistical analyses were performed with the Statistical Package for the Social Sciences (SPSS) version 22.0 (SPSS, Inc., Chicago, IL, USA), GraphPad Prism 6 (GraphPad Software, San Diego,

CA, USA) and R software (version 3.3.1). Differences between categorical variables were examined using a chi-square test. Parametric data were assessed using an independent-sample *t*-test, whereas nonparametric data were assessed using the Mann-Whitney *U*-test. All analyses were controlled for age and sex. The nomogram was constructed, and calibration plots were generated using the “rms” package. The DCA was performed with the “dca.R” package. Results with a two-tailed *P* < 0.05 were considered significant.

## RESULTS

### Comparison of Patients' Clinical Data

Significant differences in Hoehn-Yahr staging were observed between patients in the three datasets (training set, test set and SWEDD set), but other clinical features were not significantly different, as shown in **Table 1**. However, a family history of PD, impaired olfaction and CD were significantly different between HCs and patients with PD in both the training and test sets, and RBD was significantly different between HCs and patients with PD in the test set. No other significant differences existed, as shown in **Table 2**.

### Development and Accuracy of the Radiomic Biomarker

After dimensionality reduction was applied to the 378 extracted features, four features were ultimately selected to construct the radiomics biomarker using logistic regression analysis. Detailed information on the dimensionality reduction process and features is provided in the **Supplementary Materials**. The rad-score was calculated from the formula for the radiomics biomarker, and it displayed favorable predictive efficacy in the training and test sets (the area under the curve (AUC) values were 0.838 and 0.826, respectively; the specificity was 83.8 and 84.3%, respectively; and the sensitivity was 71.8 and 74.5%, respectively). In addition, the nonmotor symptoms of patients with PD were compared using the rad-score. We observed a significant difference in rad-scores between patients with PD without olfactory disturbances and patients with PD and olfactory impairment, as illustrated in **Figure 4**.

### Development of an Integrative Nomogram

A family history of PD, impaired olfaction, CD and radiomics biomarkers were independent predictors of PD according to the univariate logistic regression analysis. ROC curves showed that radiomics biomarkers had the highest diagnostic efficacy among these independent predictors (**Figure 5**). Then, impaired olfaction, CD and radiomics biomarkers were selected as the factors to construct the integrated model using a stepwise logistic regression analysis, as shown in **Table 3**. Based on three independent predictors, five machine learning methods were used to construct the model. The AUC values of the SVM, Bayes, logistic regression, random forest, and decision tree classifiers in the training set were 0.927, 0.903, 0.937, 0.914, and 0.897, respectively. The predictive performance of the different machine learning methods is presented in the **Supplementary Material**. The DeLong test showed a

significant difference in the AUC value of the logistic regression model compared with the other machine learning methods. Accordingly, the logistic regression classifier was used to build the models and develop an integrative nomogram, as depicted in **Figure 6**.

## Performance of the Nomogram

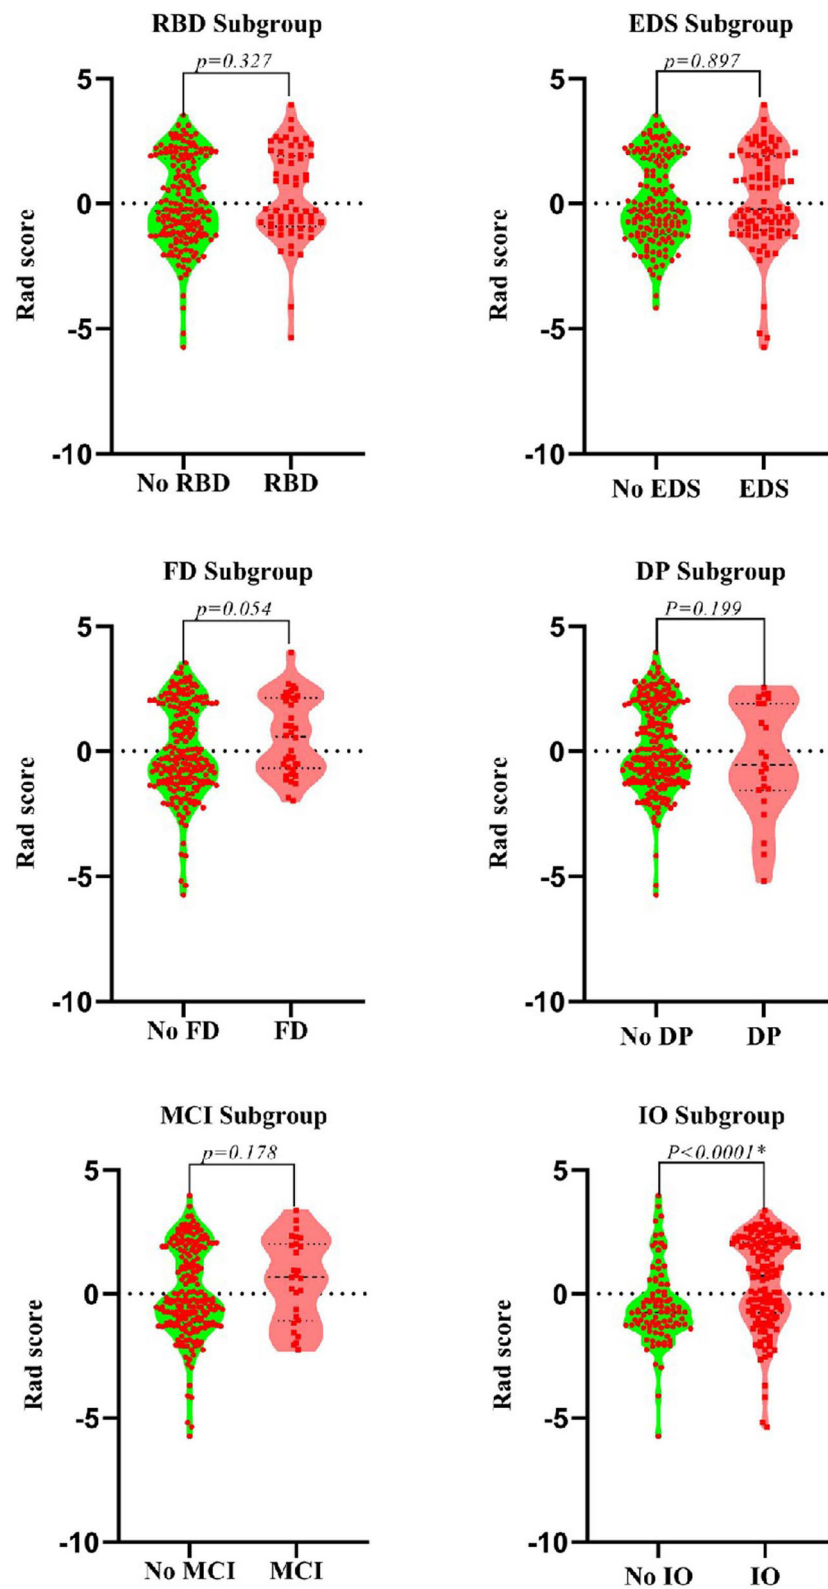

The calibration curves showed the consistency between the predicted PD probability and the actual PD probability for the nomogram in both the training and testing sets. The Hosmer-Lemeshow test did not reveal a significant difference between the performance of the nomogram in the training and testing sets ( $P > 0.05$ ), indicating the lack of a deviation from the fit. The accuracy, specificity, and sensitivity of the nomogram for identifying PD were 0.937, 83.8, and 84.6%, respectively, for the training set and 0.922, 88.2, and 82.4%, respectively, for the test set. The DCA curves also showed good net benefits, which indicated the superior diagnostic accuracy of the nomogram, as indicated in **Figure 7**. The integrative nomogram showed good classification results in the datasets containing patients with PD and SWEDD from the PPMI. The AUC, sensitivity and specificity were 0.836, 70.69, and 91.38%, respectively. Finally, the dataset was divided into a high-risk group and a low-risk group according to the best diagnostic threshold of the nomogram (cutoff value: 0.2862), and the chi-square test revealed a significant difference in the number of patients with PD between the high-risk group and the low-risk group ( $\chi^2 = 40.474$ ,  $\phi = 0.5847$ ,  $P < 0.001$ ; **Figure 8**).

## DISCUSSION

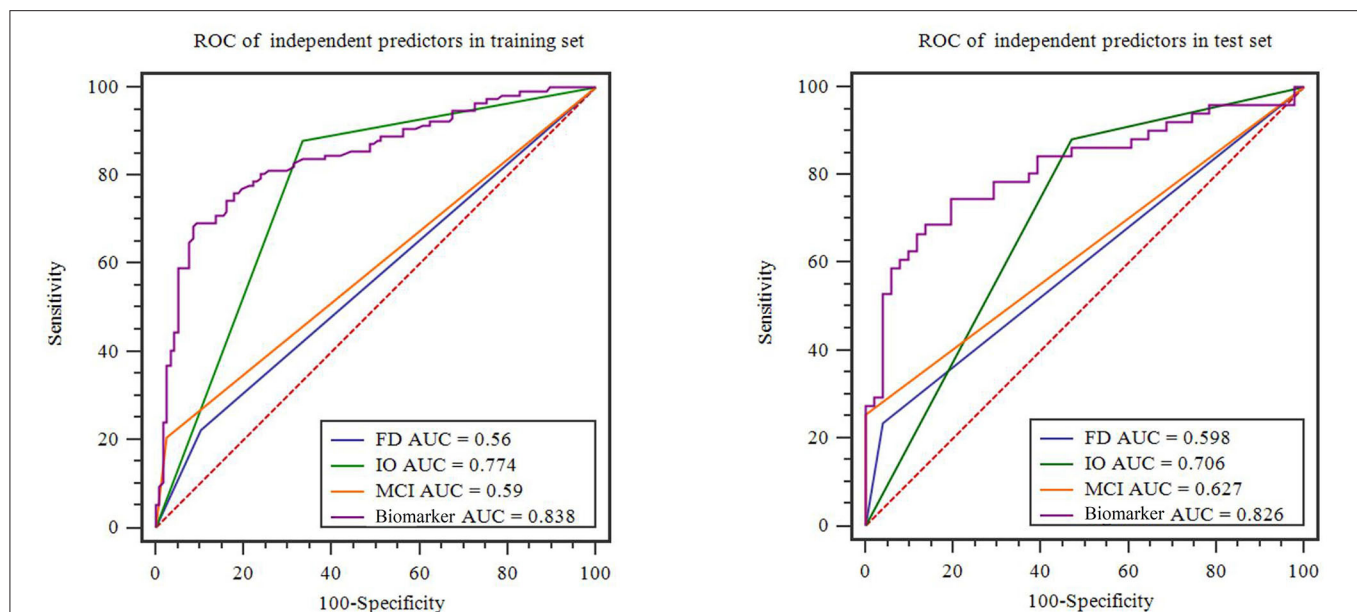

Our results show a difference in the value of radiomic biomarkers based on whole-brain white matter between patients with PD and HCs, suggesting that the microstructure of the WM in patients with PD is altered at the early disease stage (Rektor et al., 2018). Furthermore, the difference in the rad-score in the olfactory subgroup suggested that WM damage might be a risk factor for impaired olfaction. In addition, the integrative nomogram showed good performance for identifying patients with early-stage PD, particularly in the SWEDD dataset. We believe that the diagnostic model for PD will be expanded in the future, particularly given the convenience and speed of using the nomogram in the clinic.

Brain MRI is commonly used in clinical practice to evaluate the structural anatomy and pathology of the brain and is also used in the diagnostic workup of PD to exclude the presence of subcortical vascular pathology or other causes of secondary parkinsonism and to differentiate PD from atypical parkinsonism (Heim et al., 2017). However, conventional MRI does not increase the diagnostic value when the clinical diagnosis is uncertain, which is particularly true in the early stages of PD (Brooks, 2000; Meijer et al., 2012). Encouragingly, we were able to use T1-weighted images to identify patients with PD in the present study, which will further expand the application of conventional MRI sequences for the early diagnosis of PD. Similar studies using T2-weighted imaging (T2WI) from conventional MRI have constructed a radiomic model to distinguish patients with PD from HCs (Liu et al., 2020); however, the authors manually placed regions of interest at the caudate nucleus and putamen, which is a very subjective and time-consuming process. These

structures are also very small, and the segmentation is not sufficiently accurate. Overall, imaging WM is very accessible and inexpensive in clinical practice compared to imaging of the caudate nucleus and putamen. In addition, we inferred that PD might tend to cause greater damage in WM than other neurological degenerative diseases, as evidenced by the excellent performance of the WM-based radiomics integrative nomogram for distinguishing patients with PD from patients with SWEDD. This increased performance may be due to WM changes that likely represent axonal degeneration and myelin damage, which often occur early in disease progression (Burke and O'Malley, 2013) and support our hypothesis. Interestingly, WM is not the main pathological substrate of PD, and the difference in radiomics features further confirms the existence of a compensatory mechanism in the brain tissue in response

to early-stage PD (Mizuno et al., 2010), which will be studied in the future.

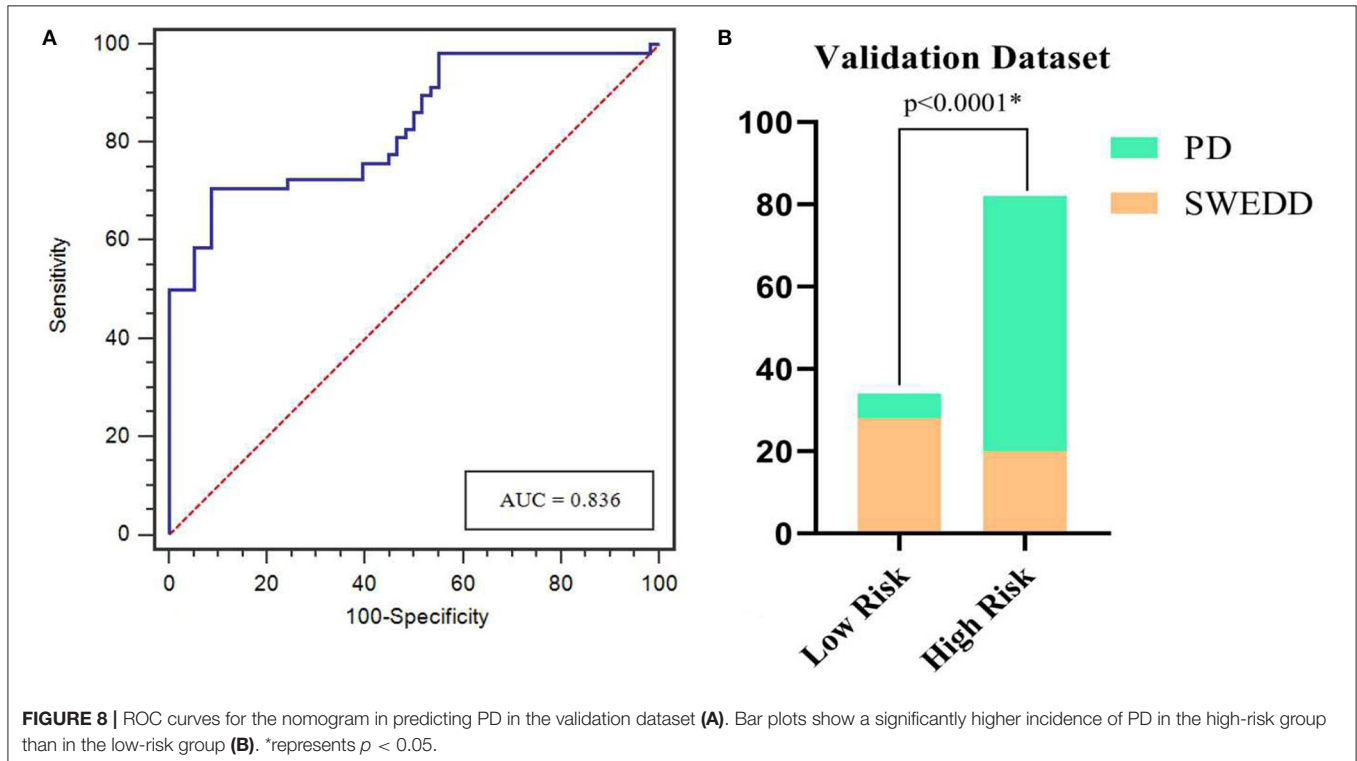

Adeli et al. combined MRI and SPECT and achieved a PD diagnostic accuracy of 97.5% (Adeli et al., 2017). Obviously, this figure exceeds the predictive accuracy reported in the current study, but the accuracy reported in the previous study mainly depended on the SPECT data, whereas the results of our study mainly depended on MRI data alone. In our results, the diagnostic efficiency of the radiomic biomarker based on MRI was 83.8%, much higher than the value for other nonmotor symptoms. Nonetheless, the diagnostic efficiency of radiomic biomarkers was lower in the present study than that the study by Wu et al. (2019), who showed that the diagnostic efficiency of radiomic biomarkers based on 18F-FDG PET images was 90.97%. However, because PET is not widely used in routine

**FIGURE 7 |** nomogram for detecting the presence of PD in the training and test sets (C,D). A DCA was performed to show the clinical effectiveness of the nomogram in predicting the presence of PD in patients included in the training and test sets (E,F). The y-axis represents the net benefit. The pink line represents the radiomics nomogram. The solid black line represents the hypothesis that all patients had PD. The black dotted line represents the hypothesis that no patients had PD. The x-axis represents the threshold probability. The threshold probability is where the expected benefit of treatment is equal to the expected benefit of avoiding treatment. For example, if the possibility of PD in a patient is over the threshold probability, then a treatment strategy for PD should be adopted. The decision curves for the test set showed that if the threshold probability is between 0 and 0.88, then the use of the radiomic nomogram to predict PD provides a greater benefit than treating either all or none of the patients.

clinical practice, the method may lack practicality. Of course, we should not ignore the other factors that were used to build the model, including CD and impaired olfaction, which also contributed substantially to the model. In fact, impaired olfaction is one of the most common and typical nonmotor disorders associated with PD (Fullard et al., 2017), and most patients with PD develop an impairment of olfaction 4–6 years before they start to present motor impairment (Reichmann, 2017). This finding may also explain why olfactory impairment is the only non-motor symptom displaying statistically significant differences in the scores of the radiomics biomarker in patients with PD, and a deterioration in the sense of smell has been postulated to reflect extrastriatal neurodegeneration in patients with PD (Schrage et al., 2017). Accordingly, we speculate that olfactory damage may also reflect early changes in the WM microstructure, but further research is needed.

The advantages of the nomogram are also reflected in other aspects of this study. We analyzed 3D WM images, while most previous studies were based largely on a cross-sectional analysis of the SN (Takahashi et al., 2018; Cheng et al., 2019; Li et al., 2019). Nevertheless, a cross-sectional image of the SN may

not completely reflect the early typical pathological changes associated with PD, and larger whole-brain changes will likely give a better representation of the global alterations associated with the disease. Four radiomic features were selected in the present study, including two features of RLM. In a previous study, RLM features, which reflect roughness and directionality, were also associated with the progression of white matter hyperintensity (WMH) (Li et al., 2017). Directionality refers to a specific route or angle of the nerve fasciculus. In normal WM, nerve fibers are properly oriented and regulated; nevertheless, when myelin is damaged, the neural structure may be disrupted (Yu et al., 2004), consistent with the white matter damage observed even in patients with early-stage PD in previous studies using advanced MRI technologies, such as DTI (Bergamino et al., 2020; Sanjari Moghaddam et al., 2020), showing that structural changes in the WM may underlie the clinical and pathologic heterogeneity of PD and cause relative cognitive impairment. Therefore, WM is a promising brain tissue to provide new insights that will be important for the early diagnosis of PD.

The correction curve and DCA showed the stability and clinical diagnostic benefits of the nomogram (AUC of 0.937),

but the sensitivity of the nomogram may still be lower than that of cerebrospinal fluid, which was the first identified biomarker of PD (Olsson et al., 2016). As shown in a similar study, early diagnosis of PD based on a cerebrospinal fluid model constructed using machine learning achieved a sensitivity of 90% (Dos Santos et al., 2018). Regardless, the nomogram used in this study as a noninvasive evaluation tool may be more suitable for clinical application than invasive detection of cerebrospinal fluid. Furthermore, the accuracy of the nomogram decreased from 0.937 to 0.836 when applied to patients with SWEDD compared with HCs. We speculate that this decrease may be due to early microstructural changes in WM caused by other neurological diseases in patients included in the SWEDD dataset, and similar to patients with early-stage PD, these changes were accelerated. However, the difference between patients with PD and patients with SWEDD is likely attributable to the lack of dopaminergic neurons (Wyman-Chick et al., 2016); therefore, the model will undoubtedly further reflect the pathological mechanism of dopaminergic damage (Liu et al., 2018). Additionally, participants classified as having SWEDD who would later be diagnosed with PD might be distinguished from patients who would not develop PD. The nomogram was able to discriminate patients without evidence of dopaminergic deficits typical of PD from patients with other neurological disorders, which might be useful to clinicians, particularly when the nomogram is combined with imaging data.

Despite the overall positive results presented here, the current study still has some limitations. First, regarding the samples used for external verification, a larger sample size from multiple research centers is needed to verify and improve the results of the present study. Second, the patients with PD who were included in this study may have been in different neurological disease stages, and differences in WM features were still observed between patients with PD and HCs (the severity of PD did not appear to affect the results of this study). Final, we did not consider the possible effect of chronic dopaminergic medications on our results; the regimen of neuropsychiatric medications provided to patients during illnesses potentially affects brain structures (Zeng et al., 2015). Nevertheless, analysis of this cohort enabled us to establish a preliminary nomogram, facilitating the future

consideration of long-term medication use in a larger and more diverse prospective study.

Although early diagnosis of PD is still based on clinical criteria, the advent of integrative nomograms will provide an imaging measure that can detect early-stage PD and may serve as a basis for future disease prediction studies in longitudinal cohorts.

## DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. This data can be found at: <http://www.ppmi-info.org>.

## ETHICS STATEMENT

The study was approved by the institutional review board and the Zhejiang provincial ethics committee. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

## AUTHOR CONTRIBUTIONS

ZS, YX, and MZ contributed to the conception and design of the study. ZS, YX, SC, XW, and PP performed the data acquisition and analysis. ZS and YX wrote and revised the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

This work was supported by grants from the Health Commission for Zhejiang Province (Grant numbers: 2020KY039 and 2020KY402).

## SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fnagi.2020.548616/full#supplementary-material>

Exercise intervention studies in mild cognitive impairment (MCI), a prodromal stage of Alzheimer's disease (AD), have demonstrated inconsistent yet promising results. Addressing the limitations of previous studies, this trial investigated the effects of a 12-month structured exercise program on the progression of MCI. The NeuroExercise study is a multicenter randomized controlled trial across three European countries (Ireland, Netherlands, Germany). Hundred and eighty-three individuals with amnesic MCI were included and were randomized to a 12-month exercise intervention (3 units of 45 min) of either aerobic exercise (AE;  $n = 60$ ), stretching and toning exercise (ST;  $n = 65$ ) or to a non-exercise control group (CG;  $n = 58$ ). The primary outcome, cognitive performance, was determined by an extensive neuropsychological test battery. For the primary complete case (CC) analyses, between-group differences were analyzed with analysis of covariance under two conditions: (1) the exercise group (EG = combined AE and ST groups) compared to the CG and (2) AE compared to ST. Primary analysis of the full cohort ( $n = 166$ , 71.5 years; 51.8% females) revealed no between-group differences in composite cognitive score [mean difference (95% CI)], 0.12 [(-0.03, 0.27),  $p = 0.13$ ] or in any cognitive domain or quality of life.  $VO_2$  peak was significantly higher in the EG compared to the CG after 12 months [-1.76 (-3.39, -0.10),  $p = 0.04$ ]. Comparing

the two intervention groups revealed a higher  $\text{VO}_2\text{peak}$  level in the aerobic exercise compared to the stretching and toning group, but no differences for the other outcomes. A 12-month exercise intervention did not change cognitive performance in individuals with amnesic MCI in comparison to a non-exercise CG. An intervention effect on physical fitness was found, which may be an important moderator for long term disease progression and warrants long-term follow-up investigations.

## INTRODUCTION

Worldwide, over 46 million people are living with dementia, with the numbers expected to rise to approximately 74 million by 2030 (Prince et al., 2015). The prevalence of mild cognitive impairment (MCI), a stage of cognitive impairment with minimal functional loss that is often, but not always, a prodromal stage of dementia (McKhann et al., 2011), is 6.7% for ages 60–64 and rises to 25.2% for ages 80–84 (Albert et al., 2011; Petersen et al., 2018). Clinicians and researchers differentiate between amnesic MCI (aMCI), which describes the dominance of memory impairments and is most likely to transition to dementia due to Alzheimer's disease (AD), and non-amnesic MCI, which is characterized by an impairment in other cognitive domains (e.g., language, visuospatial) (Petersen, 2004). Individuals with both aMCI or non-amnesic MCI have a cumulative risk of 14.9% of developing dementia within 2 years (Petersen, 2004; Winblad et al., 2004; Petersen et al., 2018). As such, cognitive decline due to dementia is a key contributor to the significant economic impact of an aging population (Prince et al., 2015), and is identified as a global health and healthcare priority.

If a primary prevention strategy could delay conversion to dementia by even two years, it would reduce the total number of patients living with dementia and have substantial public health, economic and societal benefits (Vickland et al., 2010; Brodaty et al., 2011; Sperling et al., 2011), further highlighting the importance of early detection and treatment of cognitive decline. Currently, there is no proven treatment for people with MCI that delays progression to dementia. However, the recently updated practice guidelines of the American Academy of Neurology (AAN) for the treatment of MCI suggest that exercise is a promising non-pharmacological strategy to improve cognitive function in individuals with MCI (Petersen et al., 2018). This recommendation was underpinned by only two studies that investigated the effect of a 6-month multicomponent exercise or resistance exercise intervention on the progression of MCI and demonstrated a positive effect on domain-specific cognitive function (attention and episodic memory) (Nagamatsu et al., 2012; Suzuki et al., 2012). Furthermore, the results from four systematic reviews recommend exercise as a promising treatment option and included different exercise modes from multicomponent exercises to tai chi in their reviews (Ohman et al., 2014; Wang et al., 2014; Zheng et al., 2016; Song et al.,

2018). Whereas three of them recommend aerobic exercise as probably the most effective form of exercise to maintain or improve cognitive function in individuals with MCI (Ohman et al., 2014; Zheng et al., 2016; Song et al., 2018), the other one did not define the type of exercise more specifically (Wang et al., 2014). However, these reviews recommend larger sample sizes, standardized neuropsychological testing, longer intervention periods and well-defined MCI diagnostic criteria, as these were methodological issues limiting previous studies. A recent study by Tarumi and colleagues compared 12 months of either stretching or aerobic exercise training in individuals with aMCI and concluded that both exercise modes improved executive and memory functions (Tarumi et al., 2019). However, the authors did not include a non-exercise control group, which precludes a direct comparison with their trial. Moreover, the two studies included in the AAN guideline included only women or less than 100 participants, which limits their external validity (Nagamatsu et al., 2012; Suzuki et al., 2012).

The multicenter NeuroExercise project addressed these limitations by strictly recruiting participants with aMCI, increasing the sample size compared to previous studies, extending the intervention period, involving three different countries and bringing together experts from clinical and exercise intervention trials (Devenney et al., 2017). The aim of the NeuroExercise project was to investigate the effects of a 12-month structured exercise program (either aerobic exercise or stretching and toning exercises) on the progression of cognitive decline in MCI compared to a control group. We hypothesized that participation in an extensive exercise program, of either aerobic exercise or stretching and toning exercises, would demonstrate a slower rate of cognitive decline compared to the control group.

## METHODS

### Trial Overview, Standard Protocol Approvals, and Registrations

The NeuroExercise project was a randomized controlled trial performed in three centers in Europe; the German Sport University Cologne, Germany, Radboud University Medical Center, Nijmegen, the Netherlands and at St. James's Hospital and Trinity College Dublin, Ireland. Participants were randomized to either a yearlong supervised and home-based aerobic exercise

program, an equivalent non-aerobic stretching and toning program or to a control group using a centrally controlled computer-generated randomization list (for each country), controlled by an independent statistician.

The ethics committee of the German Sport University, Cologne Germany, the Commissie Mensgebonden Onderzoek Arnhem-Nijmegen, Netherlands, and the Tallaght Hospital/St. James's Hospital Joint Research Ethics Committee Dublin Ireland, approved the study protocol, which has been described previously (Devenney et al., 2017). All participants provided written informed consent to participate in accordance with the provisions of the Declaration of Helsinki. Participants were recruited between October 2015 and September 2017. The trial is registered at Clinicaltrials.gov (trial registration number: NCT02913053).

## Participants and Study Procedure

Sedentary adults aged 50 years or older diagnosed with aMCI were recruited via hospital memory clinics affiliated with the three sites and from the community via advertisements in local newspapers. Eligibility criteria for inclusion were: (1) an education adjusted Montreal Cognitive Assessment (MoCA) score between 18 and 26; (2) stable medical condition for more than 6 months and stable medication for more than 3 months; (3) medical clearance to undergo a symptom-limited cardiopulmonary exercise test and extensive aerobic exercise training; (4) physical ability sufficient to allow performance of endurance exercise training; (5) capacity to provide written and dated informed consent form. Participants recruited from the community completed additional testing to confirm MCI status. To distinguish between amnesic and non-amnesic MCI, we applied education adjusted cut-offs of  $-2$  standard Deviation (SD) for low education ( $<10$  years of education),  $-1.5$  SD for the middle group (10–13 years of education) and  $-1$  SD for the highly educated ( $>13$  years of education), which were taken from the delayed recall portion of either the Logical Memory (story recall) subtest of the Wechsler Memory Scale IV LM (Ireland and Netherlands) or the Repeatable Battery for the Assessment of Neuropsychological Status Delayed Memory Index (Germany) (Randolph et al., 1998; Wechsler, 2008; Hendriks et al., 2014).

Exclusion criteria were: (1) a diagnosis of AD or any other type of dementia; (2) any neurological disorder or other severe chronic disease; (3) engagement in moderate-intensity aerobic exercise training for more than 30 min, three times per week, during past the 2 years. A full list of in- and exclusion criteria as well as sample size calculations have been published previously (Devenney et al., 2017).

## Interventions

In each center participants were randomly assigned to the aerobic exercise (AE), the non-aerobic stretching and toning group (ST) or the control group (CG). Both exercise groups consisted of  $3 \times 45$  min exercise sessions per week over 12 months and exercise intensity was monitored using Borg's Rating of Perceived Exertion (RPE), which is a scale from 6 ("no exertion") to 20 ("maximal exertion") that assess subjective perception of effort during exercise (Borg, 1998; Stuckenschneider et al.,

2019). Participants of the AE group had a target RPE of at least 13 while exercising, whereas participants in the ST group exercised to an RPE  $<10$  (Borg, 1998). Participants in the AE group performed indoor and outdoor walking and running exercises, whereas participants in the ST group performed light resistance, stretching, and coordination exercises such as balance. Participants attended supervised instructor led classes and completed unsupervised home exercises. Participants were asked to participate in a supervised exercise session at least once a week. Class attendance and adherence to unsupervised home sessions were recorded for all participants. Exercise diaries, which were collected by the class instructors during supervised exercise sessions once a week, were also used to record unsupervised exercise sessions. The CG received usual care and was not advised on exercise or did not attend exercise sessions (Devenney et al., 2017).

## Outcome Measures

All outcomes were measured at baseline (T0) and after 12 months (T2). Outcome assessors were not blinded to the allocated treatment arm. A neuropsychological test battery measuring six cognitive domains (verbal episodic memory, visual episodic memory, working memory, psychomotor function, executive function, and attention) was administered as the primary outcome (Devenney et al., 2017). The neuropsychological test battery consisted of: a computer-based CogState Battery (International Shopping List Task—immediate and delayed recall, Detection Task, Identification Task, One Back Task, and One Card Learning Task), Verbal fluency, and Trail Making Test. The allocation of the tests of the six cognitive domains was based on the CogState Guidelines and conventional classification of neuropsychological tests (Lezak, 2004; Maruff et al., 2004). A comprehensive description of the outcome measures for each test has been published elsewhere (Devenney et al., 2017) and an overview of the domain scores presented in **Supplementary Table 1**.

Cardiovascular fitness ( $\text{VO}_2\text{peak}$ ) was assessed as a secondary outcome measure using an incremental exercise test on a standard cycle ergometer. Participants at the German Sport University and Trinity College Dublin completed a maximal test in accordance with the World Health Organization Protocol (Fletcher et al., 2001). In Dublin,  $\text{VO}_2\text{peak}$  was based on direct spirometry [collection of expired gasses during exercise using the K4B2<sup>2</sup> equipment (K4B2<sup>2</sup> User Manual, COSMED, Italy)]. In Cologne,  $\text{VO}_2\text{peak}$  was estimated using the following equation [ $\text{VO}_2\text{peak} = (\text{exercise capacity (W)}/\text{weight (kg)} \times 10.8 + 3.5 + 3.5)$ ] (Glass et al., 2007). In Nijmegen, aerobic fitness was estimated from a submaximal exercise test completed according to the Astrand-Rhyming submaximal protocol, according to the local exercise screening protocol.  $\text{VO}_2\text{peak}$  was estimated using the average HR of minute 5 and 6 and the work load in the Astrand Nomogram (Astrand and Ryhming, 1954).  $\text{VO}_2\text{peak}$  ( $\text{mL/kg/min}$ ) was defined as outcome measure for cardiorespiratory fitness.

Health-related quality of life was evaluated using the health-related quality of life for people with Dementia (DemQOL) questionnaire, which has a good acceptability and internal

consistency in patients with MCI (Mhaolain et al., 2012). The total score of the DemQOL was calculated and analyzed.

## Statistical Analysis

The primary analysis of this study was the comparison of cognitive functioning (primary outcome measure) before (T0) and after (T2) the 1-year intervention. A composite score was calculated by averaging all six CogState domain scores into one overall cognition score. The obtained scores per test were converted into z-scores based on the standard deviation and mean of the total sample at baseline. In case of multiple tests within one domain, the average score for the domain was calculated with at least one test completed per domain (**Supplementary Tables 1, 2**). Between-group effect sizes were quantified using Cohen's *d*, with 0.2 representing a small effect, 0.5 a moderate sized effect, and 0.8 representing a large magnitude effect.

For the primary analysis, we included group (aerobic exercise, stretching and toning group, and control group) as independent variables of an ANCOVA with dependent variable the change in composite cognitive score of T2 compared to T0, and as covariates baseline cognitive functioning (T0), sex and age. Between-group differences were analyzed with analysis of covariance under two conditions: (1) the exercise group (EG = combined AE, and ST groups) compared to the control group and (2) AE compared to ST. ANCOVA analyses were chosen as they are unbiased in randomized studies and have more statistical power than repeated measures ANOVAs (Van Breukelen, 2006).

Secondary outcome measures included six separate cognitive domain scores (verbal and visual episodic memory, working memory, psychomotor function, executive function, and attention), cardiorespiratory fitness (VO<sub>2</sub>peak) and quality of life (DemQOL). Analyses for all secondary outcome parameters were carried out with similar ANCOVA analyses using the respective baseline score, age, and gender as covariates. All analyses were performed as complete cases (CC) analyses including all participants independent of adherence to the intervention with baseline and follow-up data of at least one test completed per domain. Data are presented as means and 95% confidence intervals within brackets.

For further exploration of the data and to determine the effect of center, which had a significant influence on recruitment (Sanders et al., 2018), a secondary ANCOVA analysis was performed. Moreover, the effect of per protocol participation on primary outcome measures was included in the secondary analysis. Per-protocol (PP) participation was defined as >66% adherence in the EG, which equaled an average of two exercise sessions per week, in line with recent recommendations from the AAN (Petersen et al., 2018). We included per protocol participation [not per protocol (NPP: ≤66% adherence), per protocol (PP), control group (CG)] and center [Ireland (IRE), the Netherlands (NL), Germany (GER)] as independent variables of an ANCOVA with dependent variable the change in composite cognitive score of T2, and as covariates baseline cognitive functioning (T0), sex and age. Similar secondary analyses were performed for cardiorespiratory fitness (VO<sub>2</sub>peak) and quality of life (DemQOL). In case of significant interaction effects of

center\*per protocol participation, *post-hoc* pairwise comparisons between centers [(IRE, NL, GER) and groups (PP), NPP, CG] were conducted using Bonferroni correction for multiple pairwise comparisons. SPSS 22 was used for all analyses with  $\alpha$  set at 0.05.

## RESULTS

### Participants

In total, 183 participants were recruited at the three centers (Germany: 79, Netherlands: 42, Ireland: 62) and randomly stratified into the three groups (AE = 60; ST = 65; CG = 58). Trial recruitment rates differed significantly between the three sites, as discussed previously (Sanders et al., 2018). Five participants dropped out in the AE group (8.6%), six participants in the ST group (9.2%), and six participants in the CG (10%). None of the dropouts were directly related to the intervention, but were due to personal or medical reasons, such as the loss of a relative or diagnosis of cancer. Participant recruitment, screening, enrollment, and attrition are depicted in **Figure 1**.

Participant characteristics differed between the EG and the CG. The CG had a significantly higher proportion of women and a significantly lower hand grip strength in comparison to the EG (**Table 1**).

### Complete Case Analysis

Hundred and twelve participants in the EG (AE = 53; ST = 59) and 54 participants in the CG were included in the CC analysis. Due to missing test results, outcomes have different numbers of cases included (**Supplementary Table 2**). Individuals in the AE group participated in  $96.6 \pm 45.0$  (mean  $\pm$  SD) exercise sessions throughout the 12-month intervention period, while participants in the ST group exercised  $92.0 \pm 49.3$  times.

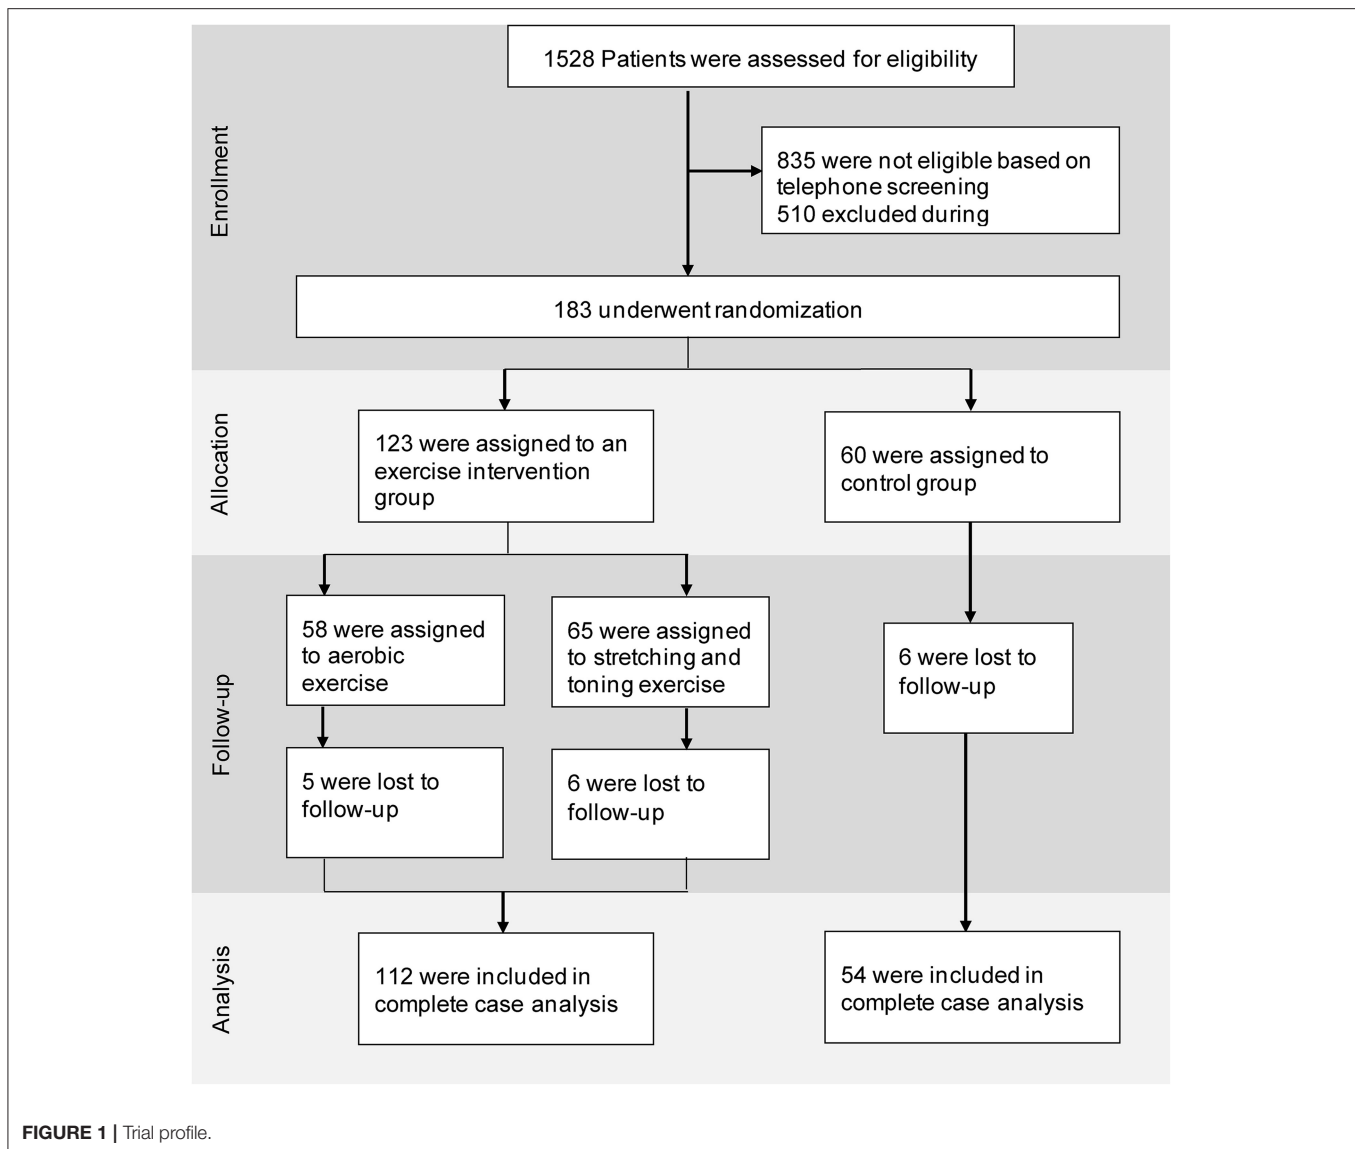

### Complete Case Analysis—Cognition and Quality of Life

ANCOVA did not show a significant difference in composite cognitive performance between the EG and the CG, nor between AE group and ST group, with effect sizes (ES) in the small range, Cohen's *d* 0.11 [exercise vs. CG, mean difference (95% CI), [0.12 (−0.03, 0.27)] and 0.22 [AE vs. ST, 0.11 (−0.08, 0.26)] (**Figure 2, Supplementary Tables 2, 3**). Age ( $p < 0.001$ ), baseline cognitive functioning ( $p < 0.001$ ), but not gender ( $p = 0.45$ ) were associated with T2 cognitive composite performance scores. Furthermore, no significant differences were identified in any of the six cognitive domains nor quality of life between the EG and the CG (**Supplementary Tables 2, 3**). ANCOVA showed a significant difference between the AE and ST groups for the domain attention [ $p = 0.011$  and small ES of 0.35, 0.39 (0.09, 0.67)], where the performance in the ST group was significantly higher compared to the AE group (**Supplementary Tables 2, 3**).

### Complete Case Analysis—VO<sub>2</sub>Peak

VO<sub>2</sub>peak improved significantly in the EG  $p = 0.04$  compared to the CG and in the AE group  $p = 0.001$  compared to ST group,

with medium ES of 0.40  $[-1.76 (-3.39, -0.10)]$  and 0.60  $[-3.10 (-4.95, -1.21)]$ . ANCOVA revealed that baseline scores were associated with  $\text{VO}_2\text{peak}$  at T2 ( $p < 0.001$ ), but not age ( $p = 0.88$ ) nor gender ( $p = 0.45$ ).

### Secondary per Protocol and per Center Analysis

One hundred and sixty-six participants (IRE = 56; NL = 36; GER = 74) were included in the secondary analysis. In IRE 19 participants were in the NPP group, 17 participants in the PP group, and 20 participants in the CG. In the Netherlands 8 participants were in each the NPP and the CG, and 20 participants in the PP group. 30 individuals were in the NPP group, 18 in the PP group, and 26 in the CG in Germany. Mean differences for composite cognitive score, quality of life and cardiorespiratory fitness for each group in each center (T2–T0) are presented in **Figure 3**.

### Secondary Analysis—Cognition

Secondary ANCOVA analysis revealed no effect of group ( $p = 0.069$ ) but an effect of center ( $p = 0.005$ ) on T2 cognitive composite scores. No significant interaction effect between center and per protocol participation for cognitive composite scores ( $p = 0.153$ ) was found. Age ( $p < 0.001$ ) and cognitive functioning at baseline ( $p < 0.001$ ) were associated with T2 cognitive composite scores. No influence of gender (0.673) was identified.

### Secondary Analysis— $\text{VO}_2\text{Peak}$

Per protocol participation ( $p < 0.001$ ), but not center ( $p = 0.772$ ) had an influence on  $\text{VO}_2\text{peak}$  at T2, and ANCOVA revealed a significant interaction effect of center\*per protocol participation ( $p = 0.021$ ). *Post hoc* pairwise comparisons showed significant differences for participants in Germany, where individuals in both the PP ( $p = 0.001$ ) and NPP ( $p = 0.019$ ) groups had a significantly higher  $\text{VO}_2\text{peak}$  compared to participants in the

Exercise, both aerobic exercise (AE) and stretching and toning (ST) exercise groups together; CG, control group; IRE, Ireland; NL, Netherlands; GER, Germany; Education categories, low <10 years of education, middle 10–13 years, high >13 years; MoCA, Montreal Cognitive Assessment, education-adjusted score; One-way ANOVA analyses were used to test differences between the exercise group and the control group or the AE and ST comparison. \*Significant difference between exercise group and CG,  $p < 0.05$ . &Significant difference between AE-ST,  $p < 0.05$ . Independent t-test was used to test differences between the number of exercise sessions in AE and ST.

CG. Baseline VO<sub>2</sub>peak ( $p < 0.001$ ), but not gender ( $p = 0.499$ ) or age ( $p = 0.726$ ) were associated with T2 VO<sub>2</sub>peak.

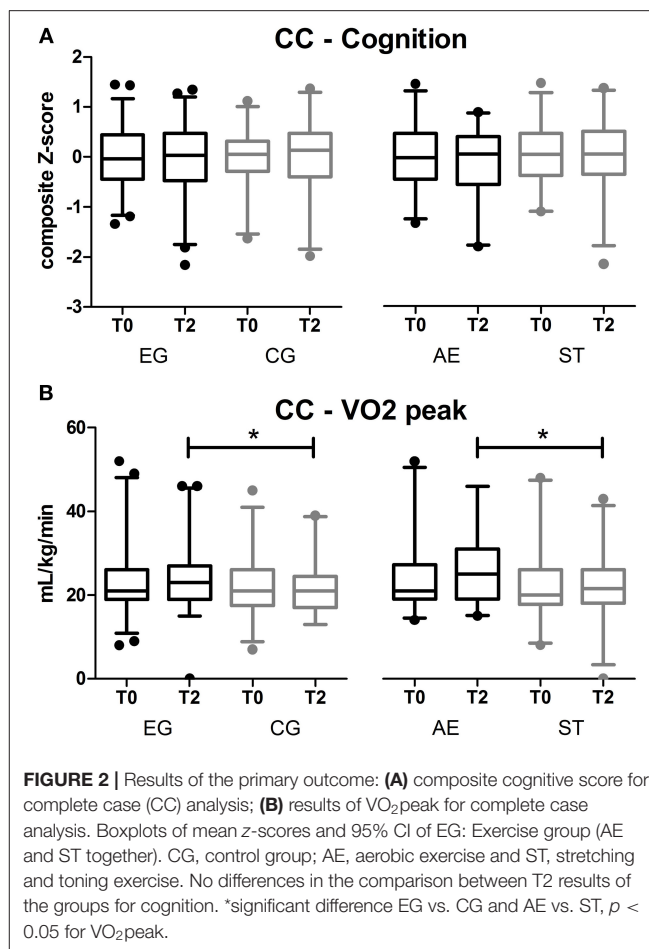

## Secondary Analysis—Quality of Life

No effect of center ( $p = 0.225$ ) or per protocol participation ( $p = 0.051$ ) was found on quality of life. However, a significant interaction effect (center\*per protocol participation) ( $p = 0.01$ ) was identified. *Post hoc* pairwise comparisons revealed that participants in the NPP group in Germany had a significantly better quality of life in comparisons to participants in IRE ( $p = 0.034$ ) and the NL ( $p = 0.01$ ). Furthermore, in Germany the NPP group had a significantly better quality of life than the CG ( $p = 0.023$ ) at T2. Baseline scores ( $p < 0.001$ ), but not age ( $p = 0.245$ ) or gender ( $p = 0.169$ ) were associated with quality of life after 12 months. No further differences were found in the secondary ANCOVA analysis.

## DISCUSSION

### Main Findings

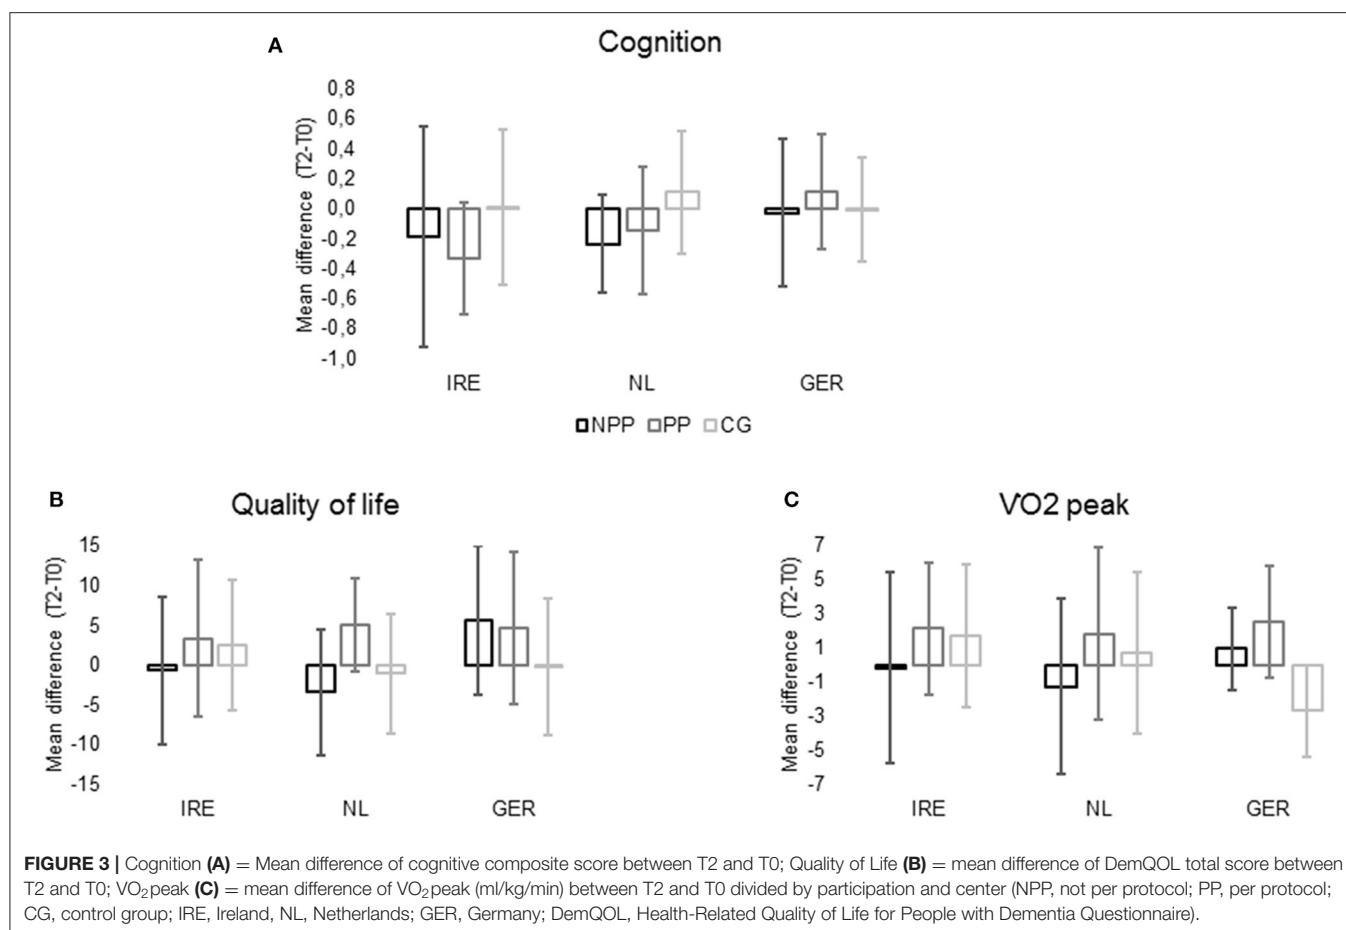

This multicenter randomized controlled trial analyzed the effects of a 12-month structured exercise program (aerobic exercise or stretching and toning) on the progression of cognitive decline in individuals with aMCI. We did not identify an intervention

effect on cognitive performance in the primary complete case analysis. Nevertheless, an intervention effect on physical fitness was identified with a medium effect size. The exercise group increased their physical fitness significantly more after 12 months than the control group.

Collaboration of three research facilities provided the opportunity to analyze aMCI populations across three different countries in North-West Europe. Furthermore, strict inclusion and exclusion criteria ensured a diagnosis of aMCI by using delayed recall scores from standardized memory tests to address limitations of previous studies. An extensive neuropsychological test battery was administered, and composite scores calculated to provide insight into both general cognitive performance and domain-specific cognitive function before and after participation.

Recently, two independent systematic reviews (Zheng et al., 2016; Song et al., 2018) as well as the American Academy of Neurology (AAN) (Petersen et al., 2018) suggested a positive effect of exercise on cognitive function in individuals with MCI. However, the results of our study do not corroborate this, as neither the EG nor the CG improved or decreased their cognitive performance over the period of 12 months. Even though it can be argued that a stable cognitive function may be positive for individuals with MCI, other studies demonstrated improvements

on specific cognitive tests after an exercise intervention (Nagamatsu et al., 2012; Suzuki et al., 2013; Nascimento et al., 2014; Tarumi et al., 2019). In contrast to previous studies, we used composite outcome measures for different cognitive domains based on standardized neuropsychological tests, which is considered the best approach to detect cognitive changes in individuals at risk of AD (Lim et al., 2016).

To date, it is unclear which people with MCI progress to dementia, remain stable, or reverse to normal cognitive function and studies report different numbers that may explain outcomes of our study. The AAN summarized findings of different studies and calculated a cumulative risk of 14.9% for the development of dementia in individuals with MCI within two years (Petersen et al., 2018). However, other studies also showed a reversion to unimpaired cognitive function on their follow-up measurements of their respective participants (Ganguli et al., 2011; Roberts et al., 2014). Individuals with aMCI are reportedly at a higher risk of progressing to dementia (Albert et al., 2011; Ganguli et al., 2011; Roberts et al., 2014), but over the course of 12 months stability in cognitive function may be the most frequently observed outcome (Ganguli et al., 2011). Ganguli and colleagues reported a progression to dementia of only 1.4% for individuals with aMCI with 77.8% remaining stable and further 15.4% improving their cognitive function back to normal after 12 months

(Ganguli et al., 2011). Therefore, mixed outcomes in different studies may be expected in a cohort of individuals with any type of MCI.

MCI does not have one single cause, but is a multicausal syndrome (Knopman and Petersen, 2014; Petersen et al., 2014), which might explain the different outcomes observed in our and other studies as it is unlikely that one single treatment (e.g., exercise) will prove to be an effective intervention for all individuals. Multidomain-type (e.g., diet, exercise, and cognitive training) interventions in the Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) showed positive results on global cognitive function, as well as on processing speed and executive function in a sample of older individuals at cerebrovascular risk for cognitive decline (Ngandu et al., 2015). However, the FINGER study showed this significant treatment benefit in a cognitively unimpaired sample of older adults at risk for future cognitive decline, but not in individuals with diagnosed MCI (Ngandu et al., 2015).

Despite the lack of significant differences in cognitive function, physical fitness—measured by VO<sub>2</sub> peak—increased significantly in the EG compared with the CG, and in the AE group compared with the ST group. These findings are in line with existing literature, as standardized exercise training increases physical fitness (Tarumi et al., 2019). Even though

a direct effect of an increased  $\text{VO}_2\text{peak}$  on cognition was not detected, higher physical fitness might be an important outcome for future disease progression. Recently published research defined changes in physical fitness as an independent risk factor for incident dementia and dementia mortality and highlighted the importance of improving fitness to delay onset of dementia (Tari et al., 2019). This is in line with previous research, which showed that higher physical fitness during mid-life and late-life (e.g., higher  $\text{VO}_2\text{peak}$  values) is positively associated with cognitive function in older adults with and without cognitive impairment (Mavros et al., 2017; Schultz et al., 2017; Stuckenschneider et al., 2018). Individuals with MCI have an increased risk of being socially isolated, which increases the risk of future progression to dementia (Fratiglioni et al., 2000; Bosma et al., 2002). Previous studies showed that higher physical fitness leads to an increase in self-confidence, which consequently may increase social participation (Perkins et al., 2008; Choi et al., 2017). Therefore, improving physical fitness may not only benefit cognitive function, but also may be the driving force for a socially integrated and fulfilling life during later life—especially in individuals with MCI. However, further evidence (e.g., longer intervention periods, longer follow-up period) is required to establish the beneficial effects of an increased  $\text{VO}_2\text{peak}$  on cognitive decline.

Moreover, increased fitness likely induces structural changes such as an increased hippocampal volume and an improved white matter integrity (Young et al., 2015; Dougherty et al., 2017; Muller et al., 2017; Ding et al., 2018). Findings to date are equivocal if exercise induced structural changes influence cognitive function directly or if structural changes may rather be beneficial for sustaining cognitive functions long-term (Hotting and Roder, 2013). To further explore this hypothesis, data from physiological measurements (e.g., MRI scans) is needed to provide insight into physiological mechanisms triggered by an increased physical fitness. Tarumi and colleagues provided insight into possible mechanisms and showed that an increased cardiorespiratory fitness following a 12 months exercise intervention was associated with an improved white matter integrity of the prefrontal cortex (Tarumi et al., 2019, 2020) as well as a redistribution of cerebral blood flow in individuals with aMCI (Thomas et al., 2020). However, the lack of a control group as well as an overall atrophy of global brain volume and particularly hippocampal areas warrants further research (Tarumi et al., 2019).

While no effective treatment currently exists for AD, a large number of mechanisms related to AD genetics and different modifiable risk factors, as well as protective factors (such as exercise) have been identified. Given the large heterogeneity in current studies, it may be time to rethink future trials whereby personalized precision prevention may be the most appropriate approach, in which an intervention is prescribed in response to each individuals' modifiable risk factors (Gillman and Hammond, 2016). A possible next step toward this may include a responder analysis to identify which individuals with MCI benefit most from an exercise intervention (Snapinn and Jiang, 2007). Further research is needed to better define the biomarkers or cognitive profile that best predicts different subtypes of MCI,

especially those at the highest risk to progress from the preclinical stages of MCI towards dementia due to AD (Sperling et al., 2011).

## Secondary Analysis—Effect of Research Setting

In none of the centers cognitive function significantly improved in the exercise groups at T2. However, participants in Germany exercising at least twice a week were the only participants in the exercise groups that showed a positive trend on their cognitive function, based on a positive difference between T2 and T0. Additionally, physical fitness and quality of life significantly improved in the exercise groups in comparison to the control group in Germany, whereas no significant changes for any outcome in Ireland and the Netherlands were found. Therefore, we speculate that a non-medical setting and a non-medical research community might have additional effects on improving fitness and may have additional benefits for quality of life in individuals with MCI (Sanders et al., 2018). Even though multicenter clinical studies in elderly with cognitive impairment are the backbone of evidence-based prevention, complete standardization is difficult to obtain in the different research facilities involved. Whereas the exercise classes in Germany were all supervised, participants in Ireland and the Netherlands partly exercised on their own. Even though all participants were instructed on exercise duration and intensity and were asked to participate in at least one supervised exercise session a week to remind and educate them about exercise intensity (Devenney et al., 2017), unsupervised exercise training may compromise treatment fidelity. Further, it is possible that methods such as self-report of exercise training are open to bias due to the so-called social desirability response bias (Aadahl and Jorgensen, 2003), which may explain findings of the secondary analysis with physical fitness only improving significantly in Germany. Besides the additional effects of supervised exercise training on  $\text{VO}_2\text{peak}$ , increased social interaction, which was achieved due to the participants exercising in groups during the supervised sessions, may also explain secondary findings for quality of life, which only improved in the German sample. However, we did not find a significant treatment effect on cognition for the German sample.

## Strength and Limitations

This study has several strengths including its large sample size, its strict inclusion of individuals with aMCI, its long intervention period (12 months), and its multicentric design. Furthermore, different cognitive tests were combined into one overall score of cognitive function (primary outcome), but also for different subdomains of cognitive function to provide a psychometrically more reliable and thus more valid construct (Lim et al., 2016). However, subtle changes may be easier detected in single tests—even though they are also prone to false positive type I errors.

One of the limitations of the study was that the recruitment aim of 225 individuals with aMCI (75 per center), was not achieved. Nevertheless, recruitment numbers were sufficient regarding the power calculation for primary analysis (16). As numbers were significantly lower in the secondary analysis, due to the differentiation by center, results of it need to be interpreted

cautiously. Despite difficulties in recruitment, dropout rates were less than 10% in all groups, which shows a good acceptance of the study and the high motivation of the participants. Participants received their individual study results after completion of the study, which may have motivated individuals to participate, especially in the CG. As cardiorespiratory fitness did not change in this CG, it is unlikely that the participants in that group as a whole altered their lifestyle only because of participating in our trial.

Only 53% of participants reached the target exercise frequency, which was defined as 100 exercise sessions (or more, at least twice a week) within the intervention period of 12 months according to recent recommendations of the AAN (Petersen et al., 2018). In comparison to previous studies the low number of participants following the per-protocol intervention may have been due to the longer intervention period (12 months), and the strict and conservative target exercise frequency. The low dropout rate and more than half of the intervention group following the strict protocol is already a promising result for this rather inactive participant selection, which is reflected by a low baseline cardiorespiratory fitness in comparison to population reference values (Edvardsen et al., 2013). As the best dose-response relationship of exercise on cognitive function is frequently discussed, yet still unknown (Gomes-Osman et al., 2018), future exercise prevention trials should concentrate on defining the best dose-response relationship. Future studies should use objective monitors such as heart rate monitors to ensure a certain exercise intensity is reached. Even though Borg's RPE scale may present a practical tool to monitor intensity, self-reporting always bears the risks to be affected by motivational aspects and over- or underestimation of the individuals' functional abilities. Therefore, monitoring intensity via heart rate may increase accuracy of the training program and, thus, lead to better study outcomes. It may be speculated that different outcomes observed in our study compared to the one conducted by Tarumi and colleagues may be due to the objective monitoring used in their study (Tarumi et al., 2019). However, cardiorespiratory fitness increased in both trials, so that further insight into these different monitoring methods is warranted.

Different tests for  $VO_{2peak}$  were applied, which was due to different regulations by the institutional review boards (Devenney et al., 2017). Effects of these differences were minimized by using standardized and validated  $VO_{2peak}$  measurements at all sites. Significant differences between the groups' baseline characteristics are reported, however, these occurred rather by chance than by bias (Altman and Dore, 1990; Moher et al., 2010), as a centrally controlled computer-generated randomization list (for each country), which was controlled by an independent statistician, was used. There is ongoing discussion whether to report differences in baseline characteristics or not (Moher et al., 2010). Given the large heterogeneity observed in individuals with MCI, we presented baseline statistics to identify possible confounders. The EG and CG had a different proportion of women and men with significantly more women being in the CG. This could have biased the results, as women have a higher risk to progress to dementia, but we performed an ANCOVA to statistically adjust for the potential effect of sex. The

different proportion of women and men might also account for the differences in hand grip strength between the EG and the CG. As men are reportedly stronger than women, a higher value in hand grip may be expected. Furthermore, the ST group used significantly more medications compared to the AE group. As investigational drug studies and unstable medication were among the exclusion criteria of our trial, it is unlikely that this baseline difference had a significant impact on our results. However, the effect of medication has not fully been investigated in previous studies on exercise interventions and should be addressed by future trials.

## Future Directions

No cure for AD currently exists, prompting increased efforts to understand the preclinical stages such as aMCI as potential opportunities for new treatment approaches. Based on results of our multicentric randomized controlled trial, future research in the field of exercise interventions should target the following aspects: Both cognitive and physiological measurements are warranted to fully establish the effects of exercise and provide insight into its underlying mechanisms. Furthermore, different and combined exercise modes (e.g., endurance, resistance), intensities (e.g., moderate, high) and exercise volume (length of exercise classes, average exercise sessions per week) need attention to identify best dose-response relationships in the future. To ensure comparability between studies researches must focus on uniform reporting of their findings and their interventions. Objective monitors such as heart rate/activity monitors should be used to measure exercise intensity and frequency. Additionally, long-term follow-ups are needed to establish the long-term effects of exercise on disease progression. Besides promoting exercise on its own, multi-domain type interventions (e.g., exercise, cognitive training, and diet) may help to address the large heterogeneity observed in individuals in preclinical stages of AD.

## CONCLUSION

This study does not support the recommendation from small and short-term RCTs that an exercise intervention has an effect on cognitive performance in individuals with amnesic MCI. Nevertheless, we found a reliable intervention effect on physical fitness, which may be an important outcome for disease progression. Future trials need to target long-term follow ups (up to 5 years) to evaluate the efficacy of an increased physical fitness on cognitive decline. Moreover, the heterogeneity between subjects and centers may explain different findings within the study. Therefore, future trials should consider personalized intervention approaches or multidomain interventions.

## DATA AVAILABILITY STATEMENT

The datasets used and analyzed during the current study will be made available by the corresponding author upon reasonable request.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethics Committee of the German Sport University, Cologne Germany, the Commissie Mensgebonden Onderzoek Arnhem-Nijmegen, Netherlands, and the Tallaght Hospital/St. James's Hospital Joint Research Ethics Committee Dublin Ireland approved the study protocol. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

SS, BL, MO, MP, R-JS, CM, MR, BW, and RM were responsible for conceptualization. TS, MS, and KD carried out data curation were responsible for the investigation. Further, TS, MS, and RK performed the formal analysis. Funding was acquired and resources and supervision were provided by SS, BL, and MO. SS, VA, TV, TS, RK, MO, JA, MS, BL, EG, and KD designed the methodology of the study. SS, BL, MO, TS, MS, and KD were responsible for the project administration. TS and MS wrote the original draft of the manuscript and were responsible for visualization, while RK, KD, MO, BL, SS, MP, VA, and EG reviewed and edited the manuscript. Validation of the analysis and the data was provided by MS, MO, RK, MR, and SS. All authors have read and approved the final version of the manuscript, and agree with the order of presentation of the authors.

Type 2 diabetes mellitus (T2DM) patients are highly susceptible to developing dementia, especially for those with mild cognitive impairment (MCI), but its underlying cause is still unclear. In this study, we performed a battery of neuropsychological tests and high-resolution sagittal T1-weighted structural imaging to explore how T2DM affects white matter volume (WMV) and cognition in 30 T2DM-MCI patients, 30 T2DM with normal cognition (T2DM-NC) patients, and 30 age-, sex-, and education-matched healthy control (HC) individuals. The WMV of the whole brain was obtained with automated segmentation methods. Correlations between the WMV of each brain region and neuropsychological tests were analyzed in the T2DM patients. The T2DM-NC patients and HC individuals did not reveal any significant differences in WMV. Compared with the T2DM-NC group, the T2DM-MCI group showed statistically significant reduction in the WMV of seven brain regions, mainly located in the frontotemporal lobe and limbic system, five of which significantly correlated with Montreal Cognitive Assessment (MoCA) scores. Subsequently, we evaluated the discriminative ability of these five regions for MCI in T2DM patients. The WMV of four regions, including left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus had high diagnostic value for MCI detection in T2DM patients (AUC > 0.7). Among these four regions, left precuneus WMV presented the best diagnostic value (AUC: 0.736; sensitivity: 70.00%; specificity: 73.33%; Youden index: 0.4333), but with no significant difference relative to the minimum AUC. In conclusion, T2DM could give rise to the white matter atrophy of several brain regions. Each WMV of left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus could be an independent imaging biomarker to detect cognitive impairment at the early stage in T2DM patients and play an important role in its pathophysiological mechanism.

**Keywords:** type 2 diabetes mellitus, mild cognitive impairment, white matter volume, magnetic resonance imaging, biomarker

## INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a common metabolic disorder characterized by insulin resistance and hyperglycemia, which has become a significant health problem throughout the world. It can cause severe multi-systemic dysfunction, such as kidney, eye, peripheral, central nervous system, etc. Epidemiological investigations have shown that T2DM is associated with a twofold increased risk of dementia and can affect a wide range of cognitive abilities (Peila et al., 2002; Biessels et al., 2006; Crane et al., 2013). Mild cognitive impairment (MCI) is considered as a precursor of dementia, which has been an increasingly common target of potential therapeutic trials (Schneider et al., 2009; Brooks and Loewenstein, 2010; Sperling et al., 2011). Currently, the occurrence of dementia is an irreversible process and has no effective cure solution. The effective and preventive treatments are needed at early phases of the dementia spectrum (Jedynak et al., 2012). Thus, the early detection of alterations in T2DM patients with MCI is important for patient care and developing future treatment.

Nowadays, the cognitive tests have been widely used for detection of cognitive impairment. However, the cognitive tests scores could be affected by the subjective judgment and drug intervention. Brain magnetic resonance (MR) imaging provided a good opportunity to explore the diabetic cerebral changes. The MR imaging biomarkers are more objective evidence, which could provide a supplement and clue for early diagnosis of cognitive impairment in T2DM patients. On conventional MR images, brain atrophy in some regions could be found (de Bresser et al., 2010; van Elderen et al., 2010; Espeland et al., 2013; Moran et al., 2019). Recently, lots of attention have been paid on the gray matter changes of T2DM patients. Several studies have shown that regional atrophy patterns of gray matter mainly located in frontal lobe, middle temporal gyrus, and posterior cingulate gyrus (Brundel et al., 2010; Moran et al., 2013; Moulton et al., 2015; Fang et al., 2018; Li et al., 2018). Despite the importance of gray matter atrophy in T2DM, white matter abnormalities played a distinct and irreplaceable role in cognitive impairments induced by T2DM. White matter has a vital role for transferring information between gray matter regions. White matter alterations include both microstructural deficits and morphological abnormalities. On one hand, studies of white matter integrity using MR diffusion tensor imaging (DTI) have demonstrated microstructural alterations in different regions in T2DM patients. These studies observed reduced white matter integrity predominantly in the cingulum, the uncinate fasciculus, the superior and inferior longitudinal fasciculus, corpus callosum, and external and internal capsule (Zhang et al., 2014; Nouwen et al., 2017; Yoon et al., 2017; Sun et al., 2018; Xiong et al., 2019). On the other hand, volumetric measurements are widely used to study morphological changes in both normal aging and in neurodegenerative disorders. Understanding changes in regional brain volumes has the potential to aid prediction of onset and progression of many neurodegenerative disorders. However, few studies have been focused on alterations of white matter volume (WMV) in T2DM patients. The loss of WMV in T2DM patients has been

observed in temporal lobe, inferior frontal triangle region, and hippocampus (Korf et al., 2006; Gold et al., 2007; Chen et al., 2012; Moran et al., 2013). The alterations of WMV in previous studies did not show a consistent pattern in T2DM. The reason for the inconsistent results may be that T2DM patients included in these studies were in different stages of diabetes-associated cognitive impairment. To our knowledge, we have not found the report of WMV changes in T2DM patients with MCI at present.

In the current study, we enrolled T2DM patients with mild cognitive impairments (T2DM-MCI), T2DM patients with normal cognition (T2DM-NC), and healthy controls (HC) who performed clinical assessment, a battery of neuropsychological tests, and high-resolution sagittal T1-weighted structural MR imaging to explore how T2DM affects white matter and cognition. Automated segmentation analyses were applied to investigate the WMV difference of the whole brain in these three groups. Then, we assessed the relationship between the WMV of each brain region and neuropsychological tests in the T2DM groups. Finally, we identified the imaging biomarkers to detect MCI in T2DM patients. We expect that our study could provide imaging biomarkers and new insight into the neuropathological mechanisms of T2DM-related cognitive impairment.

## MATERIALS AND METHODS

### Participants

Samples were collected from 90 patients, consisting of 30 HC, 30 patients with T2DM-NC (T2DM-NC group), 30 patients with T2DM with MCI (T2DM-MCI group). Their overall data were accumulated and categorized by gender, age, and years of education. From October 2015 to June 2020, our hospital recruited all the T2DM patients with and without MCI. The World Health Organization's criteria were adopted to diagnose T2DM. The accurate diagnosis of MCI was made on the basis of the criteria set up in European Alzheimer's Disease Consortium in 2006, which involves Mini-Mental State Examination (MMSE) score  $> 24$ , clinical dementia rating (CDR)  $\geq 0.5$ , MoCA score  $< 26$ , normal activities of daily living (ADL) score, and complaints of hypomnesia. Each patient was tested by structural MRI, neurological, and neuropsychological examinations. All the participants signed informed consent before the study started and were right-handed. If participants had a history of brain injury, epilepsy, alcoholism, Parkinson's disease, major depression, or other psychiatric or neurological disorder, they were excluded. The participants with severe claustrophobia or contraindications to MRI, severe depression (Hamilton Depression Rating Scale  $\geq 18$ ), and dementia (MMSE  $\leq 24$ ) were also excluded. If patients with T2DM had microvascular complications including nephropathy, retinopathy, and neuropathy, they were excluded. Thirty volunteers with no cognitive complaints or psychiatric illnesses, nervous system diseases, and vascular risk factors were enlisted as the HC. Participant was excluded if white matter hyperintense lesions on fluid-attenuated inversion recovery (FLAIR) imaging were found. The white matter lesions were also evaluated according to a 10-level scale from barely detectable white matter changes (grade 1) to extensive, confluent changes

(grade 9) (Manolio et al., 1994; Chen et al., 2012), and grade 0 (normal white matter) and grade 1 (barely detectable white matter changes) were included and other grades were excluded in this study. Each individual was measured for height, weight, and body mass index (BMI). The Medical Ethics Committee of our institution approved this study, which was conducted in accordance with the principles of the Declaration of Helsinki.

## Neuropsychological Assessments

The Montreal Cognitive Assessment (MoCA), MMSE, Rey-Osterrieth Complex Figure Test (ROCF), Trail-Making Test (TMT), Auditory Verbal Learning Test (AVLT), Verbal Fluency Test (VFT), Digit Span Test (DST), Digit Symbol Coding Test (DSCT), and Hamilton Depression Scale (HAMD) were included in the neuropsychological assessments.

## Standard Laboratory Tests

Standard laboratory tests were executed to evaluate glycosylated hemoglobin (HbA1c), fasting plasma glucose (FPG), fasting insulin, fasting C-peptide, high-density lipoprotein (HDL), low-density lipoprotein (LDL), total cholesterol (TC), triglycerides (TG), urinary microalbumin, homocysteine, blood urea nitrogen (BUN), uric acid, cystatin C, serum creatine, free thyroxine (FT), free triiodothyronine (FT3), and thyroid stimulating hormone (TSH).

## MR Image Acquisition

A 3 T Trio MRI system (Siemens Healthcare, Erlangen, Germany) equipped with a 12-channel phase-array head coil was adopted to collect all MRI data. During the image acquisition, the tested subjects were asked not to move and to keep calm with their eyes closed. By using a T1-weighted magnetization prepared rapid acquisition gradient echo (MPRAGE) sequence (repetition time = 1,900 ms, echo time = 2.52 ms, inversion time = 900 ms, flip angle = 9°, matrix = 256 × 256, thickness = 1.0 mm, 176 slices with voxel size = 1 × 1 × 1 mm<sup>3</sup>), the 3D high-resolution structural images were procured. Afterward, conventional brain T1-weighted imaging (TR/TE = 200/2.78 ms, flip angle = 70°, matrix = 384 × 384, thickness = 4.0 mm, 25 slices, voxel size = 0.7 × 0.6 × 5 mm<sup>3</sup>) and FLAIR imaging (TR/TE/TI = 9,000/93/2,500 ms, flip angle = 130°, matrix = 256 × 256, thickness = 4.0 mm, 25 slices, voxel size = 0.9 × 0.9 × 4 mm<sup>3</sup>) were subjected to all the subjects to exclude white matter hyperintense lesions and organic diseases.

## Image Processing

The data were outputted to a personal computer from the MRI scanner. Off-line analysis was carried out and Linux Operating System was the operating system. Firstly, all the images were confirmed not affected by head motion prior to further analysis of the 3D brain images. Afterward, we converted all the data to MGZ (compressed Massachusetts General Hospital file) format. Meanwhile, by using FreeSurfer software (version 5.3.0, available at <http://surfer.nmr.mgh.harvard.edu>), the whole brain WMVs were measured. There were multiple steps of the

automated processing stream of FreeSurfer, which contained Talairach transformation, removal of non-brain tissue, automatic correction of topological defects, inflation of the folded surface, and registration into an average spherical surface template. In order to segment the gray/white matter tissue and CSF with sub-millimeter precision, a deformable surface algorithm was utilized. Raw volumes for the total WMV were extracted as well as segmented volumes of 68 WMVs (34 regions in each hemisphere) in white matter regions (based on Killiany-Desikan atlas) (Harrisberger et al., 2018; Guo et al., 2019).

## Statistical Analyses

Statistical analyses were performed using SPSS software (version 20.0; IBM Corp., Armonk, NY). The data distribution was verified using the Kolmogorov–Smirnov test. For WMV, comparisons among the three groups were performed by using ANOVA test, with the level of significance setting at  $P < 0.05$ , false discovery rate (FDR) corrected. For demographics and neuropsychological testing, comparisons among the three groups were performed by using the analysis of variance (ANOVA) test, if the data distribution was normal. The level of significance for intergroup differences was set at  $P < 0.05$ . The chi-squared analyses were applied to nonparametric analyses if the data distribution was not normal. *Post hoc* tests with Bonferroni correction were performed after observing statistical differences among the three groups.  $P < 0.017$  (0.05/3) was considered significant after Bonferroni correction. For the T2DM patients, the correlations between the WMV of each brain region and the neuropsychological scale scores were tested using Pearson correlation analyses. For receiver operating characteristic (ROC) analysis, areas under the curves (AUCs) were used to evaluate the diagnostic value of each marker. Generally, an AUC greater than 0.9 indicated excellent diagnostic efficacy, between 0.7 and 0.9 indicated good diagnostic efficacy, between 0.5 and 0.7 indicated poor diagnostic efficacy, and no more than 0.5 indicated the lack of a diagnostic value. MedCalc Statistical Software (version 19.3.1; MedCalc Software Ltd, Ostend, Belgium) was used to compare differences in AUCs.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Demographics and Neuropsychological Testing

The demographic, clinical, and neuropsychological data for the T2DM-MCI, T2DM-NC, and HC groups are shown in **Tables 1, 2**. No significant intergroup difference was observed in age, gender, years of education, systolic, or diastolic blood pressure, LDL, total cholesterol, and triglycerides. T2DM-NC patients presented higher FPG and HbA1c and lower HDL than HC (Bonferroni correction,  $P < 0.017$ ); T2DM-MCI patients presented higher BMI, FPG, and HbA1c and lower HDL than HC (Bonferroni-correction,  $P < 0.017$ ), while no significant differences were found between T2DM-NC and T2DM-MCI patients. As expected, cognitive function evaluated by various neuropsychological tests showed the worst performance in

**TABLE 1 |** Demographic and clinical data of the subjects.

	T2DM-MCI	T2DM-NC	HC	F-value ( $t/\chi^2$ )	P-values
Numbers	30	30	30	–	–

T2DM-MCI patients than HC and T2DM-NC patients. No significant difference was shown between T2DM-NC patients and HC (Bonferroni correction,  $P > 0.017$ ). Furthermore, T2DM-MCI patients exhibited significant decreases in multiple

domains of cognitive function including episodic memory, working memory, executive function, and attention domains when compared with T2DM-NC patients and HC, but no differences in language ability and spatial processing.

**TABLE 3 |** Differences in the white matter volume among T2DM-MCI, T2DM-NC, and HC groups.

Regions	White matter volume			F-values	ANOVA (P-values)
	HC	T2DM-NC	T2DM-MCI		
Left isthmus cingulate	3,931.40 ± 569.78	3,819.84 ± 570.83	3,470.82 ± 603.25	5.122	0.048
Left lateral orbitofrontal gyrus	6,700.99 ± 838.21	6,702.80 ± 570.27	6,267.02 ± 770.28	3.500	0.042
Left posterior cingulate	4,379.01 ± 610.81	4,652.48 ± 500.46	4,231.84 ± 441.51	5.010	0.027*
Left precuneus	9,442.53 ± 1,743.27	9,833.90 ± 1,242.31	8,847.39 ± 1,264.13	3.593	0.048*
Left insula	8,918.20 ± 946.21	9,140.63 ± 746.48	8,618.25 ± 695.40	3.194	0.046*
Right lateral orbitofrontal gyrus	6,569.96 ± 721.97	6,734.11 ± 641.00	6,196.94 ± 765.54	4.492	0.049*
Right pars orbitalis	1,134.16 ± 232.18	1,209.77 ± 168.79	1,063.01 ± 187.21	4.128	0.044*
Right rostral middle frontal gyrus	12,509.42 ± 2,160.15	12,959.35 ± 1,604.56	11,768.02 ± 1,791.73	3.116	0.049*
Right temporal pole	687.63 ± 128.12	745.50 ± 113.06	669.06 ± 119.51	3.290	0.049*

Values are the mean ± standard deviation. The comparisons of white matter volume of each region among three groups were performed with ANOVA. The level of significance for intergroup differences was set at  $P < 0.05$ , false discovery rate (FDR) corrected. \*Denotes  $P < 0.017$  (0.05/3) T2DM-MCI vs. T2DM-NC with post hoc test, Bonferroni corrected. No significant difference was shown between the T2DM-NC group and HC group with post hoc test, Bonferroni corrected.

## Group Differences in WMV Among the Groups

The WMV of the whole brain of T2DM-MCI, T2DM-NC, and HC groups were analyzed. If statistical differences among the three groups were observed, then a *post hoc* test was performed. It was not surprising that obvious difference in WMV among these three groups were observed in 13 regions ( $P < 0.05$ , FDR corrected, **Table 3**). Subsequently, we performed a *post hoc* test and Bonferroni correction. Significant difference of regional WMV was observed in T2DM-MCI patients relative to T2DM-NC patients. Regions of the white matter atrophy were the left insula, posterior cingulate, and precuneus, right lateral orbitofrontal gyrus, pars orbitalis gyrus, rostral middle frontal gyrus, and temporal pole (Bonferroni-correction,  $P < 0.017$ ) (**Table 3**). However, there was no significant difference between T2DM-NC and HC groups (**Table 3**). In addition, the included T2DM patients had no obvious white matter hyperintensity lesions on T2 FLAIR, which indicates that brain white matter atrophy rather than cerebrovascular lesions may substantially mediate the relationship between T2DM and cognitive impairment.

## WMV in Relation to Cognitive Performance in T2DM Patients

Based on the WMV and cognition scores with significant intergroup differences, we explored the relationship between WMV of these regions and the neuropsychological testing scores in all T2DM patients. The results revealed that MoCA scores were significantly correlated with the WMV of the left posterior cingulate ( $r = 0.387$ ,  $P = 0.002$ ), precuneus ( $r = 0.319$ ,  $P = 0.013$ ), insula ( $r = 0.328$ ,  $P = 0.011$ ), right rostral middle frontal gyrus ( $r = 0.297$ ,  $P = 0.021$ ), and temporal pole ( $r = 0.259$ ,  $P = 0.045$ ) (**Figure 1**).

## Discriminative Ability of White Matter Atrophy for MCI Detection in T2DM Patients

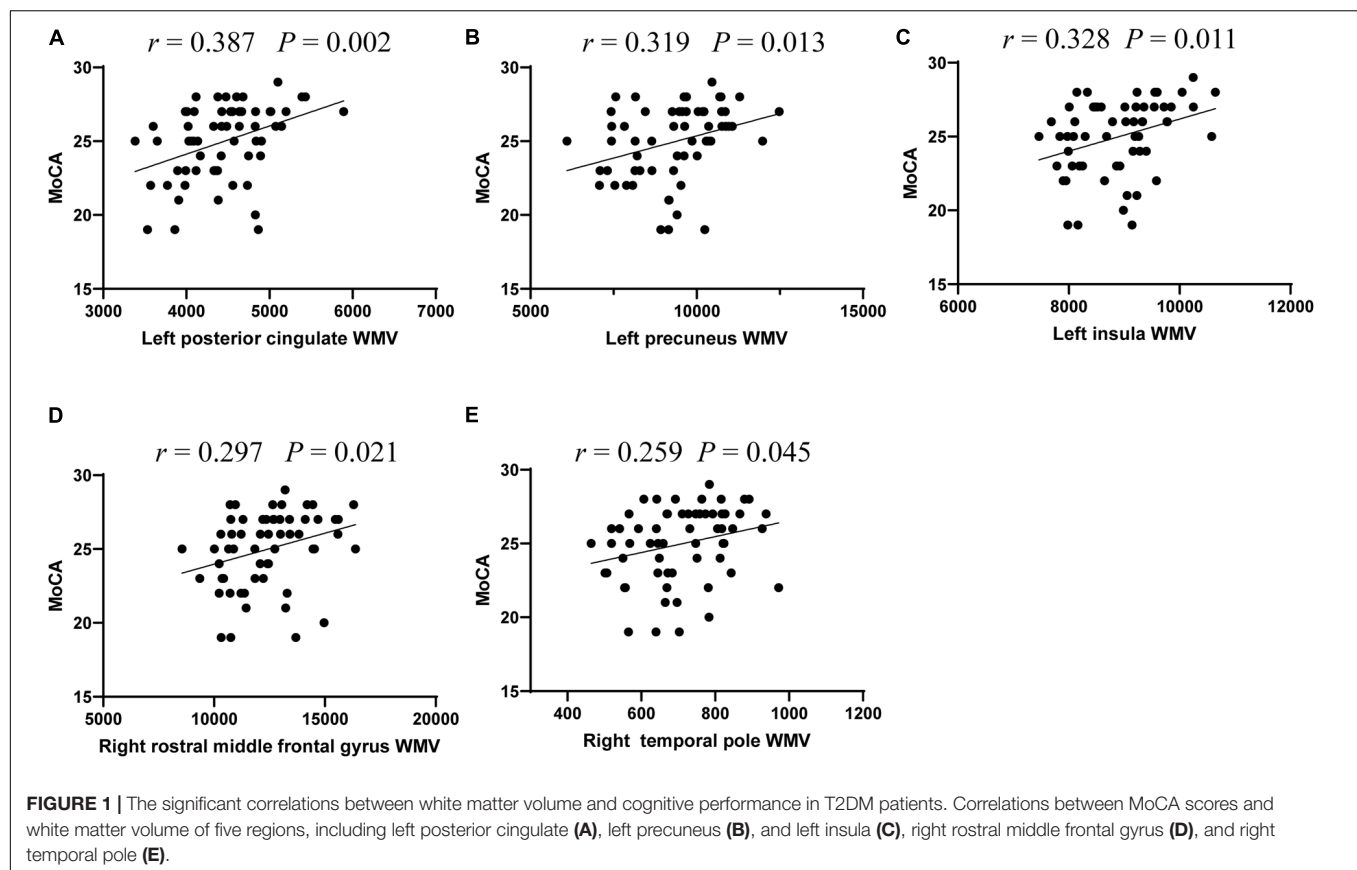

Considering that the WMV of eight brain regions significantly correlated with MoCA scores, we evaluated the discriminative

ability of the white matter atrophy of these regions for MCI detection in T2DM patients. The ROC results showed that, when used alone, the WMV of left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus had high diagnostic value for MCI detection in T2DM patients (AUC > 0.7, **Table 4**), among which the value of WMV of left precuneus was the highest (AUC: 0.736, sensitivity: 70%, specificity: 73.33%). While the other region, right temporal pole, demonstrated little significance to identify T2DM-MCI patients (AUC = 0.686, **Table 4**). Furthermore, there was no significant difference between the minimum AUC (right rostral middle frontal gyrus) and the maximum AUC (left precuneus) among these four single markers ( $Z = 0.597$ ,  $P = 0.551$ ), which had high diagnostic value for MCI detection in T2DM patients (**Figure 2**). Above all, each WMV of these four regions, including left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus, could be the independent imaging biomarkers for MCI identification in T2DM patients.

## DISCUSSION

In this study, cognitive function assessed by various neuropsychological tests showed that T2DM-MCI patients performed worst among these three groups, while there was no significant difference between T2DM-NC patients and HC. Subsequently, T2DM-MCI patients had white matter atrophy of several regions, and T2DM-NC patients did not show any white matter deficits. In particular, WMV of five regions including the left posterior cingulate, precuneus, insula, right rostral middle frontal gyrus, and temporal pole were significantly correlated with MoCA scores in T2DM patients. More importantly, we identified that each WMV of left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus could be the independent imaging biomarkers for T2DM-associated MCI detection.

To explore the white matter atrophy due to T2DM and T2DM-associated cognitive impairments, we compared the difference of WMV among T2DM-MCI, T2DM-NC, and HC groups. As expected, the WMV was considerably different in some

**TABLE 4 |** Diagnostic values of single imaging marker for MCI in T2DM patients.

Regions (white matter volume)	SEN (%)	SPE (%)	+LR	−LR	Yden	Cutoff	AUC
Left posterior cingulate	70.00	73.33	2.62	0.41	0.4333	4,419.8	0.729
Left precuneus	70.00	73.33	2.62	0.41	0.4333	9,413.7	0.736
Left insula	90.00	46.67	1.69	0.21	0.3667	9,283	0.712
Right rostral middle frontal gyrus	63.33	76.67	2.71	0.48	0.4000	12,077.7	0.704
Right temporal pole	70.00	66.67	2.10	0.45	0.3667	702.7	0.686

SEN, sensitivity; SPE, specificity; +LR, positive likelihood ratio; −LR, negative likelihood ratio; Yden, Youden index; AUC, areas under the curves.

regions among these three groups with FDR correction. After a *post hoc* test and Bonferroni correction, T2DM-MCI patients had white matter atrophy in the left insula, posterior cingulate, and precuneus, right lateral orbitofrontal gyrus, pars orbitalis gyrus, rostral middle frontal gyrus, and temporal pole, when compared with T2DM-NC patients without clinically confirmed cognitive impairment. Additionally, the T2DM-NC patients did not show significant atrophy in brain white matter compared with the HC. These results indicated that the observed atrophy in brain white matter is strongly associated with cognitive impairment in T2DM patients. Previous studies reported that T2DM was associated with white matter loss mainly in frontal and temporal white matter, which were partly in line with our findings (Chen et al., 2012; Moran et al., 2013). However, some other studies revealed that individuals with T2DM had reductions in hippocampus volumes but superior temporal gyrus had no volume loss, which were not in accordance with our results (Korf et al., 2006;

Gold et al., 2007; Cherbuin et al., 2012). In addition, we found that some limbic structures and precuneus, which have been reported associated with cognitive functions (Cavanna and Trimble, 2006; McCrimmon et al., 2012; Hoogenboom et al., 2014), had obviously reduced WMV. The reason of the inconsistent results may be associated with the cognitive state of the included T2DM patients. T2DM patients included in these previous studies were in different stages of diabetes-associated cognitive impairment, whereas in our study, we enrolled T2DM-MCI, the early stages of cognitive impairment in T2DM patients, and T2DM-NC without clinically confirmed cognitive impairments to provide early signs of cognitive dysfunction, which may help clinicians with the earlier prevention of severe cognitive decline in T2DM patients.

The MoCA scores, which served as an index of the cognitive status of the patients, are known to distinguish patients with MCI from the normal population (Petersen et al., 1999). MoCA has shown higher sensitivity in detecting cognitive decline than the

**FIGURE 2 |** ROC curves of white matter volume of four single regions for mild cognitive impairments in T2DM patients. No significant difference ( $Z = 0.597$ ,  $P = 0.551$ ) was found between minimum AUC (right rostral middle frontal gyrus) and the maximum AUC (left precuneus).

MMSE (Nasreddine et al., 2005). Our results revealed that no significant differences were shown in MMSE scores among these three groups, while MoCA scores were significantly higher in HC when compared with T2DM-MCI and T2DM-NC patients, and T2DM-NC patients performed better than T2DM-MCI patients. Furthermore, WMV of five brain regions significantly correlated with the MoCA scores, mainly located in frontotemporal lobe and limbic system, which have been implicated in memory and learning (McCrimmon et al., 2012). Among them, the correlation coefficient of the left posterior cingulate WMV was higher than others. Cingulate gyrus, as one of the important limbic structures, has been reported to be disrupted in T2DM patients (Yau et al., 2010; Hoogenboom et al., 2014; Tan et al., 2016; Nouwen et al., 2017; Groeneveld et al., 2018; Yu et al., 2019). More importantly, its disruption was associated with impairments in cognitive functions including memory, psychomotor speed performance, and executive function in T2DM patients (Hoogenboom et al., 2014). Previous studies have discovered reduced functional connectivity in the default mode network between posterior cingulate gyrus and left medial frontal gyrus in middle-aged T2DM patients. Moreover, reduced FA in the cingulum was correlated with lower functional connectivity between cingulate and medial frontal gyrus (Hoogenboom et al., 2014). Moreover, the white matter loss was also reported in cingulate gyrus attributed to T2DM (Chen et al., 2012). More interestingly, our study also showed that the WMV of left posterior cingulate had a high discriminative ability for T2DM patients with MCI. Thus, the white matter disruption of cingulate gyrus has a possible relationship with cognitive impairments at the early stage in T2DM patients.

In addition, to find non-invasive biomarkers for early detection of cognitive impairment in T2DM patients, we evaluated the discriminative ability of these five regions for MCI in T2DM patients. Four regions had high diagnostic value for MCI detection in T2DM patients by performing ROC analysis of a single region, among which the value of left precuneus was

the highest. The precuneus has been reported to play a central role in a wide spectrum of highly integrated tasks, including visuo-spatial imagery (Simon et al., 2002; Malouin et al., 2003; Wenderoth et al., 2005), episodic memory retrieval (Platel et al., 2003; Addis et al., 2004; Lundstrom et al., 2005), and self-processing operations (Vogeley et al., 2004; den Ouden et al., 2005; Cavanna and Trimble, 2006). Moreover, the white matter disruption and reduced functional connectivity of the precuneus were found in T2DM patients and significantly correlated with disease duration (Zhou et al., 2010; Hsu et al., 2012; Wood et al., 2016). Thus, the white matter atrophy of precuneus could be a part of mild cognitive dysfunction in T2DM patients. Then, we compared the AUC of these four regions' WMV, which presented high diagnostic value for MCI detection in T2DM patients. The results showed that no significant difference was found in maximum AUC relative to the minimum AUC among the four regions' WMV. Therefore, each WMV of the four regions, including left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus, could be the independent imaging biomarker for detecting mild cognitive dysfunction in T2DM patients.

There are also several limitations in our study. First, this current research is a cross-sectional study with a relatively small sample size, and a longitudinal study with a larger sample size is needed in the future to test whether these WMV atrophy could predict the development of cognitive impairment in T2DM patients. Second, although we enrolled age-, sex-, and education-matched HC, T2DM-MCI patients had higher BMI index than HC. However, there were no significant difference in BMI between T2DM-MCI and T2DM-NC patients, with the result that the effect of BMI on the results should be little. Third, although education has been used as a control variable in this study, the participants with different levels of educational achievement may show different effects. Fourth, we only focused on the white matter atrophy in T2DM patients with MCI. Some microstructural damage of white matter could not be detected

on conventional MR images. Exploring the WMV, integrity, and network connection in the same participants will provide more details on the pathophysiological mechanism of white matter. Thus, multimodal imaging methods are needed to investigate the white matter damage in T2DM association with cognitive deficits in future.

## CONCLUSION

In conclusion, the present study revealed that T2DM-NC patients did not show any white matter damage, and T2DM-MCI patients showed significantly reduced WMV in several regions, which suggests that significant white matter atrophy occurred in MCI stage in T2DM patients. In particular, MoCA scores in T2DM patients had significant correlations with the white matter loss of the five regions mainly in the frontotemporal lobe and limbic system. Moreover, each WMV of the four regions, including left posterior cingulate, precuneus, insula, and right rostral middle frontal gyrus, could be the independent imaging biomarker for T2DM-associated cognitive impairment at the early stage and play an important role in its pathophysiological mechanism.

Jia-Ji electro-acupuncture (EA) has been widely applied in clinic to exhibit curative effects on spinal cord injury (SCI). However, its underlying mechanisms leading to improvement of motor function after SCI remain unclear. Allen's method was made by NYU Impactor M-III equipment to create the SCI rats model. Rats were randomly divided into four groups: Sham (only laminectomy), Model (SCI group), EA (SCI + Jia-Ji EA treatment), EA + CQ (SCI + Jia-Ji EA treatment + inhibitor chloroquine). Basso-Beattie-Bresnahan assessment showed improvement of hind limb motor function after Jia-Ji electro-acupuncture treatment. Histological change of injured spinal cord tissue was alleviated after treatment, observed by hematoxylin-eosin and Nissl staining. The mRNA and protein expression levels of RIPK1, RIPK3 and MLKL were decreased in EA group. Besides, the increased expression of LC3 and reduced expression of P62 after treatment compared with Model group, confirmed that Jia-Ji electro-acupuncture could enhance the autophagy flux. Electron microscopy imaging showed increasing the number of lysosomes, autophagosomes, and autolysosomes after Jia-Ji electro-acupuncture treatment. Furthermore, inhibition of lysosome function with CQ led to partly eliminate the effect of EA on reducing necroptosis. These data make the case that Jia-Ji electro-acupuncture treatment may improve locomotor function by promoting autophagy flux and inhibiting necroptosis.

**Keywords:** Jia-Ji electro-acupuncture, spinal cord injury, motor function repair, autophagy flux, necroptosis, lysosome

## INTRODUCTION

Spinal cord injury (SCI) may cause structural and functional impairment of the spinal cord, leading to sensory, motor or autonomic nerve dysfunction, and ultimately affecting the patient's physical, psychological, and social abilities (Singh et al., 2014). With its secondary complications in the long term, SCI is life-threatening and constitutes a considerable portion of the global social and economic burden (GBD 2016 Traumatic Brain Injury and Spinal Cord Injury Collaborators, 2019). The annual incidence of SCI in the United States is about 17,000 new

cases per year (National Spinal Cord Injury Statistical Center, 2016). The global incidence of traumatic SCI ranges from 3.6 to 195.4 patients per million, and the numbers are still rising (Jazayeri et al., 2015).

The pathological mechanism of traumatic SCI involves primary injury (irreversible mechanical injury), and secondary injury (reversible) which is caused by a progressive cascade of tissue destruction and microenvironment changes, including oxidative stress, ischemia, inflammation, edema, glutamatergic excitotoxicity, ion imbalance, and apoptosis (Kumar et al., 2018). Rapid diagnosis and neuroprotective interventions at the stage of acute injury are therefore critical, and these treatments have the potential to significantly improve subsequent long-term functional recovery. Recent medical treatments attempt to reduce secondary damage and protect neurons that survive primary damage (Kwon et al., 2004). Some adjunctive therapies are used as an effective treatment of acute SCI clinically, such as corticosteroids (Schroeder et al., 2014), neuroprotectant agents (Grossman et al., 2014), and alternative therapy (electro-acupuncture) (Xiong et al., 2019).

As a Traditional Chinese medicine method, electro-acupuncture (EA) is a therapy in which a needle is inserted at an acupuncture point and attached to a trace amount of pulsed current to produce a synthetic electro-acupuncture stimulation. Previous studies have proved that the application of EA in the treatment of SCI is beneficial to the neurological and functional recovery of SCI (Ding et al., 2011; Huang et al., 2011). EA has been widely used in SCI therapy in the clinic to improve functional recovery after spinal cord and nerve muscle damage. However, its work mechanism is still unclear.

Inhibition of lysosomal/autophagy pathways and activation of necroptosis have been shown to lead to cell loss and tissue damage in some CNS trauma models (Sarkar et al., 2014; Lipinski et al., 2015). Necroptosis is proved to be associated with the pathogenesis of some neurodegenerative diseases, such as multiple sclerosis and amyotrophic lateral sclerosis (Ofengeim et al., 2015; Ito et al., 2016). It has been previously demonstrated that autophagy flux is inhibited after SCI in the mouse model, with obvious accumulation of autophagy markers LC3-II and autophagy substrate P62/SQSTM1 in ventral motor neurons (Liu et al., 2015b). Inhibition of autophagy flux is proved to be caused by rapid lysosomal dysfunction, contributing to accumulation of RIPK1, RIPK3, and MLKL after SCI, which were located in neurons destroyed by autophagy (Liu et al., 2018). The receptor-interacting protein kinases 1 (RIPK1) and the sequential activation of downstream RIPK3 and the mixed lineage pseudo-kinase MLKL regulates necroptosis which leads to neuronal and glial cell death after SCI (Liu et al., 2015a; Weinlich et al., 2017). As necroptosis markers, RIPK1, RIPK3, and MLKL are expressed in damaged spinal cord tissue and are negatively correlated with motor function recovery (Wang et al., 2018). Specific inhibition of RIPK1 kinase activity is found to block necroptosis and inflammation (Degterev et al., 2008). Thus, the interaction of lysosomal/autophagy and necroptosis may play a key role in improving neuronal survival and functional outcomes after SCI injury.

In this study, the effects of EA on improvement of lower limb function in rat modal would be investigated to explore

its mechanism of autophagy flux and necroptosis regulated by lysosomal dysfunction after SCI, and to provide a potential effective therapy for SCI.

## MATERIALS AND METHODS

### Animals Model

Female Sprague Dawley rats (220–250 g body weight), aged 10 weeks old, were obtained from the central animal of Heilongjiang Chinese Medicine university. Animals use and care protocols conform to guidelines by the International Council for Laboratory Animal Science (ICLAS) and Animal Care and Use Committee of China.

Rats were randomly divided into four groups: Sham group, SCI group, EA group, and EA + CQ group. The sham group received only laminectomy. Model group underwent T9-T11 SCI. Electro-acupuncture group (EA) performed Jia-Ji electro-acupuncture therapy 6 h after SCI. Electro-acupuncture + inhibitor chloroquine group (EA + CQ) received both EA and inhibitor CQ treatment after SCI. 6 h after the injury, the rats were treated with electro-acupuncture. At the same time, the rats were intraperitoneally injected with inhibitor chloroquine (CQ, C6628, United States, Sigma) at an injection dose of 50 mg/kg/d, until the rats were killed. The Sham group, Model group and EA group were injected daily with the same dose of normal saline as CQ. Rats in the SCI, EA and EA + CQ groups were further divided into four subgroups by various time points of treatment: 6 h, 1, 3, and 7 days. And 3 and 7 days subgroups were focus of subsequent studies.

Allen's model was made by application of NYU Impactor M-III strike. After anesthesia with 10% chloral hydrate (3.0 mL/kg body weight) *via* intraperitoneal injection, a 5 cm longitudinal incision was made dorsally on the rats. Expose the T9-T11 spinous processes, and resect the T10 lamina to create a gap around vertebral arch plate. Repeat extend the gap and remove the vertebral plate and T10 spinous process, and expose the intact spinal cord. For Sham group, only laminectomy was performed. The SCI model was then produced using a NYU Impactor M-III strike (a 10 g pouching rod of 2.5 mm diameter with drop of 50 mm and damage of 50 g-cm) at the T10 segment to create relatively serious injury (Verma et al., 2019). All SCI rats conformed to the following injury criteria: spinal cord ischemia and edema, formation of tail sway reflex, flicking of both body and legs, and the appearance of sluggish paralysis. After the strike was completed, marked the skin on both sides of the wound, and applied antibiotics (amoxicillin) to the incision site. Ensure adequate food and water, assist urination once in the morning and evening until the reflex of urination was restored, and massaged the abdomen of rats clockwise every day to prevent flatulence and difficulty in defecation.

Electro-acupuncture treatment method (EA): 6 h after injury, Jia-Ji electro-acupuncture therapy was performed. Operation method: The upper and lower spinous process gaps (proximal end at the top, distal end at the bottom) in the damaged area were selected to open points within 7 mm. After routine disinfection, inserted the needle into the spine with a needle tip

to the lamina (depth is 13 mm). With Micro Plus type pulse electro-acupuncture (BioMedical Life Systems, Inc., Vista, CA, United States), the positive pole was connected to the upper needle handle, and the negative pole to the lower needle body on the same side. Selection parameters: Pulse wave type: continuous pulse waveform; Pulse repetition frequency: 100 Hz; Current output intensity: slight twitch of back muscle (about 1 mA). It lasted for 30 min, once a day.

## Behavioral Assessment

The Basso-Beattie-Bresnahan (BBB) scores was used to evaluate the functional recovery of the hind limbs in rats with SCI (Basso et al., 1995). The scale ranged from 0 to 21 (0 = complete hind limb paralysis, 21 = normal locomotion) for joint movement, gait and hind limb coordination, and fine motion of the toes. The higher the score, the better the motor function. The rats in each group were dynamically evaluated according to the 6 h, 1, 3, and 7 days after SCI. The rats were placed in the open field and moved freely for 5 min. Two trained observers scored performance of the rats blindly and recorded the average value (Hong et al., 2019).

## Hematoxylin-Eosin Staining and Nissl Staining

Rats in Sham, Model, and EA groups ( $n = 6$ ) were subjected to deep anesthesia with 10% chloral hydrate (3.5 ml/kg, I.P.) at different time points. The rats were sacrificed by cutting off their heads quickly, and the spinal cord in the damaged area was quickly removed on the ice bag and then fixed with 4% paraformaldehyde. Paraffin-embedded lesion. Transverse paraffin sections (5  $\mu$ m thick) were placed on slides. HE staining was performed for histopathological examination. The sections were incubated in 1% toluidine blue for Nissl staining and observed under light microscope.

## Immunohistochemistry

Rats in Sham, Model, EA, and EA + CQ groups were deeply anesthetized with 10% chloral hydrate and executed, then the injury section of spinal cord tissue were fixed in 4% paraformaldehyde. A 5  $\mu$ m thick of paraffin embedding spinal cord section was incubated with primary antibody 4°C overnight after dewaxing, transparency, hydrogen peroxide incubation, antigen repair, and blocking. The mixture was placed in room temperature for 30 min, rinsed with PBS for 3 times, incubated with secondary antibody at 37°C for 30 min. Finally, sections were incubated with DAB, hematoxylin redyeing, and mounted on coverslips. Photographic results were taken under a light microscope (400  $\times$ ) and quantitative assessment of immunohistochemical staining was performed by Image-Pro Plus 6.0 software. Primary antibodies: RIPK1 (1:100, RIPK1 Rabbit PolyClonal antibody, United States Proteintech), RIPK3 (1:40, Rabbit PolyClonal antibody, Beijing BIOSS), MLKL (1:200, Rabbit PolyClonal antibody, United States Affinity), LC3B (1:500, Rabbit polyclonal antibody, United States Proteintech), P62 (1:200, Rabbit polyclonal antibody, United States Proteintech). Second antibody: anti-rabbit (PV-6,001, Beijing Zhongshanjinjiao).

## Transmission Electron Microscopy

Rats in Sham, Model, and EA groups ( $n = 6$ ) at 3 and 7 days time points were euthanized. The spinal cord tissues at the injured sites were removed, cut into small pieces of about 1 mm  $\times$  1.5 mm  $\times$  1.5 mm, and fixed with 2.5% glutaraldehyde for more than 24 h and then with 2% osmium acid for 2 h. After dehydration in acetone, the embedded spinal cord sections were stain with toluene ammonia blue to select required sites for observation. Sweden made LKB-III ultra-thin slicing machine was used to section with the thickness of about 500A. The samples were stained with uranium acetate and lead nitrate and observed by transmission electron microscope.

## Real-Time Quantitative Polymerase Chain Reaction (qRT-PCR)

The spinal cord tissue at the damaged site in each group was quickly removed and put into liquid nitrogen, and then transferred to the  $-80^{\circ}\text{C}$  refrigerator for use. Total RNA was isolated using BufferRL1. The mRNA expression of RIPK1, RIPK3, MLKL were measured using the RT-qPCR system. The reverse transcription system was as follows: RNase Free dH<sub>2</sub>O: 10  $\mu$ l, 5X PrimeScript Buffer 2 (for Real Time): 4  $\mu$ l, RNA: 4  $\mu$ l, RT Primer Mix (4  $\times$ ): 1  $\mu$ l, Primescript RT Enzyme Mix I: 1  $\mu$ l. 42°C for 15 min and 85°C for 5 s for reverse transcription. PCR reaction solution was as follows: TBGreen Premix Ex TaqI (Tli RNaseH Plus) (2  $\times$ ): 10  $\mu$ l, PCR Forward Primer (10  $\mu$ M): 0.8  $\mu$ l, PCR Reverse Primer (10  $\mu$ M): 0.8  $\mu$ l, RT reaction solution (cDNA): 2  $\mu$ l, sterilized water: 6.4  $\mu$ l, Total: 20  $\mu$ l. Target gene primer sequence: RIPK1 (For 5'-GAGGAGGAAAGGAAGCGAAG-3', Rev 5'-TGACTGGTTGTGCTGGGATA-3') 113 bp, RIPK3 (For 5'-GAGTGGGACTACGTGTACGG-3', Rev 5'-CAGCAGAACA TTGGAGGGCT-3') 204 bp, MLKL (For 5'-AGCCTCCCCAGT GACATTAC-3', Rev 5'-GCCACAGTAGCAAACCTTCC-3') 120 bp,  $\beta$ -actin (For 5'-CCTGTGGCATCCATGAAACTAC-3', Rev 5'-CCAGGGCAGTAATCTCCTTCTG-3') 150 bp. PCR amplification procedure followed by 40 cycles of 95°C for 5 s, 60°C for 30 s. Delta-delta Ct ( $\Delta\Delta\text{Ct}$ ) method was used to calculate the relative expression of the target gene. PrimeScript RT reagent Kit with gDNA Eraser (Perfect Real Time) (Japan, Takara), TB Green Premix Ex Taq II (Tli RNaseH Plus) (Japan, Takara).

## Western Blot Assay

Rats in Sham, Model, EA, and EA + CQ groups ( $n = 6$ ) at 3 and 7 days time points were euthanized, and the spinal cord tissues at the damaged sites were removed rapidly and homogenized in lysis buffer. With PMSF15 ml, 12,000 rpm, centrifuged for 5 min, the supernatant was absorbed, and the protein concentration was determined by BCA. Loading sample for electrophoresis and then transferred the protein to the PVDF membrane. After blocking for 1 h, the PVDF membrane was incubated with the primary antibody at 4°C overnight, as shown below: LC3B (1:2,000, Rabbit polyclonal antibody, United States Proteintech), P62 (1:1,000, Rabbit polyclonal antibody, United States Proteintech), RIPK1 (1:1,000, RIPK1 Rabbit PolyClonal antibody, United States

Proteintech), RIPK3 (1:2,000, Rabbit polyclonal antibody, Beijing BIOSS), MLKL (1:1,000, Rabbit polyclonal antibody, United States Affinity),  $\beta$ -actin (1:5,000, mouse monoclonal antibody, United States Proteintech). The membrane were washed 3 times with Tris-buffered saline Tween, and incubated with secondary antibody at 37°C for 1 h as shown below: HRP-Goat-Anti-Rabbit IgG(H + L) (1:5,000, United States Proteintech), HRP-Goat-Anti-Mouse IgG(H + L) (1:5,000, United States Proteintech). The immunoreactive bands were visualized by ECL chemiluminescence. The grayscale values of bands were quantified by Image Lab 5.2.1 software, and the relative expression of protein was calculated according to the ratio of target protein to  $\beta$ -actin.

## Statistical Analyses

SPSS 25.0 software was used for statistical analysis. The data were presented as mean  $\pm$  standard deviation ( $\pm$  SD). One-way analysis of variance (ANOVA) was used for comparison between groups. For further comparison between groups, the least significant difference (LSD) test was used for those with homogeneous variance, and Dunnett's T3 test was used for those with heterogeneous variance.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Electro-Acupuncture Improved Motor Function

BBB scale scores were used to assess movement of hind limb. The first part mainly evaluates the range of motion of joints, with a score of 0–7. The second part mainly evaluates the gait and hind limb coordination ability, with a score of 8–13. The third part mainly assessed the fine movement of the toes, with a score of 14–21 points. After SCI, the rats were paralyzed in the hind limbs, without any movement phenomenon, with reduced diet and water, accompanied by urinary retention, and entered the stage of spinal cord shock, with a score of 0 point. The evaluation results of Sham group were all scored 21 points at the four time points of 6 h, 1, 3, and 7 days, and the rats walked as usual, indicating no dyskinesia. The scores of Model group at each time point after SCI were significantly lower than Sham group ( $P < 0.01$ ), which means a significant movement disorder following SCI. After EA treatment, there was little change in the score at 6 h and 1 day, and no statistical significance was found compared with the Model group ( $P > 0.05$ ). The scores were significantly greater in the EA group compared with the SCI group on days 3 and 7 after injury ( $P < 0.01$ ; **Figure 1**). Motor dysfunction of the hind limbs could be improved in the rats with EA treatment at 3 and 7 days.

### Effects of Electro-Acupuncture on Histological Changes in Spinal Cord

At the time points of 3 and 7 days, the appearance and structure of the spinal cord tissues in Sham group was normal. The hematoma after SCI in Model group was most severe on 3 day. After the

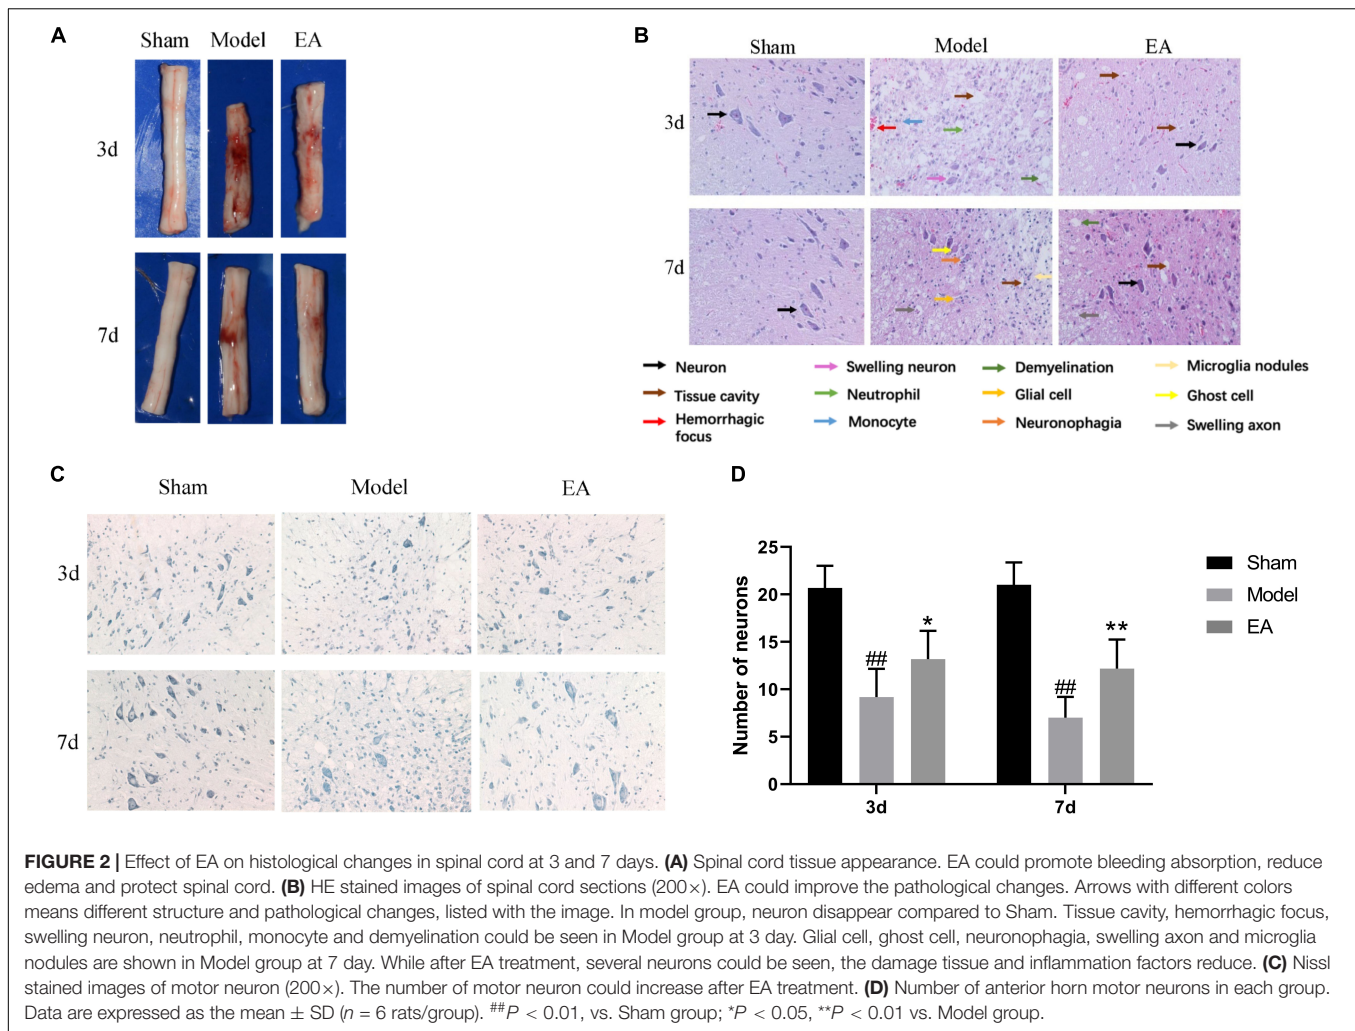

**FIGURE 1 |** BBB scores of four different time points. Data are expressed as the mean  $\pm$  SD ( $n = 6$  rats/group). ##  $P < 0.01$ , vs. Sham group; &  $P > 0.05$ , \*\* $P < 0.01$ , vs. Model group. BBB: Basso, Beattie and Bresnahan rating scale, used to evaluated hind limb locomotor. Sham, laminectomy only; Model, spinal cord injury; EA, electro-acupuncture.

EA treatment, the hematoma area became significantly smaller at each time point (**Figure 2A**).

In the SCI group on 3 day, pathological change was most obvious with gray structure disorder, necrosis and inflammation worsen, a large number of neurons lost, the serious neurons swelling, neutrophils, and monocytes infiltration, white matter demyelinating and scattered focus of hemorrhage. Compared with the Model group, the EA group had fewer necrotic cavities, improved neuronal swelling, more orderly gray matter structure, less neuron loss, and improved inflammatory cell infiltration. At the time point 7 days after SCI, the loss of gray matter neurons in the Model group was still significant, the necrotic cavity gradually expanded, which showed the ghost cell of dead neurons, the decrease of inflammatory cells compared with that at 3 day, and a large number of glial cells proliferated. In this figure, the image of neuronophagia and nodular microglia could be seen. There are numerous voids in the white matter, marked demyelinating changes, and the ends of axons swell into a spherical shape. The hemorrhagic lesion was reduced compared with that of 3 day, while the above pathological symptoms were improved after treatment in the EA group. The gray matter structure was relatively complete, the nerve fibers were arranged in a more orderly manner, the boundary between gray matter and white matter could be observed, the number of neurons was more, the number of cavities was less, and the inflammatory cell infiltration was improved (**Figure 2B**).

Nissl staining was used to observe the morphology and number of motor neurons in the anterior horn of spinal cord in each group. In Sham group, the anterior horn motor neurons were orderly arranged without significant reduction, deep blue staining. At 3 and 7 days time points, there were statistically significant reducing in the number of anterior angular motor neurons in Model group compared to Sham group ( $P < 0.01$ ). Although the number of neurons in the EA group decreased, the number of neurons in the EA group was still higher than that in the Model group, and the staining was relatively deeper. The comparison between the two groups was statistically significant (3 day:  $P < 0.05$ , 7 day:  $P < 0.01$ ) (**Figures 2C,D**).

## Electro-Acupuncture Inhibited the Expression of Necroptosis Markers RIPK1, RIPK3, and MLKL

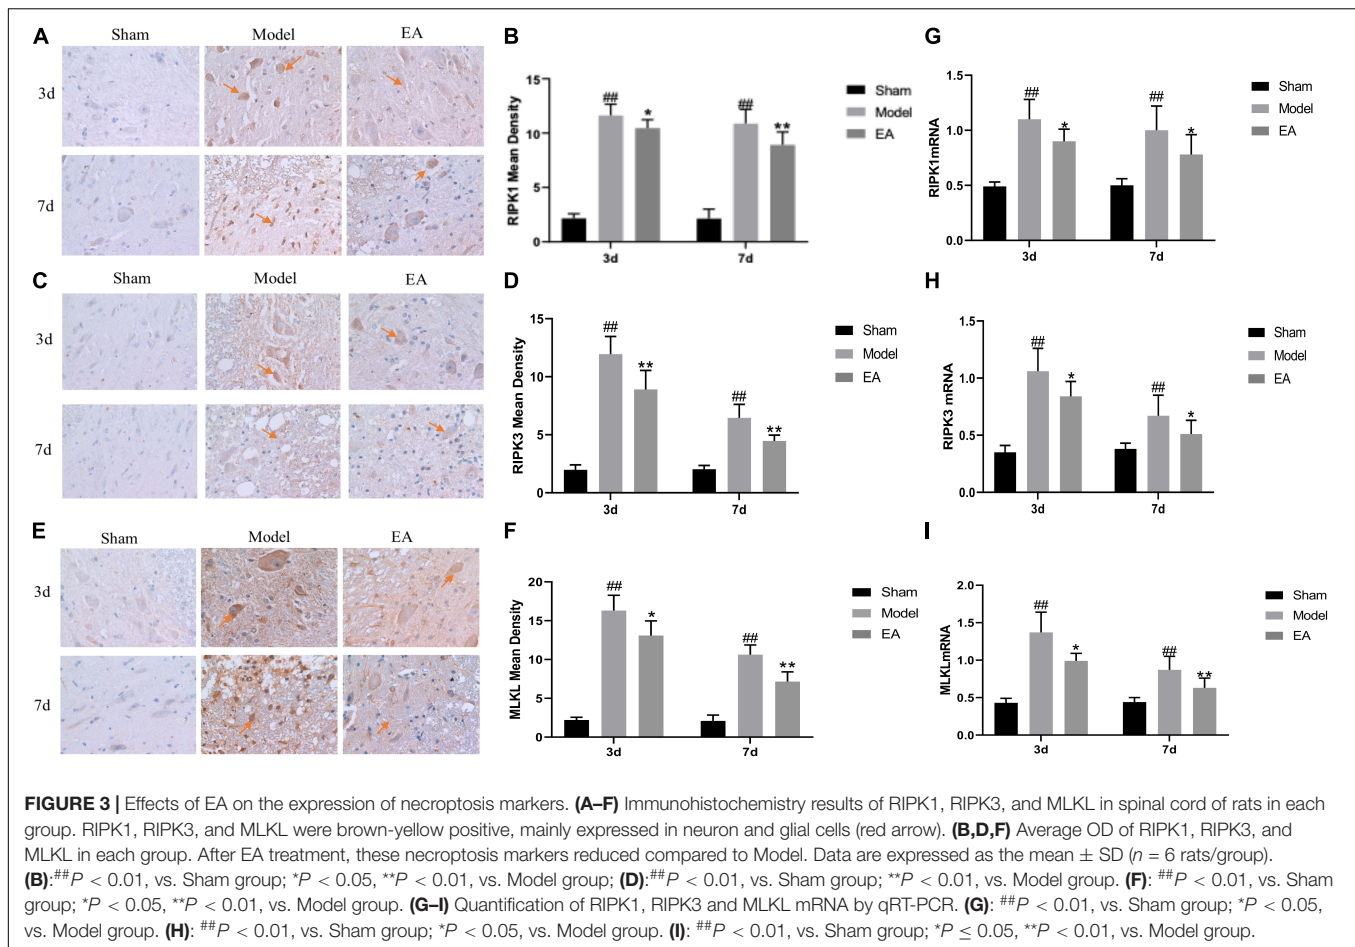

RIPK1, RIPK3, and MLKL were mainly expressed in the cytoplasm of neurons and glial cells. The average OD value of RIPK1, RIPK3, and MLKL in the Model group was significantly higher than that of the Sham group at 3 and 7 days after injury ( $P < 0.01$ ). After EA treatment, the mean OD value of RIPK1, RIPK3, and MLKL decreased, and the comparison between the EA group and the Model group was statistically significant at the time points of 3 and 7 days (RIPK1, 3 day:  $P < 0.01$ , 7 day:  $P < 0.05$ ; RIPK3, 3 day/7 day:  $P < 0.01$ ; MLKL, 3 day:  $P < 0.05$ , 7 day:  $P < 0.01$ . **Figures 3A–F**). It may illustrate that the expression level of RIPK1, RIPK3, and MLKL increased after SCI, and the EA had the effect of inhibiting the necroptosis factors.

qRT-PCR results showed that the expression of RIPK1, RIPK3, and MLKL mRNA in the Model group was significantly higher than that in the Sham group at 3 and 7 days after SCI ( $P < 0.01$ ). After treatment, the expression level of those mRNA in the EA group was decreased, and the difference between the EA group and the Model group was statistically significant at 3 and 7 days

time points (RIPK1, RIPK3,  $P < 0.05$ ; MLKL, 3 day:  $P \leq 0.05$ , 7 day:  $P < 0.01$ . **Figures 3G–I**). This result is consistent with immunohistochemistry results.

## Electro-Acupuncture Enhanced Autophagy Flux and Inhibited Necroptosis Electro-Acupuncture Increased Numbers of Autolysosomes

Electron microscopy was used to observe the structure changes of spinal cord tissue after injury. In the Sham group, the nuclei were intact and uniformly stained, the number and structure of organelles in the cytoplasm were normal, the myelin sheath was arranged in concentric circles around the axons, and microfilaments and microtubules could be seen in the axons in regular arrangement. No axonal denaturation and granular disintegration were observed, no autolysosome was found, and several primary lysosomes could be seen (**Figure 4A**). On 3 day after SCI, the cytoplasm of neurons in the spinal cord tissue had sustained extensive edema, the mitochondria were swollen significantly, the myelin lamina was broken,

the rough endoplasmic reticulum was loose, the number of lysosomes increased (Figure 4B). In the EA + CQ group, autophagosomes increased much more than that in EA group, while only several autolysosomes could be seen (Figure 4C). CQ destroyed lysosome function by inhibiting the fusion of lysosome and autophagosomes, leading to the accumulation of autophagosomes, and blockage of autophagy flux. The number of lysosomes, especially secondary lysosomes/active lysosomes, autophagosomes, and autolysosomes in the EA group was greater than that in the model group (Figure 4D). This results may illustrate that EA have effects on increasing the numbers and function of lysosomes and autolysosomes and enhancing autophagy flux.

### Lysosomes Inhibitor CQ Eliminated Effect of EA on Motor Function Improvement and Histological Changes

The EA group scored higher than the Model group on both 3 and 7 days, with statistically significant differences ( $P < 0.05$ ,  $P < 0.01$ , Figure 5A). However, after injection of lysosomes inhibitor CQ, the EA + CQ group had lower scores on 3 and 7 days than the EA group significantly ( $P < 0.01$ ), indicating that CQ could partially eliminate the therapeutic effect of EA on improvement of motor function.

At the time points of 3 and 7 days after surgery, the number of neurons in the Model group was significantly reduced, while neurons relatively increased after treatment in the EA group, statistically significant compared with the Model group at each time point ( $P < 0.05$ ,  $P < 0.01$ ). However, the neurons in the EA + CQ group decreased after injection of inhibitor CQ at 3 and 7 days compared with that in the EA group ( $P < 0.01$ ), indicating that injection of inhibitor CQ could partially eliminate the therapeutic effect of EA and reduce the number of neurons (Figures 5B,C).

### Electro-Acupuncture Promoted Autophagy Flux Blocked by Lysosomes Inhibitor

Immunohistochemistry results showed that LC3 and P62 were mainly expressed in cytoplasm of neurons and glial cells. At postoperative 3 and 7 days, the mean density value of LC3 and P62 in Model group were significantly higher than Sham group ( $P < 0.01$ ). After treatment at 3 and 7 days, LC3 in the EA group increased significantly compared with the Model group ( $P < 0.05$ ,  $P < 0.01$ ), while the value of P62 in EA group was lower than that in Model group ( $P < 0.05$ ). The mean density value of LC3 and P62 both increased in EA + CQ group at each time point after injection of inhibitor CQ, compared to that in EA group ( $P < 0.05$ ,  $P < 0.01$ ). The results showed that the expression of

**FIGURE 4 |** Electron microscopy results of the spinal cord tissue sections after EA. **(A)** Ultrastructure of the sham group (13,000 $\times$ ). Nuclei is intact (red arrow), with obvious nucleoli. The myelin sheath is arranged around the axon in concentric circles. No autophagosome is found. **(B)** Ultrastructure of spinal cord tissue after injury in 3 day (18,000 $\times$ ). In model group, the myelin sheath and the nucleus shrinks and several lysosomes (Red arrow) and autolysosomes (purple arrow) are shown. **(C)** EA + CQ group in 3 day (44,000 $\times$ ). Autophagosomes accumulated significantly. Several active lysosomes could be seen. **(D)** EA group in 3 day (18,000 $\times$ ). The number of lysosomes, autophagosomes and autolysosomes increased in EA group, especially active lysosomes. Yellow arrow: secondary lysosome (active lysosome). Blue arrow: autophagosomes with two membranes. Red: primary lysosomes. Purple: autolysosomes with single membrane.

LC3 increased after SCI, which may be related to the decreased autophagosomal degradation caused by lysosomal dysfunction. While electro-acupuncture could promote the expression of LC3 and increase the formation of autophagosome. After SCI, the expression level of autophagy degradation substrate P62 was increased, and the acupuncture could reduce the expression of P62, promote autophagy degradation, and accelerate autophagy flux. On the basis of the acupuncture treatment, lysosomal inhibitor CQ was injected to enhance the expression of LC3 and P62, leading to excessive accumulation of autophagosomes and blocking of autophagy flux (Figure 6).

It is further verified by Western Blot. LC3-II protein expression in Model group was significantly higher than that in Sham group at 3 and 7 days postoperatively ( $P < 0.01$ ). After EA treatment, the expression level of LC3-II protein increased, which was statistically significant compared with the Model group at the time points of 3 and 7 days ( $P < 0.01$ ). However, LC3-II protein in the EA + CQ group continued to increase after injection of inhibitor CQ, and the difference between the EA group and the EA group was statistically significant ( $P < 0.05$ ). These results indicate that the expression of LC3-II protein increases and autophagy increases after SCI, which may be caused by the blockage of autophagy flux. The continued increase of LC3-II protein expression after acupuncture treatment may be related to

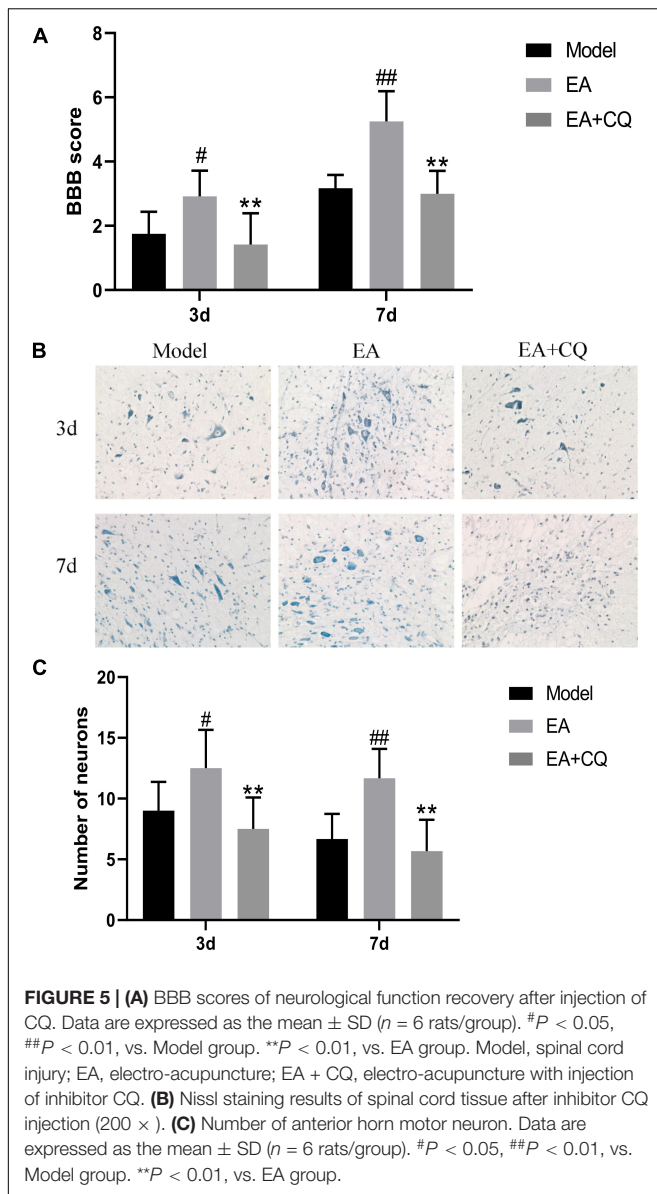

the promotion of autophagy. The inhibitor CQ was injected on the basis of the electro-acupuncture treatment, resulting in the further increase of LC3-II protein expression and a large amount of autophagosome accumulation (Figure 7A).

P62 protein expression in the Model group was significantly increased compared with that in the Sham group ( $P < 0.01$ ), while it was decreased in EA group, which was statistically significant compared to Model group at 3 and 7 days after treatment ( $P < 0.05$ ). After injection of inhibitor CQ, the expression of P62 protein in the EA + CQ group was higher than that in the EA group at each time point ( $P < 0.01$ ). These results indicated that P62 protein expression increased after SCI. After EA treatment, the expression of P62 protein was decreased, autophagy degradation was promoted, and autophagy flux was enhanced. The inhibitor CQ could partly eliminated the effect of the EA on reducing P62 protein expression, but promoted its increase (Figure 7B).

### Lysosomes Inhibition Eliminated the Effect of Electro-Acupuncture on Reducing Necroptosis Markers Expression

At 3 and 7 days after surgery, the average optical density value of RIPK1, RIPK3, MLKL in the EA group were lower than that of the Model group (RIPK1, MLKL:  $P < 0.05$ ,  $P < 0.01$ ;

RIPK3:  $P < 0.05$ ), while the value of them in EA + CQ group increased after the injection of inhibitor CQ, and the comparison between the EA + CQ group and the EA group was statistically significant at 3 and 7 days after surgery ( $P < 0.05$ ,  $P < 0.01$ , **Figure 8**). These results indicated that EA treatment could inhibit the formation of necroptosis factor RIPK1, RIPK3, MLKL, reduce the formation of necrotic complex, and protect the remaining neurons. However, after injection of inhibitor CQ, the effect of EA on necroptosis factors reduction was partially eliminated, so as to increase the value of necroptosis factor and reduce the survival rate of neurons.

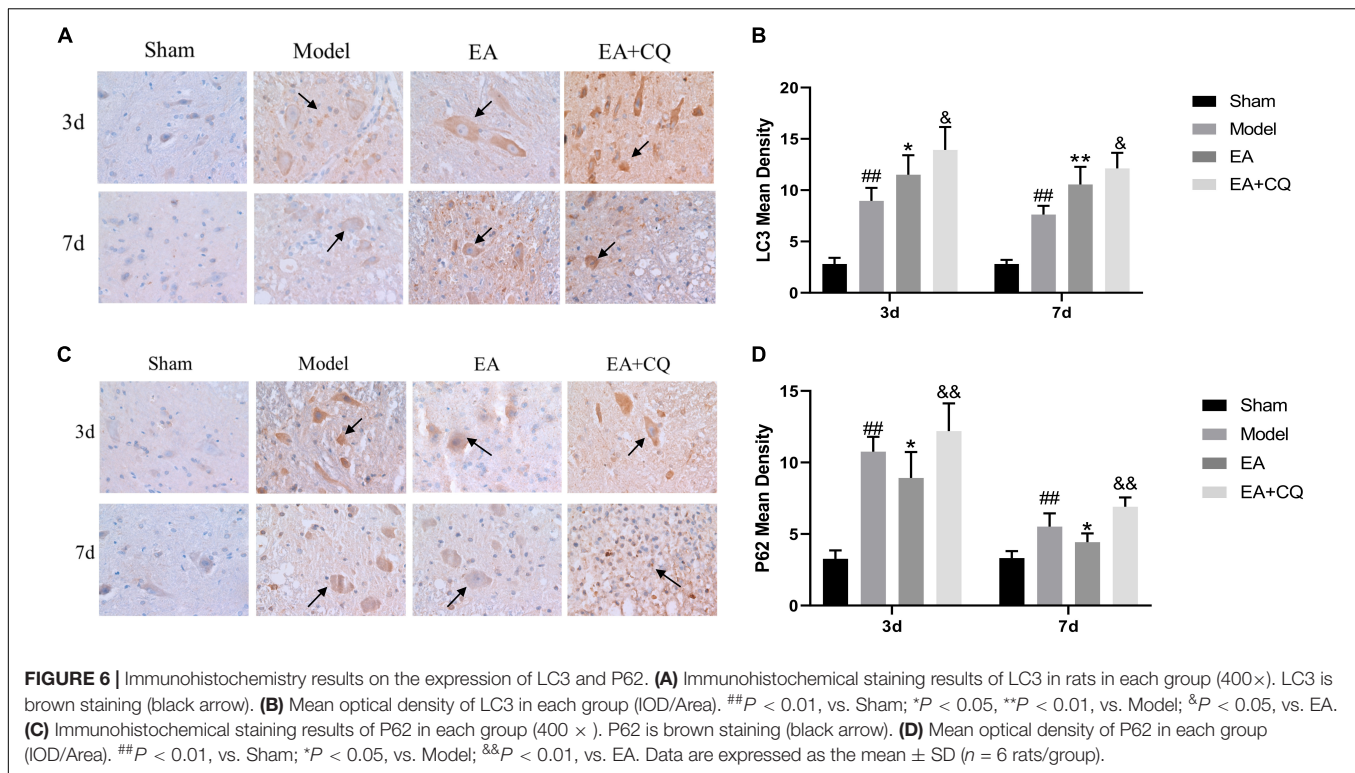

The expression of RIPK1, RIPK3, and MLKL in the Model group was significantly increased compared with that in the Sham group at 3 and 7 days ( $P < 0.01$ ), while it was decreased after treatment in the EA group. At the time points of 3 and 7 days, the difference was statistically significant compared with

that in the Model group (RIPK1:  $P \leq 0.05$ ; RIPK3:  $P < 0.05$ ; MLKL:  $P < 0.05$ ,  $P < 0.01$ ). Compared with the EA group, RIPK1, RIPK3, and MLKL protein expression in the EA + CQ group increased significantly at each time points after injection of inhibitor CQ (RIPK1:  $P < 0.01$ ,  $P < 0.05$ ; RIPK3:  $P < 0.05$ ,  $P < 0.01$ ; MLKL:  $P < 0.01$ , **Figure 9**). The results show that RIPK1, RIPK3, and MLKL protein expression increased after SCI, and EA treatment could reduce these necroptosis factors expression and necrosis complex formation. Inhibitor CQ could partly eliminate the effect of EA on reducing RIPK1, RIPK3, and MLKL protein expression, instead promoting its elevation, which is available in the formation of necrotic complexes and exacerbates neuronal necrosis.

## DISCUSSION

Clinically, EA as a traditional Chinese medicine therapy has been widely used to improve the prognosis of spinal cord and neuromuscular injury. Electro-acupuncture at Jia-Ji points is a combination of acupuncture effect and electric field effect on injured spinal cord after SCI. In this study, we investigated the molecular biological mechanism of EA treatment on improvement of lower hind motor and autophagy regulation of necroptosis. Our data showed that lysosome function was inhibited after SCI with increasing the expression of LC3-II and P62. LC3-II reflects the number of autophagosomes and P62 is autophagy cargo protein. The number of autophagosomes and the degradation of autophagy cargo protein increased after EA treatment, which proved that the electro-acupuncture has the effect of enhancing autophagy flux. Consistent with previous study (Liu et al., 2018), we found that necroptosis markers were accumulated after SCI in neurons with inhibiting of autophagy flux and lysosomal damage. The accumulation of RIPK1, RIPK3, and MLKL were inhibited in neurons and glial cells by using Jia-Ji EA treatment, which may reduce necroptosis. Besides, the lysosome inhibitor CQ partially eliminated the therapeutic effect of EA on promoting autophagy flux and inhibiting necroptosis. This study suggests that Jia-Ji EA treatment may promote the recovery of motor function through the mechanism of accelerating autophagy flux and alleviating necroptosis.

Rodent models have become standard in the past 30 years and have been widely used in SCI research (Kwon et al., 2015). Rats are the best choice and the most widely used due to the limit field of vision of mice (Verma et al., 2019). In rat model of SCI, we observed that there was a significant improvement on motor function after EA treatment compared to Model group at 3 and 7 days time points ( $P < 0.01$ ). The improvement of hind limb motor function was not obvious after treatment for 6 h or 1 day. So 3 and 7 days time points were selected as time points in the following study. It is further proved by the histological changes. At the time points of 3 and 7 days, the appearance and structure of the spinal cord tissues in the Sham group were normal, while the hematoma in the spinal cord attack area in the Model group was obvious. However, the hematoma was the most severe in 3 day, indicating that the vascular hemorrhage of the spinal cord after external impact caused congestive necrosis, leading to further

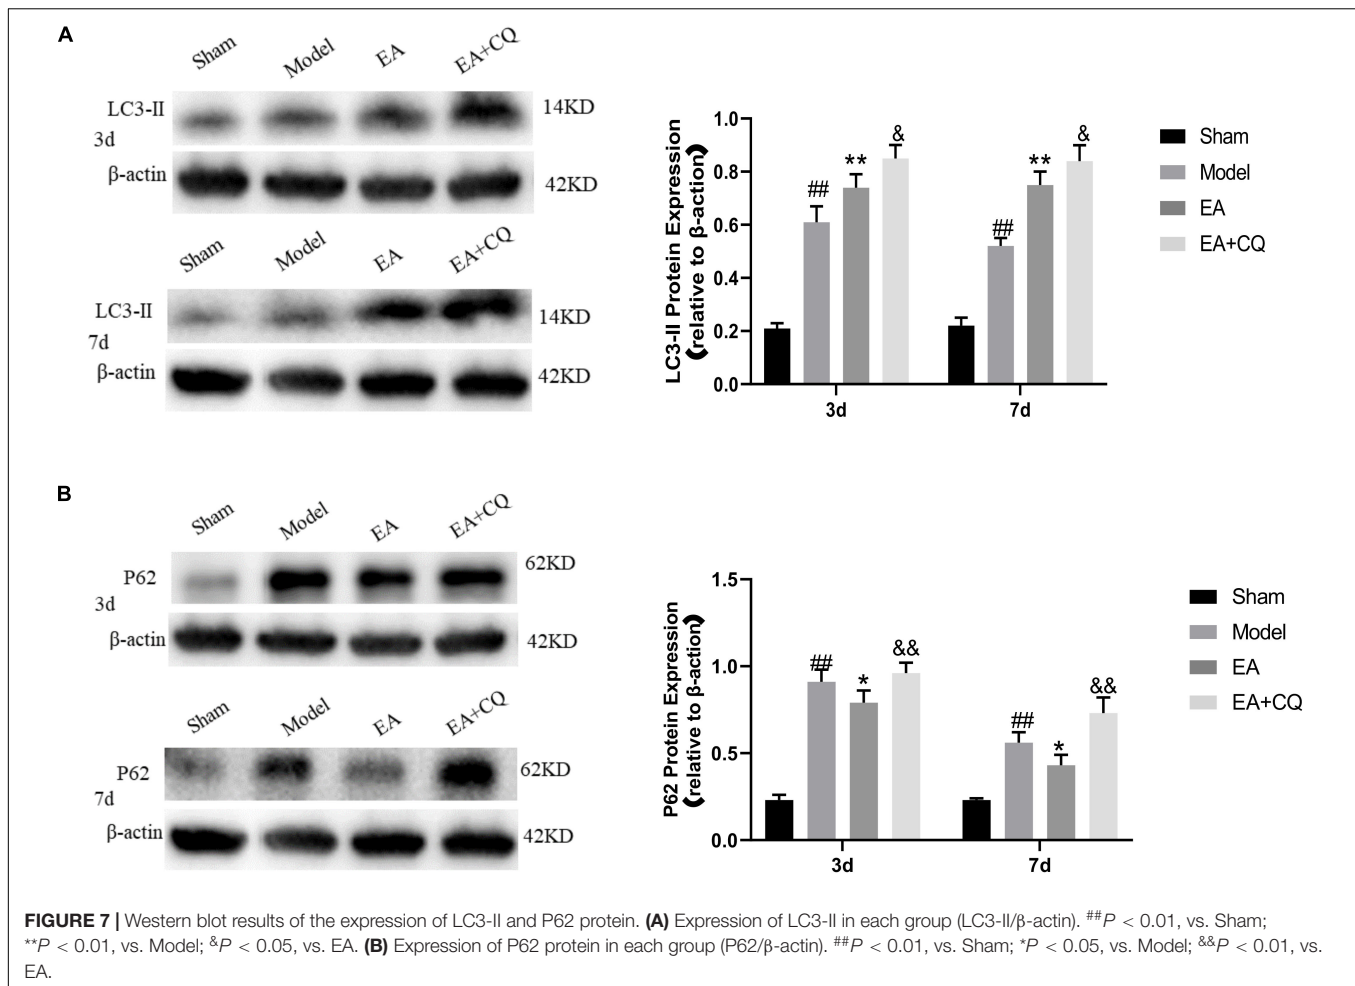

aggravation of tissue ischemia. After EA treatment, the range of hematoma in EA group at each time point became smaller and the color became lighter. Spinal cord structure was disorder at 3 day after SCI in Model group, with nerve fibers arranged loosely, flake bleeding lesions, the massive death of neurons, retained a large number of neurons die cavity. These pathology changes are associated with cells and necrotic neurons apoptosis, known as vacuolization of neurons. While at 7 day after SCI, inflammatory cells infiltration reducing, hyperplasia of glial cells, and phagocytosis phenomenon of neurons could be seen on HE stain, suggests that microglia have the effect of the removal of necrotic neurons, leaving ghost necrotic neurons observed. These pathological findings are consistent with previous reports (Alexander and Popovich, 2009; Mortazavi et al., 2015; Quadri et al., 2020). The Nissl body is a marker of the functional state of neurons. From Nissl staining, we found that the number of residual neurons in the Model group increased after EA treatment ( $P < 0.05$ ), indicating that the death of neurons was reduced. The results showed that the EA could improve the microcirculation and inhibit neuronal death, which may be related to the improvement of motor function at 3 and 7 days time points.

Necroptosis is a regulatory necrosis activated downstream of tumor necrosis factor receptor 1 (TNFR1), dependent on the activity of receptor interaction protein kinases 1 (RIPK1) and 3 (RIPK3), and recruits mixed lineage pseudo-kinase MLKL to form necrosome complex (Necrosome), mediating cell rupture and death (Vandenabeele et al., 2010). The accumulation of necroptosis markers RIPK1, RIPK3, and MLKL was found after SCI, which may contribute to neuronal and glial cell death

(Liu et al., 2015a). The RIPK1 inhibitor NEC-1 and the MLKL inhibitor NSA was found to inhibit the expression of necrosis factor and improve the lower limb motor function (Wang et al., 2014, 2018). In our results, RIPK1, RIPK3, and MLKL were mainly expressed in the cytoplasm of neurons and glial cells, but also shown in the intercellular substance, possibly because necroptosis factors in the cytoplasm were released into the intercellular after cell rupture. The mean optical density values of spinal cord tissues RIPK1, RIPK3, and MLKL in the Model group were significantly higher than those in the Sham group at 3 and 7 days after surgery ( $P < 0.01$ ). This indicated that necrotic complexes accumulated in large quantities after SCI, while the average optical density values of RIPK1, RIPK3, and MLKL were decreased at all-time points after treatment in the EA group ( $P < 0.05$ ). It may illustrate that EA could inhibit necrosome accumulation and reduce necroptosis of neuron.

As an important and conserved lysosomal degradation pathway, autophagy is thought to be involved in many physiological and pathological processes. It has been shown that inhibiting autophagy may have a neuroprotective effect (Siracusa et al., 2016; Wei et al., 2016). Autophagy flux is a dynamic process involving the formation, transmission, and degradation of autophagosomes. The increase of autophagosomes alone does not mean the enhancement of autophagy, and the accumulation of autophagosomes may occur due to the reduction of autophagosome degradation or the inability to degrade with the increase of autophagosome formation, thus inhibiting autophagy flux. The beneficial or harmful functions of autophagy may depend on the induction or inhibition of autophagy flux after central nervous system injury. Smooth autophagy flux

often leads to cell protection, while blocked autophagy flux contributes to cell death. In our results, LC3 and P62 were mainly expressed in the cytoplasm of neurons and glial cells, consistent with the location of necrotic apoptotic factors. Average optical density values of LC3 and P62 were significantly higher than that of Sham group at 3 and 7 days postoperatively ( $P < 0.01$ ). Besides, the expression peak of LC3 and P62 at 3 day was in accordance with that of necroptosis factors. The increase of LC3 and P62 after SCI indicates the blockage of autophagy flux, which may be caused by dysfunction of lysosomes on fusion and degradation of autophagosome after injury. The average optical density value of LC3 in the EA group was higher than that of the Model group at all-time points ( $P < 0.05$ ), while the average optical density value of P62 was lower than that of the Model group ( $P < 0.05$ ), indicating that EA treatment promoted the increase of LC3, reduced the expression of P62, and accelerated autophagy flux. LC3-II is generally considered as an autophagosome marker, because the content of LC3-II reflects the number of autophagosomes. However, LC3-II may not be able to estimate autophagy activity. Not only autophagy activation, but also inhibition of autophagosomal degradation greatly increases the content of LC3-II. The degradation of autophagy substrate P62/SQSTM1 is another marker widely

used to evaluate autophagy activity, which can recruit ubiquitin substrates into autophagosome and degrade with it (Yoshii and Mizushima, 2017). When autophagy flux is high, the level of p62 protein decreases. Conversely, a reduction in autophagy flux may lead to P62 protein accumulation. Moreover, it was observed by electron microscopy that the number of lysosomes, autophagosomes and autolysosomes were increased compared with the model group after SCI was treated by EA. This result also indicates that EA could increase autophagy flux and promote autophagy degradation, consistent with the results that increase of LC3 expression and decrease of P62 expression mentioned before. More active lysosomes appeared after EA treatment, indicating Jia-Ji EA may stimulate lysosome function. The mechanism of EA on increasing autophagy flux may be related to the increase of autophagosome formation and the improvement of lysosomal function. However, the mechanism of Jia-Ji EA on increasing the number of lysosomes and enhancing its function still needs further study.

Lysosome function plays an important role in promoting autophagy flux. When autophagy flux is blocked due to lysosome dysfunction, the accumulation of autophagosomes would possibly lead to cell death (Lipinski et al., 2015). The autophagosome can be used as a basis to assemble necrotic

complexes (Goodall et al., 2016). RIPK1 is recruited by P62 [the ZZ domain of P62 can interact with RIPK1 (Puissant et al., 2012)] to the autophagosome, which activates the assembly of necrosome and further mediates cell death. After inhibition of lysosomal function, autophagosomes accumulated, and could not be successfully degraded, contributing to the increase of LC3 and P62 contents. It has been previously demonstrated that autophagy flux was inhibited after SCI and treatment with rapamycin could attenuated accumulation of P62 by improving lysosomal function and autophagy flux (Liu et al., 2018). To further explore the effect of autophagy flux on rat hind limb function, lysosome inhibitor chloroquine CQ was applied. Many studies supported lysosomal luminal alkalinizer chloroquine (CQ) as an inhibitor of autophagy flux in rats with SCI (Hu et al., 2017; Zhang et al., 2017). CQ could improve the pH-value of lysosomes and then destroy the function of lysosomes, inhibit fusion of lysosomes and autophagosomes, thus leading to the accumulation of autophagosomes and blockage of the autophagy flux. BBB score and Nissl staining were observed after injecting CQ on the basis of EA treatment. At the time points of 3 and 7

days, BBB score was lower than that of the EA group ( $P < 0.01$ ). The staining of motor neurons in the anterior horn was relatively light and the number of them was decreased compared with that of the EA group ( $P < 0.01$ ), indicating that injection inhibitor CQ partially eliminated the therapeutic effect of EA, reduced the number of motor neurons in the anterior horn, and aggravated dysfunction of hind limbs in rats.

After treatment, the average optical density values of RIPK1, RIPK3, and MLKL in the EA group were lower than those in the Model group at each time point ( $P < 0.05$ ), indicating the inhibitory effect of EA on necroptosis. After the injection of inhibitor CQ, the average optical density values of LC3, P62, RIPK1, RIPK3, and MLKL in the EA + CQ group increased at each time point, which was statistically significant compared with the EA group at each time point ( $P < 0.05$ ). These results indicated that CQ partially eliminated the effect of EA on promoting autophagy flux and inhibiting necrotizing apoptosis. The results above were further confirmed by Western blot. Protein expression levels of LC3, P62, RIPK1, RIPK3, and MLKL were significantly higher than that of Sham group at 3 and 7 days

**FIGURE 9 |** Western blot results on the expression of RIPK1, RIPK3, and MLKL. **(A)** Expression of RIPK1 protein in each group (RIPK1/ $\beta$ -actin). <sup>##</sup> $P < 0.01$ , vs. Sham; <sup>\*</sup> $P \leq 0.05$ , vs. Model; <sup>&&</sup> $P < 0.01$ , <sup>&</sup> $P < 0.05$ , vs. EA. **(B)** Expression of RIPK3 protein in each group (RIPK3/ $\beta$ -actin). <sup>##</sup> $P < 0.01$ , vs. Sham; <sup>\*</sup> $P < 0.05$ , vs. Model; <sup>&</sup> $P < 0.05$ , <sup>&&</sup> $P < 0.01$ , vs. EA. **(C)** Expression of MLKL protein in each group (MLKL/ $\beta$ -actin). <sup>##</sup> $P < 0.01$ , vs. Sham; <sup>\*</sup> $P < 0.05$ , <sup>\*\*</sup> $P < 0.01$ , vs. Model; <sup>&&</sup> $P < 0.01$ , vs. EA.

after surgery ( $P < 0.01$ ), indicating autophagy flux blocked and necrotic protein expression enhanced after SCI. The expression of LC3-II was all higher than that in the Model group at each time point ( $P < 0.01$ ) after EA treatment, while the protein expression levels of P62, RIPK1, RIPK3, and MLKL were all lower than that in the Model group ( $P < 0.05$ ), indicating that EA could promote autophagy flux and inhibit necroptosis at the same time. It proved that autophagy may have relationship with necroptosis regulation. Blockage of autophagy flux by CQ may lead to the accumulation of the autophagosomes and increase of P62 expression, which may recruit and interact with RIPK1 to the autophagosomes and then activate necroptosis. By promoting autophagy flux, Jia-Ji EA could inhibit the necroptosis

of neuron, then further inhibit the reduction of the number of anterior motor neurons, and eventually improve the recovery of motor function. Furthermore, we still need to extend the observation time to the regeneration and repair period of SCI in the future study.

## CONCLUSION

Together our data suggest that, Jia-Ji electro-acupuncture may improve the motor function of hind limbs in rats after SCI by improving lysosomal function, promoting the autophagy flux, then reducing necroptosis and inhibiting the loss of neuron.

It showed that the mechanism of Jia-Ji electro-acupuncture treatment were involved in lysosome/autophagy flux/necroptosis pathway. This study provides a potential mechanism and a better understanding of the neuroprotective effect of the electro-acupuncture. In future studies, we will explore the mechanism of Jia-Ji electro-acupuncture on lysosomal function and whether it could induce neuron regeneration and remodeling through this pathway.

Patients with type 2 diabetes mellitus (T2DM) are highly susceptible to developing dementia, especially for those with mild cognitive impairment (MCI), but its underlying cause is still unclear. This study aims to investigate the early detection of white matter structural network changes in T2DM patients with MCI and assess the relationship between cognitive impairment and structural network alterations in T2DM patients. In this study, we performed a battery of neuropsychological tests and diffusion tensor MRI in 30 T2MD-MCI patients, 30 T2DM patients with normal cognition (T2DM-NC) and 30 age-, sex-, and education-matched healthy control (HC) individuals. Cognitive performance exhibited obvious differences among the three groups. The structural network was significantly disrupted in both global and regional levels in T2DM patients. The T2DM-MCI group showed more severe impairment of global network efficiency, and lower nodal efficiency and fewer connections within multiple regions like the limbic system, basal ganglia, and several cortical structures. Moreover, a subnetwork impaired in T2DM-MCI patients was characterized by cortical-limbic fibers, and commissural fibers and pathways within the frontal, temporal, and occipital lobes. These altered global and nodal parameters were significantly correlated with cognitive function in T2DM-MCI patients. In particular, executive dysfunction and working memory impairment in T2DM-MCI patients correlated with nodal efficiency in the right opercular part and triangular part of the inferior frontal gyrus, which indicated that white matter disruption in these regions may act as potential biomarkers for T2DM-associated MCI detection. Our investigation provides a novel insight into the neuropathological effects of white matter network disruption on cognition impairments induced by T2DM.

**Keywords:** type 2 diabetes mellitus, mild cognitive impairment, diffusion tensor imaging, white matter network, network-based statistics

## INTRODUCTION

Type 2 diabetes mellitus (T2DM) is a common metabolic disorder characterized by insulin resistance and hyperglycemia, which can lead to severe multi-systemic impairments. Patients with T2DM have a considerably high risk of developing cognitive dysfunction (Cukierman et al., 2005; Koekkoek et al., 2015). A significant portion of T2DM patients with cognitive impairment eventually progress to dementia (Cheng et al., 2012; Ninomiya, 2014). Mild cognitive impairment (MCI) is the early stage of diabetic cognitive impairment, which is a modifiable stage between normal cognitive aging and dementia (Sperling et al., 2011). The occurrence of dementia is an irreversible process making the pre-dementia stage, which includes MCI, the best time to treat T2DM patients (Mitchell and Shiri-Feshki, 2008). Therefore, early identification and detection of alterations in T2DM-MCI patients may help clinicians with early prevention of severe cognitive decline.

Previous studies have reported that changes in white matter (WM) in T2DM patients are correlated with cognitive impairment (Reijmer et al., 2013a; Hoogenboom et al., 2014; Zhang et al., 2014). Diffusion tensor imaging (DTI), a sophisticated magnetic resonance (MR) imaging technique, is sensitive in detecting microstructural alterations of the WM in T2DM (Hsu et al., 2012; Tan et al., 2016). These results revealed that significant alterations of WM integrity were predominantly found in the cingulum, the uncinate fasciculus, the superior and inferior longitudinal fasciculus, corpus callosum, and external and internal capsule in T2DM patients (Reijmer et al., 2013a; Hoogenboom et al., 2014; Zhang et al., 2014; Nouwen et al., 2017; Yoon et al., 2017; Sun et al., 2018; Xiong et al., 2019). However, these previous studies mainly focused on the regional abnormalities in WM integrity in T2DM.

The human brain is a complex network which comprises multiple brain regions connected to each other. Recently, there has been much interest in mapping the “connectome” to investigate and fully understand the complexity of brain structural network connections (Sporns et al., 2005; Lichtman et al., 2008). So far, four studies have examined the topological properties of the structural brain network in patients with diabetes (Reijmer et al., 2013b; Kim et al., 2016; Zhang et al., 2016, 2019). The results showed disruptions in network integration parameters which represent the slower speed and lowered capacity of a network to exchange information. However, indicators of small-world alteration and local information integration capability did not show a consistent pattern in T2DM. The reason for the inconsistent results may be that the T2DM patients studied were in different stages of diabetes-associated cognitive impairment in this research. Therefore, our study aimed to explore the WM structural network connectome mechanism in T2DM patients with and without MCI.

In this study, we enrolled T2DM patients with MCI (T2DM-MCI), T2DM patients with normal cognition (T2DM-NC), and healthy controls (HC) to perform a clinical assessment, a battery of neuropsychological tests, and DTI MR imaging. Network-based statistics (NBS) and graph theory analysis were conducted to investigate WM

structural network connectome differences in these three groups, and then we assessed the relationship between structural topological network disruptions and cognitive performance in T2DM-MCI patients. Our study may provide insights into the neuropathological mechanisms of T2DM-related cognitive impairment.

## MATERIALS AND METHODS

### Participants

Thirty patients with T2DM-NC and 30 patients with T2DM-MCI were enrolled in the study from October 2015 to November 2019. T2DM was diagnosed using the 1999 criteria proposed by the World Health Organization. The diagnosis of MCI was based on the criteria established in the 2006 European Alzheimer's Disease Consortium, which includes complaints of hypomnesia, an MoCA score < 26, a mini mental state exam (MMSE) score > 24, a clinical dementia rating (CDR)  $\geq$  0.5, and a normal activities of daily living (ADL) score. Participants were excluded if they had a history of brain injury, alcoholism, epilepsy, Parkinson disease, major depression, or other psychiatric or neurological disorders. Participants with dementia (MMSE  $\leq$  24), severe depression (Hamilton Depression Rating Scale  $\geq$  18), severe claustrophobia, or contraindications to MRI were also excluded. T2DM patients were excluded if they had microvascular complications, including nephropathy, retinopathy, and neuropathy. Thirty volunteers without vascular risk factors, nervous system diseases, cognitive complaints, or psychiatric illnesses were recruited as HC. Thirty HCs had no T2DM, psychiatric or neurological disorder, and had an MoCA score  $\geq$  26, and an MMSE score > 24. Height, weight, and body mass index (BMI) were measured for each participant. All participants were tested by neurological, neuropsychological, and structural MRI examinations. All participants were right-handed and native Chinese speakers. Glycosylated hemoglobin (HbA1c), fasting plasma glucose (FPG), fasting C-peptide, fasting insulin, triglycerides (TGs), total cholesterol (TC), low-density lipoprotein (LDL), high-density lipoprotein (HDL), homocysteine, urinary microalbumin, blood urea nitrogen (BUN), uric acid, serum creatine, cystatin C, free thyroxine (FT), free triiodothyronine (FT3), and thyroid-stimulating hormone (TSH) were measured via standard laboratory testing. This study was carried out in accordance with the Declaration of Helsinki. The Research Ethics Committee of Southwest Hospital, Army Medical University approved the study. All participants voluntarily provided written informed consent.

### Neuropsychological Testing

All participants completed a battery of neuropsychological tests, including MMSE, Montreal Cognitive Assessment (MoCA), Digit Symbol Coding Test (DSCT), Complex Figure Test (CFT), Trail-Making Test (TMT), Digit Span Test (DST), Verbal Fluency Test (VFT), and Auditory Verbal Learning Tests (AVLT) which contains 12 variants, including coat, trousers, kerchief, glove, driver, carpenter, soldier, lawyer, crabapple, lily, wintersweet, and yulan.

## Imaging Acquisition

All imaging data were obtained on a 3-Tesla Trio MRI system (Siemens Healthcare, Erlangen, Germany) equipped with a 12-channel phase-array head coil. DTI images were acquired by a single-shot echo planar imaging (EPI) sequence with the following parameters: repetition time (TR) = 10,000 ms; echo time (TE) = 92 ms; flip angle = 90°; field of view (FOV) = 256 mm × 256 mm; matrix = 128 × 128; slice thickness = 2 mm, no gap; 75 axial slices; 64 encoding diffusion directions with  $b = 1,000 \text{ s/mm}^2$ ; and 1 non-diffusion  $b = 0 \text{ s/mm}^2$  images. The 3D high-resolution structural images were obtained using a T1-weighted magnetization prepared rapid acquisition gradient echo (MPRAGE) sequence, as follows: TR = 1,900 ms, TE = 2.52 ms, TI = 900 ms, flip angle (FA) = 9°, matrix = 256 × 256, thickness = 1.0 mm, 176 slices with voxel size =  $1 \times 1 \times 1 \text{ mm}$ . Then, all the subjects were required to undergo conventional brain T1-weighted and fluid attenuated inversion recovery (FLAIR) images to exclude organic diseases and white matter (WM) hyperintense lesions.

## Imaging Preprocessing

For the DTI data, they were preprocessed and analyzed by the Pipeline for Analyzing Brain Diffusion Images toolkit (PANDA, [www.nitrc.org/projects/panda](http://www.nitrc.org/projects/panda)) (Cui et al., 2013) based on the FMRIB Software Library (FSL) (Behrens et al., 2003). The specific preprocessing steps were performed as previously reported (Xie X. et al., 2017). In brief, first, we converted the image format from DICOM to NIFTI. Second, we removed the skull and extracted the brain tissue. Third, we corrected head motion and eddy-current induced distortions by realigning each diffusion-weighted image to the non-weighted b0 image.

## Network Construction

The network nodes and edges were defined by the following procedures. An Automated Anatomical Labeling (AAL) template was used to parcellate the cerebral cortex into 90 anatomical regions (45 for each hemisphere), each representing a node of the constructed network. The 3D T1-weighted images were co-registered to the original b0 images using SPM ([www.fil.ion.ucl.ac.uk/spm](http://www.fil.ion.ucl.ac.uk/spm)), and then the co-registered 3D-T1 images were normalized to the Montreal Neurologic Institute (MNI) space. Finally, the inverse transformations were applied to the AAL atlas, resulting in corresponding AAL regions in the individual DTI native-space.

A deterministic fiber assignment with the continuous tracking (FACT) algorithm was used to track the whole-brain white matter fibers for each subject in the native diffusion space. All voxels with an FA  $\geq 0.2$  were used as seed points; the tracking continued to one of the seed points unless the tracking angle between two adjacent voxels was  $> 45^\circ$  or the FA was  $< 0.2$  (Mori et al., 1999). To determine the edges of the brain network, two brain regions were considered connected by an edge in cases in which at least three fibers were present between the regions. A threshold of three fibers ensures that influence from spurious connections is reduced (Lo et al., 2010). For each edge of the network, the mean FA along the fiber bundles were defined as the weights of a network edge between two connected nodes. FA value is

an important index to evaluate fiber integrity (Beaulieu, 2002). Previous studies proposed that mean FA has the ability to subtly detect local brain lesions (Lim and Helpert, 2002). At last, a  $90 \times 90$  matrix was generated, representing the FA-weighted structural network of each subject.

## Network Measures

The global and nodal topological metrics were calculated with the graph theoretical network analysis toolbox (GRETNA; <http://www.nitrc.org/projects/gretna>). A sparsity threshold range of 10–30% with an interval of 1%, which was checked by previous studies and showed good small-world characteristics, was applied to minimize the possible discrepancies among all FA-weighted matrices (Watts and Strogatz, 1998; Zhang et al., 2011; Korgaonkar et al., 2014). Within every threshold, the global network metrics were calculated. Specifically, the global metrics of each structural network were constant and ranged from 15 to 30% (**Supplementary Figure 1**). Hence, the threshold at different levels of sparsity, ranging from 10 to 15%, was employed in our study. During these thresholds, we calculated the following global network parameters of the weighted brain structural network (see detailed computational formulas of these parameters in the **Supplementary Material**): clustering coefficient ( $C_p$ ), characteristic path length ( $L_p$ ), normalized  $C_p$  ( $\gamma$ ), normalized  $L_p$  ( $\lambda$ ), small-worldness ( $\sigma$ ), global efficiency ( $E_{\text{glob}}$ ), and local efficiency ( $E_{\text{loc}}$ ).  $C_p$  represented the average clustering coefficients of all nodes.  $L_p$  was defined as the average of the shortest path length between any two nodes.  $E_{\text{glob}}$  is considered as an important parameter to estimate the global transmission efficiency of the network.  $E_{\text{loc}}$  demonstrated the network interconnection among the nodes. We investigated the “small worldness” by generating 1,000 random networks to compare with the real networks.  $\gamma$  and  $\lambda$  were defined as the ratio of real world network's  $C_p$  and  $L_p$  to the random network's. And  $\sigma$  was defined as the ratio of  $\gamma$  to  $\lambda$ , which quantifies the organization of a network, with  $\sigma > 1$  indicating a network has a small-world property. Nodal efficiency and betweenness centrality were also computed to represent regional characteristics of the structural network. Among these nodes, there were a number of specific nodes that interacted with many other nodes, which were defined as hubs that play a vital role in maintaining network stability. As a hub, the condition should be the betweenness centrality of a node greater than or equal to the average value plus SD of the network betweenness centrality.

Moreover, a network-based statistic (NBS) was used to identify the altered structural connections in patients (Zalesky et al., 2010). We first applied one-way ANOVA (*post-hoc*: two-sample two-tailed *t*-tests) to compare the strength of the edge at each individual element of the connectivity matrix. Second, a primary component-forming threshold ( $P < 0.01$ , uncorrected) was applied to search for potential connected edges. Third, the size of the largest remaining subthreshold connected component was computed. Then, the groups were randomly shuffled (5,000 permutations) and the largest subthreshold connected component size was calculated by repeating steps 1, 2, and 3. In this way, an empirical null distribution was generated to evaluate the statistical significance of the network connected component

sizes. Finally, for any connected component of size  $M$  that found in the right grouping of controls and patients, the corrected  $P$ -value was determined by calculating the proportion of the 5,000 permutations for which the maximal connected component was larger than  $M$ . The NBS identifies the subnetworks of connected edges that differ the most among groups ( $P < 0.05$  NBS corrected for multiple comparisons). The results of the nodal and edge comparisons were visualized using the BrainNet viewer software (<http://www.nitrc.org/projects/bnv/>).

## Statistical Analysis

All statistical analyses were performed in SPSS (version 22, Chicago, IL). For demographic and neuropsychological testing, a one-way analysis of variance (ANOVA) test was used to compare among groups. *Post-hoc* tests with Bonferroni correction were performed after observing statistical differences among the three groups. An  $\chi^2$  test was used to compare sex variables. Instead of using single threshold metrics, we calculated the area under the curve (AUC) of each metric above to summarize the topological characteristic of the structural brain network. The group differences in AUC values of global network metrics ( $C_p$ ,  $L_p$ ,  $E_{glob}$ , and  $E_{loc}$ ) and nodal properties (nodal efficiency and nodal betweenness centrality) were investigated with one-way ANOVA, while age and gender were adjusted as potential confounders. Metrics showing the main effect of group differences in the ANOVA model were further evaluated by *post-hoc* tests. A significance threshold of  $P < 0.05$  was applied to each test, and the false discovery rate (FDR)-correction was applied for multiple comparison corrections. In addition, to explore the relationships between the topological properties of the network measures and clinical outcomes in cognitive function, we further performed Spearman's correlation between the topological properties and cognitive test scores in the T2DM-MCI patient groups.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Demographics and Neuropsychological Testing

There were no significant differences in age, gender, years of education, systolic or diastolic blood pressure, LDL, total cholesterol, and triglycerides among the T2DM-MCI, T2DM-NC, and HC groups. Compared with HC, T2DM-NC patients had higher FPG and HbA1c and lower HDL (Bonferroni-correction,  $P < 0.05$ ). T2DM-MCI patients had higher BMI, HbA1c, and FPG and lower HDL than HC (Bonferroni-correction,  $P < 0.05$ ). But no significant difference was found between T2DM-NC and T2DM-MCI patients (Bonferroni-correction,  $P > 0.05$ ). In the neuropsychological test, T2DM-MCI patients performed worst among the three groups, while no significant difference was shown between T2DM-NC patients and HC (Bonferroni-correction,  $P > 0.05$ ). Moreover, T2DM-MCI patients presented an obvious reduction in multiple domains of cognitive function including episodic memory, executive function, working memory, and attention when compared with T2DM-NC patients and HC. However, no significant differences in spatial processing and language ability

among the three groups were found. Demographic data and neuropsychological testing are presented in **Table 1**.

### Global Network Properties

The brain networks of the T2DM-MCI, T2DM-NC, and HC groups exhibited good small-world properties ( $\sigma > 1$ , **Supplementary Figure 2**). The global properties of the network showed no significant differences in  $C_p$ , but was observed in  $L_p$ ,  $E_{glob}$ , and  $E_{loc}$  among these three groups. In *post-hoc* comparisons, significantly higher  $L_p$  and lower  $E_{glob}$  and  $E_{loc}$  were found in the T2DM-MCI group relative to the HC group, while higher  $L_p$  and lower  $E_{glob}$  in the T2DM-NC group were found relative to the HC group. The T2DM-MCI group showed higher  $L_p$  and lower  $E_{glob}$  relative to the T2DM-NC group ( $P < 0.05$ , FDR-corrected, **Figure 1**, **Table 2**).

### Nodal Efficiency and Hubs Characteristics

#### Nodal Efficiency

All nodal properties (nodal efficiency and betweenness centrality) of the white matter network of the T2DM-MCI, T2DM-NC, and HC groups were analyzed. Significant group effects of nodal efficiency were found in 33 of 90 nodes among the three groups, while the *post-hoc* comparison showed that nodal efficiency was widely reduced at 32 nodes in the T2DM-MCI group compared with the HC group and 12 nodes in the T2DM-NC group compared with the HC group ( $P < 0.05$ , FDR-corrected, **Table 3**, **Figure 2**). To reveal regions specifically related to cognitive impairments associated with T2DM, we carried out a *post hoc* comparison between T2DM-MCI and T2DM-NC. Compared to T2DM-NC group, T2DM-MCI group showed lower nodal efficiency in 11 nodes mainly located in the limbic system, basal ganglia, parts of frontal, temporal and parietal lobe, including right inferior frontal gyrus (opercular part and triangular part), left hippocampus, parahippocampal gyrus, fusiform gyrus, superior parietal gyrus, precuneus, caudate nucleus, middle temporal gyrus, inferior temporal gyrus, inferior parietal, but supramarginal and angular gyri ( $P < 0.05$ , FDR-corrected, **Table 3**). There were also group effects and between-group differences of betweenness centrality in 5 of 90 nodes ( $P < 0.05$ ). However, the differences did not survive after FDR correction for multiple comparisons (**Supplementary Table 2**).

#### Hubs Characteristics

The hubs of the brain network of these three groups were identified, including 13 hubs in HC, 12 hubs in T2DM-NC patients, and 11 hubs in T2DM-MCI patients (**Table 4**). Among them, 10 hubs were shared by these three groups, mostly distributed in the bilateral precentral gyrus, calcarine fissure and surrounding cortex, superior occipital gyrus, precuneus, and putamen. Compared with HC, T2DM-NC patients had decreased hubs at the right hippocampus, right caudate nucleus, and left thalamus, while two new hubs appeared at the caudate nucleus and middle temporal gyrus on the left side (**Figure 3**). T2DM-MCI patients had decreased hubs at the right hippocampus and right caudate nucleus relative to HC, while they had decreased hubs at the left caudate nucleus and left middle temporal gyrus,

and increased hubs at the left thalamus relative to T2DM-NC patients (Figure 3).

## Network Measure Correlates With Cognitive Function Score

The correlations between brain network parameters, including global network properties and nodal efficiency, and cognitive function scores were analyzed for the T2DM-MCI group. For global network properties,  $L_p$ ,  $E_{glob}$ , and  $E_{loc}$  were significantly correlated with DST scores ( $r = -0.4149$ ,  $P =$

0.0226;  $r = 0.4051$ ,  $P = 0.0264$ ;  $r = 0.4934$ ,  $P = 0.0056$ , uncorrected), and  $E_{loc}$  was significantly correlated with TMT-A scores in the T2DM-MCI group ( $r = -0.3620$ ,  $P = 0.0494$ , uncorrected) (Figures 4A–D). Furthermore, the nodal efficiency of the right opercular part of the inferior frontal gyrus was significantly correlated with DST scores ( $r = 0.4049$ ,  $P = 0.0265$ , uncorrected) in the T2DM-MCI group (Figure 4E). And the nodal efficiency of the right triangular part of the inferior frontal gyrus was significantly correlated with TMT-A scores ( $r = -0.3736$ ,  $P = 0.0420$ , uncorrected) and TMT-B

scores ( $r = -0.5238$ ,  $P = 0.00297$ , uncorrected), respectively (Figures 4F,G).

## Network-Based Statistical Analysis

Differences of the connectivity component between groups were detected using the NBS method. A subnetwork of 9 nodes

and 8 edges was found impaired in the T2DM-MCI group, compared with the HC group ( $P < 0.05$ , NBS corrected, Figure 5). Nevertheless, no significant differences were found between the T2DM-NC group and HC group or T2DM-MCI group and T2DM-NC group. The impaired subnetwork included the left hippocampus, calcarine fissure and surrounding cortex, the

## DISCUSSION

The purpose of this current study was to early detect the neuroimaging alterations of T2DM-associated cognitive impairments. All participants in the T2DM-MCI, T2DM-NC, and HC groups had good small-world properties. The global properties of the structural network showed a significant decrease of  $E_{glob}$  and an increase of  $L_p$  in T2DM-MCI patients, when compared with T2DM-NC patients. Then nodal efficiency analysis showed the impaired efficiency of widespread brain

regions in T2DM-MCI and T2DM-NC patients. While nodal efficiency, primarily located in the limbic system, basal ganglia, parts of the frontal, temporal, and parietal lobes, suffered more severely in T2DM-MCI patients than T2DM-NC. Moreover, a subnetwork impaired in T2DM-MCI was identified and characterized by cortical-limbic fibers, commissural fibers and pathways within frontal, temporal and occipital lobes. In particular, these network abnormalities were correlated with cognitive function performance in T2DM-MCI patients. Our investigations highlighted the importance of structural network analysis in our understanding of T2DM-related cognitive impairment symptoms.

In this study, decreased  $E_{glob}$  and increased  $L_p$  were observed in T2DM-MCI and T2DM-NC patients, which was in line with previous studies related to T2DM and cognitive impairments

using DTI-based graph theoretical network analysis (Reijmer et al., 2013b; Kim et al., 2016; Zhang et al., 2016). Meanwhile,  $E_{loc}$  was also found significantly deceased in T2DM-MCI patients when compared with HC. These above findings imply that efficiency of network information transmission was decreased with the cognition decline of T2DM patients. However, no

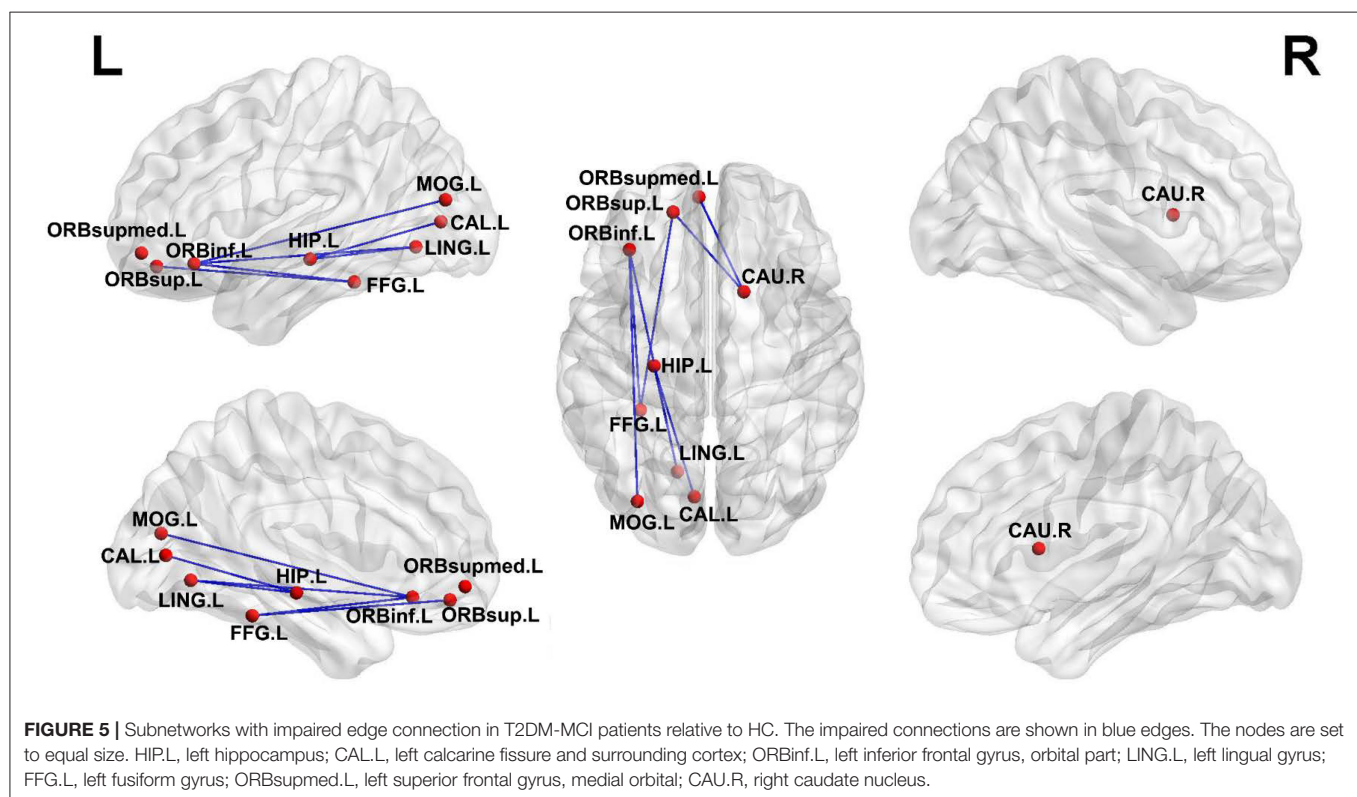

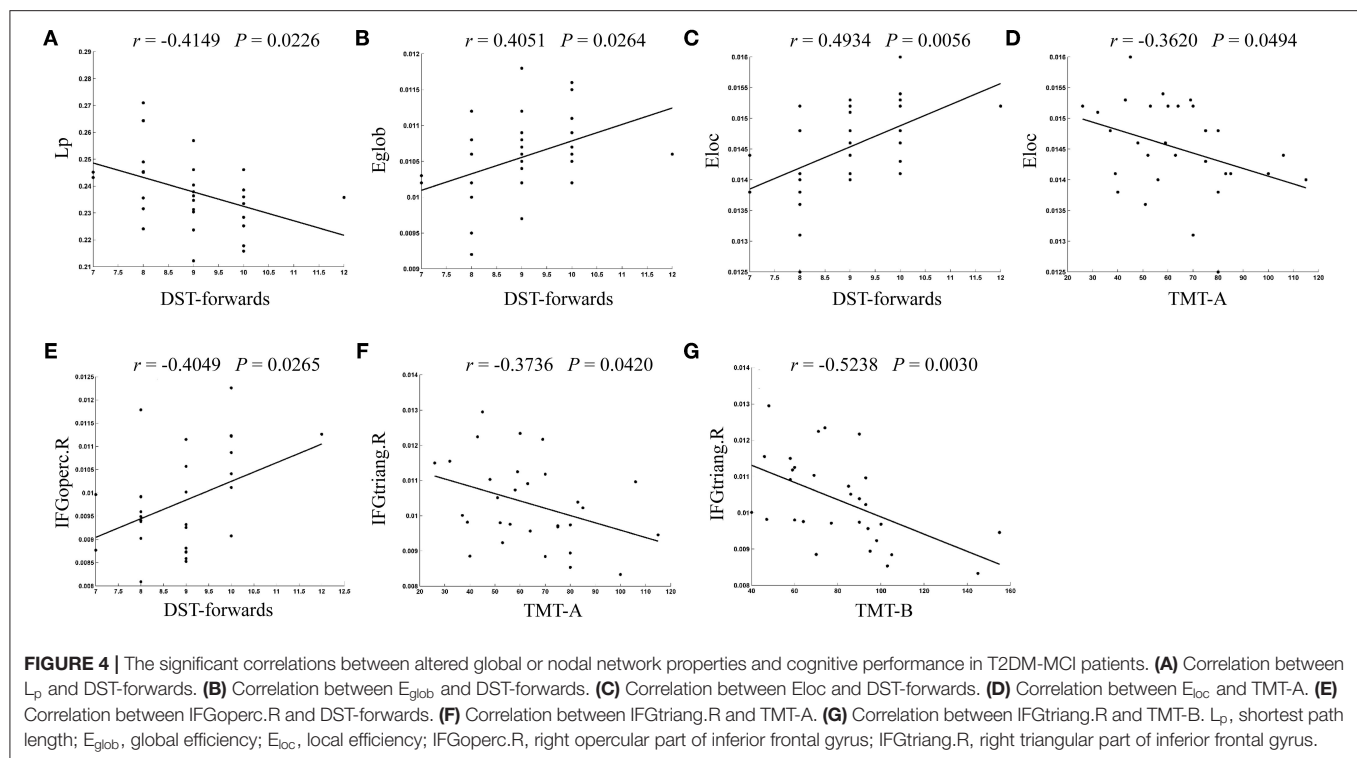

significant changes were found on  $C_p$  of T2DM-MCI and T2DM-NC patients in our study. The changing pattern of  $C_p$  reported in white matter network studies of T2DM have been controversial. Reijmer et al. found decreased  $C_p$  in well-controlled diabetic patients (Reijmer et al., 2013b), while Zhang et al. reported increased  $C_p$  in T2DM patients free of clinical vascular complications (Zhang et al., 2019). Two other studies detected no change in  $C_p$  in T2DM, which were similar to our current study (Kim et al., 2016; Zhang et al., 2016). These inconsistencies may be explained by the differences in sample sizes, age, and complications of the enrolled patients. Therefore, more studies are needed to draw a reliable conclusion about the impact of T2DM on the topological properties of the brain network.

T2DM-MCI patients exhibited significantly reduced nodal efficiency in 11 nodes, mainly located in the limbic system, basal ganglia, and parts of the frontal, temporal, and parietal lobes. Previous studies have reported that the temporal lobe and in

particular the limbic system seem to be susceptible to T2DM (Den Heijer et al., 2003; Korf et al., 2006; Gold et al., 2007; Mccrimmon et al., 2012; Xie Y. et al., 2017). Our results are in agreement with previous literature showing microstructural and network impairment in different regions of the temporal lobe and limbic system, and also in their corresponding association fibers in T2DM. In addition, T2DM is also associated with the abnormal pattern of functional connectivity in these regions (Xia et al., 2017). These structures have been implicated in memory formation and learning (Mccrimmon et al., 2012). Furthermore, it had been well-documented that deficits in either frontal cortex or WM may be the underlying reasons for executive dysfunction and memory loss in patients with T2DM (Duncan and Owen, 2000; Preston and Eichenbaum, 2013; Reijmer et al., 2013b; Duan et al., 2015). Of note, our findings revealed that the nodal efficiency in the right opercular part and triangular part of the inferior frontal gyrus had a close relationship with multiple cognitive function scores, especially

working memory, attention, and executive function, which was in line with previous studies (Li et al., 2018). The opercular part of the inferior frontal gyrus has many important functions in

the brain, some of which are involved in semantic processing, language production, and phonological processing (Tonkonogy and Goodglass, 1981; Sainson et al., 2014). Moreover, the loss

of white matter volume in the inferior frontal triangle region has been reported in T2DM patients (Chen et al., 2012). Both the opercular part and triangular part of the inferior frontal gyrus are involved in higher cognitive functions such as memory, emotion, and learning (Maess et al., 2006; Badre and Wagner, 2007). These results suggested that WM in the right opercular part and triangular part of the inferior frontal gyrus may act as potential biomarkers for T2DM-associated MCI detection.

More importantly, brain hubs, defined as some specific nodes interacting with many other nodes, play an important role in maintaining network stability and enabling efficient information transmission (Albert et al., 2000). The loss of hubs could affect network connection and information processing (Van Den Heuvel and Sporns, 2013). In hubs analysis, there were almost similar hub organizations in the T2DM-MCI, T2DM-NC, and HC groups, but differences still existed in the distribution of hubs among these three groups at the right hippocampus, bilateral caudate nucleus, and right middle temporal gyrus. T2DM-NC patients lost hubs at the right hippocampus and caudate nucleus, while two new hubs were found at the left caudate nucleus and middle temporal gyrus when compared to HC. These increased hub nodes may represent compensation for those lost, which may maintain the normal cognitive function in T2DM-NC patients (Liu et al., 2018; Yu et al., 2019; Wang et al., 2020). Meanwhile, T2DM-MCI patients lost hubs at the right hippocampus and caudate nucleus relative to HC, and lost hubs at the left caudate nucleus and middle temporal gyrus compared to T2DM-NC. These lost hubs are more likely to be related to cognitive performance (Den Heijer et al., 2003; Gold et al., 2007; Falvey et al., 2013; Rofey et al., 2015). Also, some regions with decreased nodal efficiency belonged to the lost hubs in T2DM-MCI. This suggests that the hub nodes, to some extent, were yet to be damaged, resulting in cognitive impairments in T2DM-MCI patients. This subsequently explains that T2DM cognitive dysfunction might disrupt the structural network and reorganize the network's hubs.

In addition, T2DM-NC patients showed disrupted topological organization of the white matter network including global network properties, nodal efficiency, and hubs, which indicates that the topological organization of structural brain networks have already been altered in T2DM-NC patients. Our results are partly in accordance with previous studies that explored changes of structural and functional brain networks in cognitively intact T2DM patients (Chen et al., 2017; Zhang et al., 2019). However, T2DM-MCI patients showed another disrupted structural network that was worse than T2DM-NC patients. These differences illustrated the severity of the disease condition. Therefore, a longitudinal study is necessary to confirm the dynamic changes in brain network topological organization in T2DM patients as the disease progresses in future.

However, our study has a few limitations. First, the current study is a cross-sectional study with a relatively small sample size, and a longitudinal study with a larger sample size is needed in future to detect the dynamic changes in structural network

properties and to test whether structural network properties can predict the development of cognitive impairment in T2DM patients. Second, there was a higher BMI index in groups with T2DM than healthy controls. However, there were no significant intergroup differences in BMI between T2DM-MCI and T2DM-NC patients, and the effect of BMI on the results should be small. Last but not least, we only focused on the structural network properties and their relationship with neurophysiological tests in T2DM patients. Exploring the overlap between functional and structural connectivity in the same participants will achieve more convincing and reliable results. Thus, multimodal imaging methods are needed to investigate the structural and functional dysconnectivity in T2DM associated with cognitive deficits in the future.

## CONCLUSION

In conclusion, the present study revealed disrupted network measures in T2DM patients. T2DM-MCI patients showed sporadic impairments of the structural network, primarily located in the limbic system, basal ganglia, and parts of the frontal, temporal, and parietal lobes when compared with T2DM-NC patients. Moreover, these network abnormalities were correlated with cognitive function performance in T2DM-MCI patients. In particular, the executive dysfunction and working memory impairment in T2DM-MCI patients correlated with reduced nodal efficiency in the right opercular part and triangular part of the inferior frontal gyrus, which indicated that WM in these regions may act as potential biomarkers for T2DM-associated MCI detection. Our investigation provides a novel insight into the neuropathological effects of white matter network disruption on early cognition impairments induced by T2DM.

## DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Material**, further inquiries can be directed to the corresponding author/s.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Research Ethics Committee of Southwest Hospital, Army Medical University, Chongqing, China. The patients/participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

KX, XC, and JW conceived and designed the study. CL, YLi, and ZZ collected the data for MRI, clinical, and neuropsychological tests. JZ and MQ performed the network analysis. KL and HT performed statistics analysis. JF and YG prepared the figures and tables. XC and KL wrote the manuscript. XY and YLa edited the manuscript. All

authors revised the manuscript, read, and approved the submitted version.

# Tele-Health Intervention for Carers of Dementia Patients—A Systematic Review and Meta-Analysis of Randomized Controlled Trials

Aiyong Zhu<sup>1</sup>, Wenting Cao<sup>1</sup>, Yinghua Zhou<sup>1</sup>, Anan Xie<sup>1</sup>, Yun Cheng<sup>2</sup> and Shu-Fen Chu<sup>1\*</sup>

<sup>1</sup> College of Nursing and Health Management, Shanghai University of Medicine and Health Sciences, Shanghai, China,

<sup>2</sup> Department of Nursing, Huadong Hospital Affiliated to Fudan University, Shanghai, China

**Objective:** The purpose of this study is to evaluate the major mental health outcomes on dementia patient carers when using psychoeducational programs and psychotherapeutic interventions.

**Methods:** A meta-analysis was performed with randomized controlled trials of carers' tele-health interventions from the literature inception to December 31, 2019, using PubMed, EMBASE, and CENTRAL databases for articles.

**Results:** The meta-analysis identified 1,043 results, of which 11 were randomized control trials. Among all 11 randomized control trials, only one study addressed face-to-face contact with online modules of interventions, four studies addressed telephone-based interventions, two studies reported on combined face-to-face contact and phone call interventions, two studies focused on web-based interventions, one study used video and telephone interventions, and one study conducted a computer-telephone integration system of intervention. The updated evidence suggested that there was more efficacy via tele-health interventions in lowering depression for carers of people with dementia. We outlined the delivery formation of intervention to evaluate the effectiveness and processes of major mental health improvements, including depression, burden, anxiety, and quality of life.

**Conclusions:** In this study, tele-health intervention was shown to significantly lower depression and also lower the risk of mental health impairment. Although there was a significant decrease of depression, there were no significant differences in burden, anxiety, and quality of life. Future researchers are encouraged to carry out larger-scale studies; also, further analysis using a standardized assessment tool is suggested for future multi-component tele-health interventions.

**Keywords:** tele-health, intervention, carers, dementia, systematic review, meta-analysis

## INTRODUCTION

Studies showed that carers of dementia family members have a poorer quality of life (QoL) (Glueckauf et al., 2007; Häusler et al., 2016; Brown et al., 2019) and higher risk for death by suicide. This risk did not decrease even after the care-recipients were institutionalized or died (Kishita et al., 2018). In 2015, there were 17.7 million informal carers who provided either in-home

substantial services or unpaid assistance to their family members and friends. Though caregiving can strengthen the relationship between carer and recipient, it can also cause emotional and physical burdens on carers, resulting in higher rates of depression, lower quality of life, and poorer overall health. However, these outcomes might be eliminated when proactively addressing the needs of families and carers. To improve the support systems for carers and the care recipients, it is suggested to have a better understanding of carers and their challenges (Edwards et al., 2020). A UK survey in 2019 found that most carers (79%) used one or more types of technology, while distance carers, who do not reside in the same home with the care recipients, used slightly fewer (77%). There are lots of studies assessing the efficacy of carer interventions on emotional well-being (Orgeta et al., 2013; Wagner and Brandt, 2018; Or and Kartal, 2019). However, only a few of these reviewed the effect of intervention by delivery mode for carers of dementia patients, such as tele-health intervention. To develop more cost-effective approaches that meet the needs of people with dementia and their family carers is urgent. Different kinds of interventions could prevent or reduce the negative effect of carers, but use of internet interventions is still very limited (Blom et al., 2013). Some interventions are designed to support carers in their role, such as skills training or education to assist in caring for people living with dementia. Evidence showed that if carers learn to deal more effectively with the stresses of caregiving, their QoL will remain at a higher level. Psychoeducational interventions are the most widely studied, and improvement in level of depression and stress have been reported. Recently, there was one study that conducted a comprehensive review that suggested psychoeducation-skill building interventions show a significant influence on burden when delivered face-to-face (Kishita et al., 2018). This meta-analysis updated the literature on interventions for carers of dementia patients published between 2006 and 2016 and evaluated the efficacy of psychoeducational programs and psychotherapeutic interventions on major mental health outcomes, such as depression, anxiety, burden, and QoL. This study demonstrated strong empirical support for treating anxiety and depression by all modes of delivery (Kishita et al., 2018). Face-to-face intervention is very costly compared to the tele-health-based interventions. Tele-health interventions are much more convenient as carers can receive help when it is necessary, especially in a time such as the COVID-19 pandemic, when social distancing is crucial. Therefore, the purpose of the research is to assess the efficacy of tele-health interventions for carers of dementia patients.

## MATERIALS AND METHODS

### Data Sources and Searches

Inception to December 31, 2019, we developed the search strategy, without language restriction, for PubMed, EMBASE, and CENTRAL for articles. The search terms included caregiver, carer, dementia, cognitive decline, cognitive impairment, web-based intervention, technology intervention, internet intervention, tele-health intervention, and randomized controlled trials. Titles and abstracts were screened by three

reviewers independently, while full texts were sourced for relevant articles. Inclusion criteria were assessed independently, and inconsistencies were resolved by consensus. The reference lists of included trials and other published meta-analyses were also reviewed for relevant articles.

### Eligibility Criteria

According to the American Psychiatric Association's Diagnostic and Statistical Manual (DSM-5), dementia is typically diagnosed when acquired cognitive impairment has become severe enough to compromise social and/or occupational functioning. Symptoms of memory loss are caused by a range of cognitive abilities, or a general cognitive decline, and not just memory (Hugo and Ganguli, 2014). Trials were considered eligible if they were randomized clinical trials, comparing the key mental health states of anxiety, depression, and burden, and associated with poor QoL in dementia carers. Trials were required to report at least one of the following forms of intervention: blending face-to-face contact with online modules, telephone-based, combined face-to-face contact and phone calls or web-based intervention, using video and telephone interventions, or a computer-telephone integration system (Table 1). Also, trials were required to report at least one of the following outcomes: symptoms of depression, anxiety, burden, or QoL. Trials that recruited participants with face-to-face intervention only were excluded.

### Data Extraction

Data were collected independently by two authors using a standardized data extraction form, entered into a dedicated database, and checked independently by four authors. The data included study characteristics, baseline demographics of participants, description of the intervention, incidence of dementia, the forms of intervention, main treatment components, and length of each session (min)/treatment. We reported outcomes at the point of the longest follow-up. Eleven majority delivery modules of intervention were defined as those in which more than 50% had tele-health interventions.

### Outcomes

For our primary analysis, we used a hierarchical approach in which we included trials that reported delivery mode of intervention including blending face-to-face contact with online modules, telephone-based, combined face-to-face contact and phone calls, or web-based intervention using video and telephone interventions, or a computer-telephone integration system. We chose this approach to maximize the number of clinical trials included in our primary analysis, while also giving priority to the most tele-health intervention relevant mental health outcomes reported in trials. The main outcomes of this meta-analysis were depression, anxiety, burden, and QoL on follow-up carers of people with dementia. The outcome measures for studies were efficacy carer interventions on anxiety, depression, burden, and quality of life.

**TABLE 1** | Characteristics of included studies.

First author	Year of publish	Method of study	Diagnosis of care-recipient	Target of population	Format of intervention	Main outcomes
Boots L. M.	2018	RCT	People with mild dementia of all subtypes (Clinical Dementia Rating, score 0.5–1)	Family caregivers	Blending face-to-face contacts with online modules	Depression
Tremont G.	2015	RCT	Most care recipients were diagnosed with Alzheimer's disease	Family caregivers	Telephone contacts	Depression
Prick A. E.	2015	RCT	Community-dwelling people with dementia	Family caregivers	Experimental group: home visits Comparison group: information bulletins and phone calls	Depression

Gallagher-Thompson D.	2007	RCT	People with dementia	Female Chinese American caregivers	Telephone contacts	Depressive symptoms
Finkel S.	2007	RCT	People with Alzheimer's disease	Caregivers	Computer-Telephone Integration System (CTIS)	Depression
Winter L.	2006	RCT	People with Alzheimer's disease or related disorders	Female family caregivers	Telephone-based support groups	Depression
Burns R.	2003	RCT	People with Alzheimer's disease	Caregivers	Face-to -face and telephone contact	General Health and Mental Health

## Risk of Bias Assessment

Cochrane risk of bias tool (Higgins et al., 2011) was applied to assess the methodological quality of eligible trials on random sequence generation, allocation concealment, blinded outcome assessment, completeness of outcome data, evidence of selective reporting, and other biases. The risk of bias was independently assessed by two reviewers, while a third reviewer resolved the disagreements. A risk-of-bias summary table was created in Review Manager version 5.3. and the study was considered to be at high risk of bias if two of the domains were rated as high.

## Data Synthesis and Analysis

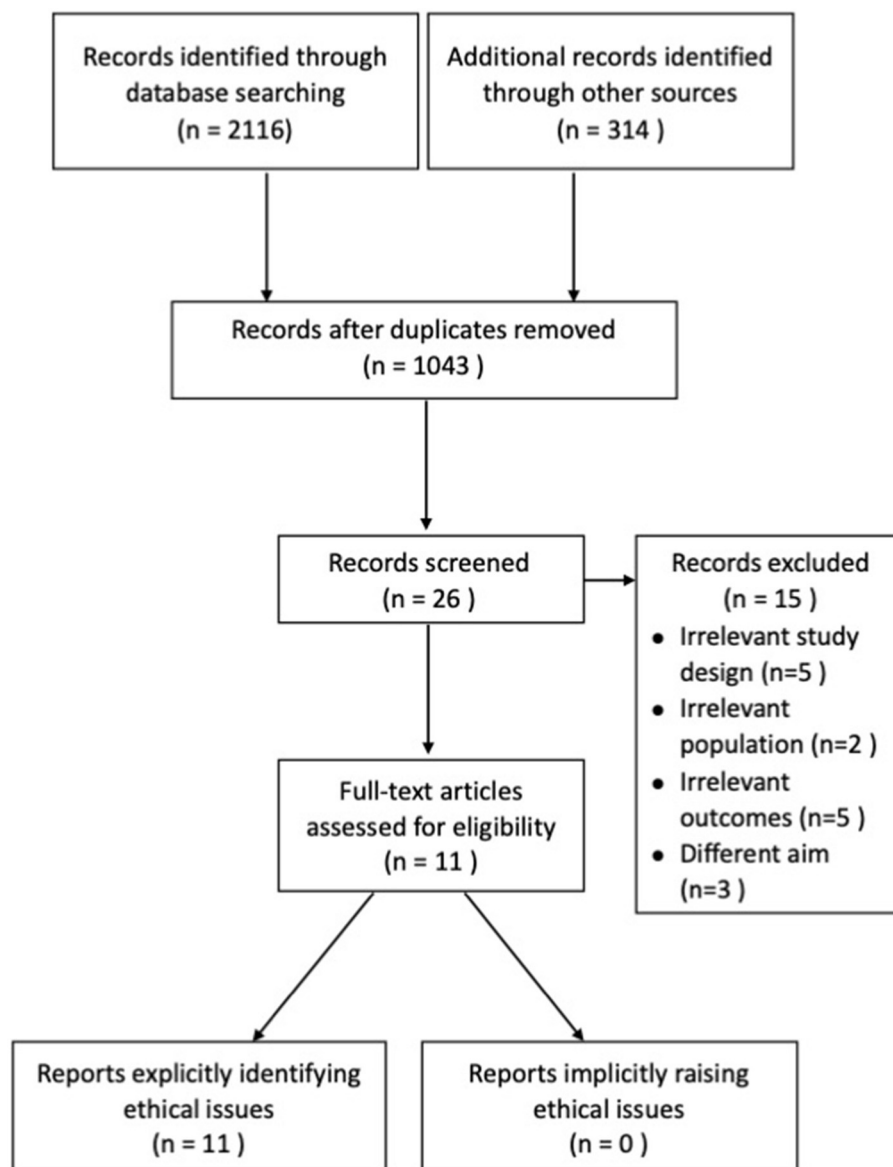

A descriptive analysis of each trial is provided in **Table 1**. Outcomes of depression, anxiety, burden, and QoL were estimated for each trial. Weighted pooled treatment effects were calculated using restricted maximum likelihood estimation to fit a random-effects meta-analysis model. A pooled mean difference and 95% CI was calculated using a random-effects meta-analysis. If this was not reported, the mean between-group difference reported at follow-up was used.

## RESULT

### Study Selection

The systematic search of articles published from database inception to December 31, 2019, identified 1,043 results.

After title and abstract screening, 26 articles were considered potentially relevant. Twenty studies were included after full-text review. Eleven studies reported the intervention via blending face-to-face contact with online modules ( $n = 1$ ), four were telephone-based ( $n = 4$ ), two combined face-to-face contacts and phone calls ( $n = 2$ ), two used web-based intervention ( $n = 2$ ), one used video and telephone interventions ( $n = 1$ ), and one used a computer-telephone integration system ( $n = 1$ ). These were included in the primary meta-analysis (**Figure 1**). Seven out of 11 studies were conducted in the United States (Burns et al., 2003; Winter and Gitlin, 2006; Finkel et al., 2007; Gallagher-Thompson et al., 2007, 2010; Glueckauf et al., 2012; Tremont et al., 2015), and the rest were in the Netherlands ( $n = 3$ ) (Blom et al., 2015; Prick et al., 2015; Boots et al., 2018) and France ( $n = 1$ ) (Cristancho-Lacroix et al., 2015). Of the 11 studies, five studies recruited carers of people with Alzheimer's disease. Most studies involved carers of people with various diagnoses of dementia grouped as a whole. In total, 1,087 participants were enrolled. The mean (SD) age of trial participants was 64.22 (5.4) years old. The publication year ranged from 2003 to 2018. Eleven trials' main outcome measurement were of depression, two trials were of anxiety, six trials were of burden, and two trials were QoL. The most commonly used measurement was the Centre for Epidemiologic Studies Depression scale (CESD). Data were available to calculate the effect size for six of the eleven studies that included burden as one of the outcome measures. The majority of studies used

**FIGURE 1 |** Flow diagram of the studies' selection process.

the Zarit Burden Interview (ZBI). Two studies reported the efficacy of interventions on anxiety. The most commonly used measure was the psychological complaints measure [Hospital Anxiety and Depression Scale-Anxiety (HADS-A)]. Two studies reported the efficacy of interventions on QoL. They used the Investigation Choice Experiments for the Preferences of Older People (ICECAP-O) and Euro-QoL to measure the efficacy.

## Study Characteristics

### Blending Face-To-Face Contact With Online Modules and Key Mental Health

This category contained a description of only one trial on follow-up (81 participants). Carers of people with mild dementia of all

subtypes (Clinical Dementia Rating, score 0.5–1) were divided into the intervention group (31 participants) and the control group (37 participants). The primary outcome was self-efficacy and symptoms of depression. Secondary outcomes included QoL and psychological complaints. The main treatment component was a blended care self-management program in combination with face-to-face coaching and tailored web-based modules. The main outcome measure for depression in this study was the CESD scale. The outcome of QoL measure was the Investigation Choice Experiments for the Preferences of Older People (ICECAP-O).

### Telephone-Based and Key Mental Health

Four trials reported telephone-based therapy on follow-up (509 participants). Overall, 270 participants were in the intervention

group and 239 participants in the control group. Symptoms of depression as primary outcomes were reported in this category. Secondary outcomes included QoL and physiological responses to stress. Two studies involved psychoeducation and skills training of communication as the main treatment component. Other studies provided problem-solving, planning of pleasant activities, and a supportive social network. The main outcome measure for depression in four studies was the CESD scale. The Dutch version of the Revised Memory and Behavior Problem Checklist (RMBPC), used self-rated general health salivary cortisol levels to measure physiological responses to stress. The outcome of the QoL measure was Euro-QoL. Self-Perceived Pressure from Family Care (SPICC) was applied to measure the planning of pleasant activities.

### Combines Face-To-Face Contacts and Phone Calls and Key Mental Health

This category contained a description of two trials on follow-up (87 participants) and divided the carers of people with either dementia or Alzheimer's disease into the intervention group (43 participants) and the control group (44 participants). Symptoms of depression as the main outcome were reported in this category. One study included physical symptoms, psychosocial resources, and subjective burden secondary outcomes. The other study included general health and mental health and an assessment of how the dementia was manifested for the patient and affected the carer as the secondary outcomes. The main outcome measure for depression in this category was CESD scale. Modified Caregiver Health and Behavior Inventory, Assistance subscale of Interpersonal Support Evaluation List, Caregiver Appraisal Inventory, and modified General Well-Being scale were used to measure secondary outcomes.

### Web-Based Intervention and Key Mental Health

This category contained a description of two trials on follow-up (294 participants). Overall, 174 participants were in the intervention group and 120 participants in the control group. Symptoms of depression and stress as main outcomes were reported in this category. One study included secondary outcomes such as anxiety. The other study included self-efficacy, burden, perceived health status, and depression as the secondary outcome. The CESD scale and Perceived Stress Scale (PSS-14) were the main two outcome measures for depression and stress. Hospital Anxiety and Depression Scale (HADS-A), Revised Scale for Caregiving Self-Efficacy, Zarit Burden Interview (ZBI), the French version of the Nottingham Health Profile, and Beck Depression Inventory (BDI-II) were used to measure secondary outcomes.

### Using Video and Telephone Interventions and Key Mental Health

This category contained a description of one trial on follow-up (70 participants). Overall, 36 participants were in the intervention group and 34 participants in the control group. Symptoms of depression and stress as main outcomes were reported in this category and were measured by CESD scale

and a Chinese translation of the Revised Memory and Behavior Problems Checklist (RMBPC).

### Computer-Telephone Integration System and Key Mental Health

This category contained a description of one trial on follow-up (46 participants). Seventeen participants were in the intervention group and 19 participants were in the control group. Symptoms of depression, burden, self-care activities, and social support as outcomes were reported in this category. CESD scale, Revised Memory and Behavior Problems Checklist (RMBPC), Caregiver Health and Health Behaviors scale, and Received Social Support scale for outcomes measurement were performed.

## RISK OF BIAS

The quality of those studies included in our research was assessed by the Cochrane risk of bias summary and no study was excluded due to a high risk bias. All included studies were randomized trials and there were seven studies that described the specific randomization method. The majority of trials ( $n = 3$ ) were single-blind randomized control trials. A randomization sequence was adequately generated in seven studies and 11 adequately concealed allocation. Reporting bias was noted in one trial (**Figure 2**). In all studies, the quality of detection bias and performance bias was relatively inconsistent, whereas the quality of publication bias was relatively low.

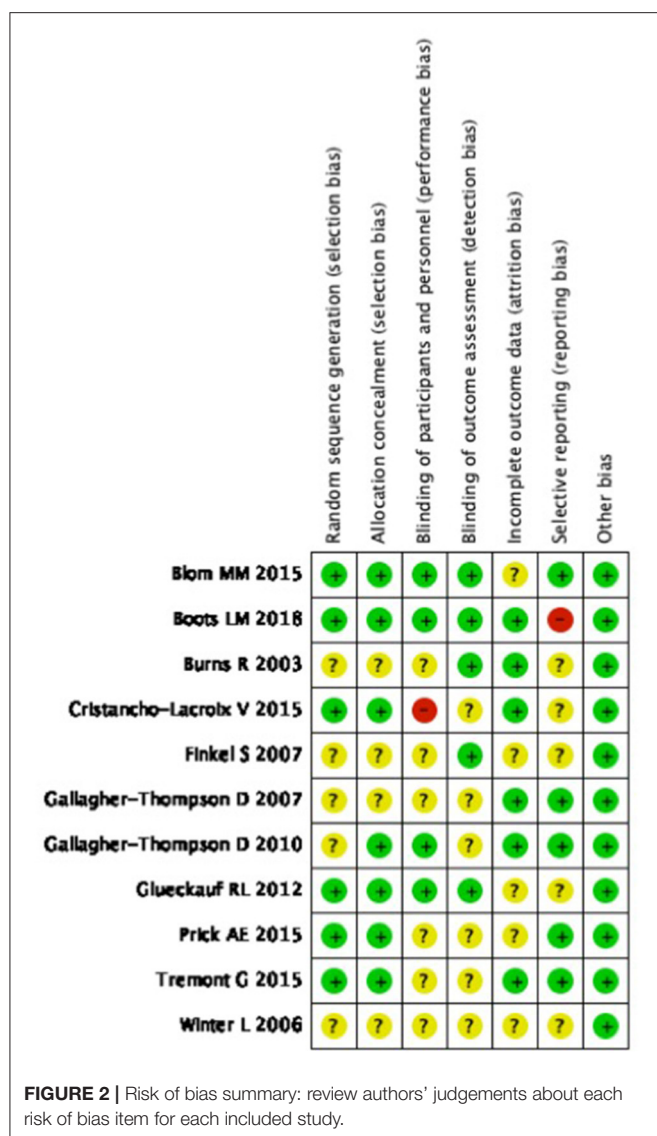

## EFFECTS OF INTERVENTIONS

A random effects model was used for depression. It showed statistically significant high heterogeneity ( $I^2 = 55\%$ ;  $p = 0.01$ ), which had a large impact on the overall effect size (Blom et al., 2015; Tremont et al., 2015). Overall effective study size for depression was low [SMD =  $-0.34$ ,  $p = 0.01$ ; 95% CI =  $-0.54$  to  $-0.14$  (**Figure 3A**)].

Symptoms of depression with intervention formations of tele-health compared with control was highly correlated with a reduction in carers of people with dementia or AD with 7.0 vs. 7.5% over a 4.1 year-follow-up; [OR, 0.93 (95% CI, 0.88–0.98); ARR, 0.39% (95% CI, 0.09–0.68%)] (**Figure 3A**). Heterogeneity was low ( $I^2 = 0.0\%$ ).

Anxiety and depression were also analyzed with a random effects model, though no heterogeneity was observed between study size. An overall effect size for anxiety was large ( $g = 2.10$ ,  $p < 0.00001$ ; 95% CI =  $-1.19$  to  $2.10$  (**Figure 3B**)). There was high heterogeneity between study effect sizes ( $Z = 0.54$ ,  $p = 0.59$ ;  $I^2 = 97\%$ ).

The efficacy of interventions on QoL and burden were evaluated with a random effects model, but the heterogeneity was not significant ( $g = 0.23$ ,  $p = 0.27$ ; 95% CI =  $-0.04$  to  $0.50$  (**Figure 3C**)) and the heterogeneity between study effect sizes were significantly low ( $Z = 1.69$ ,  $p = 0.09$ ;  $I^2 = 19\%$ ) compared with the effect size on burden, which was small [ $g = 0.04$ ,  $p = 0.72$ ; 95% CI =  $-0.23$  to  $0.14$  (**Figure 3D**)].

## DISCUSSION

Epidemiologic studies have reported a stronger association between negative states of mental health and carers of people with dementia (Phung et al., 2013). To increase carers' knowledge of the illness, develop problem-solving skills, and facilitate social support through psychoeducational interventions, interventions should be used. Technology-based interventions significantly affect burden, anxiety, depression, QoL, and self-efficacy (Frias et al., 2020). Web-based interventions for carers of people with early-stage dementia demonstrated a significant improvement in self-efficacy, mastery, and QoL (Gallagher-Thompson et al., 2010). Both telephone-based and face-to-face technology-based interventions showed improvements in depression, subjective burden, and assistance support in dementia cares (Gallagher-Thompson et al., 2007). There is a significant need for non-pharmacological interventions for persons living with dementia

that are easily available, easy to access, and facilitate the use of information and communication technologies (ICTs) (Gilson et al., 2019). This meta-analysis, which included 11 trials with 1,087 participants for the primary outcome analysis, found that there was more efficacy via tele-health interventions in lowering depression in carers of people with dementia. We outlined the delivery formation of intervention to evaluate the effectiveness and processes of key mental health improvements, including depression, burden, anxiety, and QoL.

## Primary Findings

Our research showed that depression can be relieved more through tele-health interventions than face-to-face. Steffen et al. reported on a distance intervention carried out with a small sample size by phone and by mail that could prevent the risk of negative effects on mental health [pre-intervention score (SD), 18.9 (4.9), and post-intervention score (SD), 16.1 (3.9)] (Gant et al., 2007). There was a decrease in depression in the intervention that was associated with fewer hospitalizations at 6 months ( $r = 0.18$ ,  $P = 0.02$ ) (Tremont et al., 2017). The current study found that carers in the tele-health intervention group had less case-level depression [odds ratio (OR) 0.24, 95% CI 0.07–0.76] (Livingston et al., 2014). This was also proven in Zhao et al.'s study in which depression scores dropped an average of 0.23 (95% CI  $-0.38$  to  $-0.07$ ;  $P < 0.01$ ) after web-based interventions (Zhao et al., 2019); otherwise, in the study by Kajiyama et al. (2013), it showed evidence-based interventions for carers via the internet for reducing stress was significant ( $p = 0.017$ ) but no significant changes in the bother, depression, or level of life quality. There was no significant effect on depression that was statistically significant effected by Time ( $p = 0.27$ ), Group ( $p = 0.53$ ), Ethnicity ( $p = 0.34$ ), the Group \* Time \* interaction ( $p = 0.92$ ), or the Group \* Ethnicity \* Time \* interaction ( $p = 0.08$ ) (Czaja et al., 2013). A cross-sectional study reported that carers of AD dementia patients frequently experienced hypertension (12.7%) and insomnia (11.0%) but there were no significant differences on depression and other comorbidities (Montgomery et al., 2018). However, the tele-health intervention should be an important measure to help carers of dementia in the future, especially in conjunction with the fast improvement of associated technologies.

## Secondary Findings

One report by Austrom et al. (2015) showed that a weekly web-based video conference support group for carers could relieve their anxiety (mean difference 1.5, improvement 75%) and burden (mean difference  $-1.0$ , improvement 50%). Tsolaki et al. (2015) found ICT can not only help patients with cognitive, functional, and behavioral problems, but also support health professionals and carers by reducing their anxiety compared with face-to-face interventions. There is also a meta-analysis that found that web-based interventions significantly improved the anxiety status of carers by  $-0.32$  (95% CI  $-0.50$  to  $-0.14$ ;  $P = 0.0005$ ) (Zhao et al., 2019). However, McKechnie et al. (2014) reported no change in depression or anxiety over the 12-week study period via online peer support. In one study, carers who had access to a website improved their confidence while role

A

B

C

D

**FIGURE 3 |** Effect sizes (Hedge's  $g$ ) derived from studies examining the tele-health intervention of carers. **(A)** Depression. **(B)** Anxiety. **(C)** Quality of life. **(D)** Burden.

strain, anxiety, and depression were decreased, although some of them were not significant (Zimmerman et al., 2018). However, a small sample size, low test efficiency, and a high rate of loss to follow-up over time limits this study and further research is needed to draw a conclusion.

## Burden

Our study showed that the mental health burden would be reduced through tele-health intervention. Some studies showed

a correlation between scores on depression, anxiety, and sleep quality assessments and carers' burden (Coffman et al., 2017). Online contact with a professional led to relief in burden and strain for those carers that appreciated personalized practical advice and emotional support (Hopwood et al., 2018). However, not many studies support this result. Parker et al. (2008) performed a meta-analysis study that indicated that there were no significant effects from any of the interventions. Therefore, the major outcome for web-based learning courses was the increase

in knowledge. No effects were found on the relief of burden (Hattink et al., 2015).

### Quality of Life

Our study revealed that tele-health interventions could improve quality of life for carers of dementia patients.

Although there was one study that indicated that quality of life was only moderate ( $SD = 8.21$ ) and negatively correlated with burden ( $r = -32$ ,  $p = 0.01$ ) and depression ( $r = -0.296$ ,  $p < 0.05$ ) (Papastavrou et al., 2014), the findings from Bartfay and Bartfay (2013) showed similar levels of QOL between carers who used community-based interventions. Another systemic meta-analysis showed the effectiveness of IT interventions in the carers of elderly dementia both improving the quality of life and effects on behavior (such as less falling) (Nijhof et al., 2009). However, Duggleby et al. (2018) reported no significant differences from web-based interventions on health-related quality of life, neither for carers of community-living persons with Alzheimer's disease, nor for related dementia.

### Quality of the Included Studies

All results of the quality assessment for the included studies were rated as medium, which explained the variation in many domains, such as theoretical model selection, intervention format, and evaluation tools. It also increased the difficulty in assessing the risk of bias in many areas, which resulted in inconsistent results. There is more and more evidence proving the feasibility of tele-health multicomponent interventions and suggesting the most useful and least expensive intervention components or platforms. Further research on carer-focused interventions to improve their mental health is suggested in the future.

### LIMITATIONS

There are a few limitations that may lessen the credibility of our study. First, the study was not assessed by a standardized

tool, and only limited variables were analyzed. Second, only the USA, Dutch, and France were included, which may limit the ability to conclude the result in other nationalities. Third, there were large differences in the usage of assistive technology, outcome measures, and the quality of studies. All of these created difficulties in comparing results across reviews.

### CONCLUSIONS

In this meta-analysis of randomized clinical trials, depression lowering with tele-health interventions compared with a controlled group was significantly associated with a lower risk of incident mental health impairment. Although there was a significant decrease in depression, there were no significant differences in burden, anxiety, or quality of life. More rigorous methods and larger-scale, higher-quality studies and multicomponent tele-health interventions are suggested in the future to analyze the outcome in further detail using a standardized assessment tool.

Lin L, Sun Y, Wang X, Su L, Wang X and Han Y (2021) Resilience to Plasma and Cerebrospinal Fluid Amyloid- $\beta$  in Cognitively Normal Individuals: Findings From Two Cohort Studies. *Front. Aging Neurosci.* 13:610755. doi: 10.3389/fnagi.2021.610755

**Objective:** To define resilience metrics for cognitive decline based on plasma and cerebrospinal fluid (CSF) amyloid- $\beta$  (A $\beta$ ) and examine the demographic, genetic, and neuroimaging factors associated with interindividual differences among metrics of resilience and to demonstrate the ability of such metrics to predict the diagnostic conversion to mild cognitive impairment (MCI).

**Methods:** In this study, cognitively normal (CN) participants with A $\beta$ -positive were included from the Sino Longitudinal Study on Cognitive Decline (SILCODE,  $n = 100$ ) and Alzheimer's Disease Neuroimaging Initiative (ADNI,  $n = 144$ ). Using a latent variable model of data, metrics of resilience [brain resilience (BR), cognitive resilience (CR), and global resilience (GR)] were defined based on the plasma A $\beta$  and CSF A $\beta$ . Linear regression analyses were applied to investigate the association between characteristics of individuals (age, sex, educational level, genetic, and neuroimaging factors) and their resilience. The plausibility of these metrics was tested using linear mixed-effects models and Cox regression models in longitudinal analyses. We also compared the effectiveness of these metrics with conventional metrics in predicting the clinical progression.

**Results:** Although individuals in the ADNI cohort were older (74.68 [5.65] vs. 65.38 [4.66],  $p < 0.001$ ) and had higher educational levels (16.3 [2.6] vs. 12.6 [2.8],  $p < 0.001$ ) than those in the SILCODE cohort, similar loadings between resilience and its indicators were found within both models. BR and GR were mainly associated with age, women, and brain volume in both cohorts. Prediction models showed that higher CR and GR were related to better cognitive performance, and specifically, all types of resilience to CSF A $\beta$  could predict longitudinal cognitive decline.

**Conclusion:** Different phenotypes of resilience depending on cognition and brain volumes were associated with different factors. Such comprehensive resilience provided insight into the mechanisms of susceptibility for Alzheimer's disease (AD) at the individual level, and interindividual differences in resilience had the potential to predict the disease progression in CN people.

**Keywords:** resilience, Alzheimer's disease, amyloid, cognitive decline, cognitively normal

## INTRODUCTION

Alzheimer's disease (AD) was originally defined as a clinical pathologic disease mainly based on clinical symptoms and neuropathologic changes like deposition of amyloid- $\beta$  (A $\beta$ ) and hyperphosphorylated tau. Recent developments of AD have proposed research frameworks based on biomarkers (McKhann et al., 2011; Jack et al., 2018), which enhanced the understanding of the mechanism and brought substantial research interest to the preclinical stage of AD (Dubois et al., 2018; Jessen et al., 2018; Slot et al., 2018; Li et al., 2019). However, studies have shown that biomarkers and cognitive performance were discordant in some individuals with the pathology of AD often due to individual variations in resilience to the pathology of AD (Katzman et al., 1988; Ghisays et al., 2020). Therefore, as a theoretical construct, terms like reserve, resilience, and maintenance were defined to enhance the understanding of the individual difference related to diseases of the brain (Stern et al., 2018). Resilience, which represents the degree of structural and cognitive deficits associated with the pathology of AD, can be divided into brain resilience (BR) and cognitive resilience (CR) (Rentz et al., 2017) or a combination of both [e.g., global resilience (GR); Hohman et al., 2016; Arenaza-Urquijo and Vemuri, 2018)]. High or low resilience reflects better or worse than predicted properties of the brain or cognitive performances based on the pathological burden. Compared with the traditional index of the reserve including educational level, intelligence quotient (IQ), and occupational complexity, resilience defined by residual approaches provided a feasible quantitative measure of the impact of pathology on cognition (Ewers, 2020).

Currently, studies have found that high resilience may slow the rate of cognitive decline (van Loenhoud et al., 2019; Ossenkoppele et al., 2020), and the protective effect was more notable in the early stage before the cognitive impairment (Lo et al., 2013; Arenaza-Urquijo et al., 2017), which had important implications for intervention in the cognitively normal (CN) stage. In addition, these studies generally used cerebrospinal fluid (CSF) A $\beta$  and PET A $\beta$  to measure the level of the amyloid deposition. However, both methods are invasive or expensive, which are not suitable for widespread screening in the preclinical phase of AD. The advent of plasma A $\beta$  has provided an alternative that is affordable and less invasive. Previous studies have shown the relationship between plasma A $\beta$  and central A $\beta$  (Hanon et al., 2018; Chatterjee et al., 2019; Schindler et al., 2019; Vergallo et al., 2019). The biomarker of amyloid peptide and the Alzheimer's disease risk (BALTAZAR) study found that the plasma A $\beta$  was associated with cognitive performance, apolipoprotein E (APOE)- $\epsilon$ 4 status, and CSF A $\beta$  in cross-sectional analyses (Hanon et al., 2018). In a longitudinal study, Schindler et al. found that the plasma A $\beta$  was inversely correlated with the baseline PET A $\beta$  and correlated with the baseline CSF A $\beta$  in CN older adults and could be used to predict the future amyloid status (Schindler et al., 2019).

However, it is still unclear that, in the context of CN individuals, which factors contribute to these metrics of resilience (BR, CR, and GR) to A $\beta$  and whether the levels of resilience defined by plasma A $\beta$  and CSF A $\beta$  could both help predict

the baseline and longitudinal cognitive decline. To address the questions mentioned above, we, therefore, quantified the metrics of resilience based on plasma A $\beta$  and CSF A $\beta$ . Using linear regression analyses, we tested whether demographic (age, sex, and educational level), genetic (APOE- $\epsilon$ 4), and imaging markers are associated with these metrics of resilience. Then for investigating the added predictive value of different metrics of resilience, we explored the hypothesis that these metrics of resilience could help predict the diagnostic conversion and high resilience could slow down the cognitive decline longitudinally in CN individuals.

## METHODS

### Participants

Participant data from the Sino Longitudinal Study on Cognitive Decline (SILCODE) project (Li et al., 2019) from March 2017 to October 2018 and Alzheimer's Disease Neuroimaging Initiative (ADNI) (Weiner and Veitch, 2015) were used for this retrospective study. The SILCODE is a longitudinal observational project focusing on elderly Chinese people. Its primary goal was to identify the individuals in preclinical AD who would convert to mild cognitive impairment (MCI) and understand the disease mechanism. The ADNI was launched in 2003 as a public-private partnership whose goal was to test whether biological markers and clinical assessments could be combined to measure the progression of individuals in the spectrum of AD. The A $\beta$ -positive CN participants were recruited from the SILCODE ( $N = 100$ ) and the ADNI ( $N = 144$ ). The median follow-up was 9.4 months [interquartile range (IQR): 0–17.3] for the SILCODE and 70.8 months (IQR: 35.9–91.2) for the ADNI. All CNs underwent clinical and neuropsychological assessments, plasma (SILCODE) or examination of the CSF (ADNI), MRI scans at baseline, and had a normal performance on neuropsychological tests adjusted for age, sex, and education. Participants with the following conditions were excluded: current major psychiatric diagnosis such as depression and anxiety, serious neurologic diseases, diseases that could cause cognitive decline (e.g., thyroid dysfunction, severe anemia, syphilis, or HIV), a history of brain lesions, or head traumas (additional inclusion/exclusion criteria can be found at [www.adni-info.org](http://www.adni-info.org) and <https://www.clinicaltrials.gov/ct2/show/study/NCT03370744>).

### Standard Protocol Approvals, Registrations, and Patient Consent

Informed written consent was obtained from all participants at each site, and study procedures were approved by the institutional review board at each center. The ADNI and the SILCODE are listed in the ClinicalTrials.gov registry (ADNI-1: NCT00106899; ADNI-2: NCT01231971; ADNI-GO: NCT01078636; ADNI-3: NCT02854033; and SILCODE: NCT03370744).

### Neuropsychological Assessments

Across both studies, the neuropsychological assessment covered similar cognitive domains. To aid comparability and calculate the CR, we chose six neuropsychological measures used by

both studies and combined them into three domains: memory, language, and executive. The six measures were the Boston Naming Test and the Animal Naming for the language domain, the Trail Making Test A and the Trail Making Test B for the executive domain, and the auditory verbal learning test (AVLT) delayed recall and the delayed recognition scores for the memory domain. Scores of the Mini-Mental State Examination (MMSE) and the Montreal Cognitive Assessment (MoCA) were used to assess global cognition. All test scores were z-transformed within each test to remove the bias among measures. Within each domain, z-transformed scores were averaged to obtain a composite score.

## MRI Acquisition and Processing

Structural MRI scans were acquired on 3T scanners from GE Healthcare (Chicago, USA), Philips Medical Systems (Eindhoven, Netherlands), and Siemens Medical Solutions (Erlangen, Germany) (<http://adni.loni.usc.edu/methods/documents>) in the ADNI study and acquired on 3T SIGNA PET/MR (GE Healthcare) and Tim Trio (Siemens Medical Solutions) in the SILCODE study. The mean interval between the baseline cognitive visit and related neuroimaging visit was 23 and 22 days for the SILCODE and the ADNI cohorts, respectively. Structural MR images were processed using SPM12 (<http://www.fil.ion.ucl.ac.uk/spm/software/spm12>). In the preprocessing, structural images were removed from the non-brain tissue; segmented into the gray matter (GM), the white matter (WM), and the CSF; and then modulated and normalized into the MNI template. A 6 mm full width at half maximum (FWHM) Gaussian isotropic kernel was used to spatially smooth the normalized images. The intracranial volume (ICV) was computed as the sum of the GM, the WM, and the CSF. The left and the right hippocampal were determined for subsequent analysis.

## Biomarker Collection and Analyses of the Plasma and the CSF

In the SILCODE cohort, plasma samples were collected in polypropylene tubes with ethylenediaminetetraacetic acid (EDTA). Samples were centrifugated, aliquoted, and stored at  $-80^{\circ}\text{C}$ . Plasma samples were measured using the kit: A $\beta$  Peptide Panel 1 (4G8) Kit (Mesoscale Diagnostics, Rockville, Maryland, USA), and they were randomized and measured in duplicate with the same aliquot, blinded for clinical diagnosis. Levels of A $\beta$ 42 showed good average coefficients of variation of duplicate measurements (4.14% CV) and within the detection limit (2.5–1,271 pg/ml). In the ADNI, lumbar puncture was performed as previously described (<http://www.adni-info.org/>). Values of A $\beta$ 42 in samples of the CSF were generated by a novel, fully automated electrochemiluminescence immunoassay (ElecSys assay) (Bittner et al., 2016) and downloaded from the LONI site (provided in UPENNBIOMK9.csv and UPENNBIOMK10.csv files).

## Gaussian Mixture Modeling

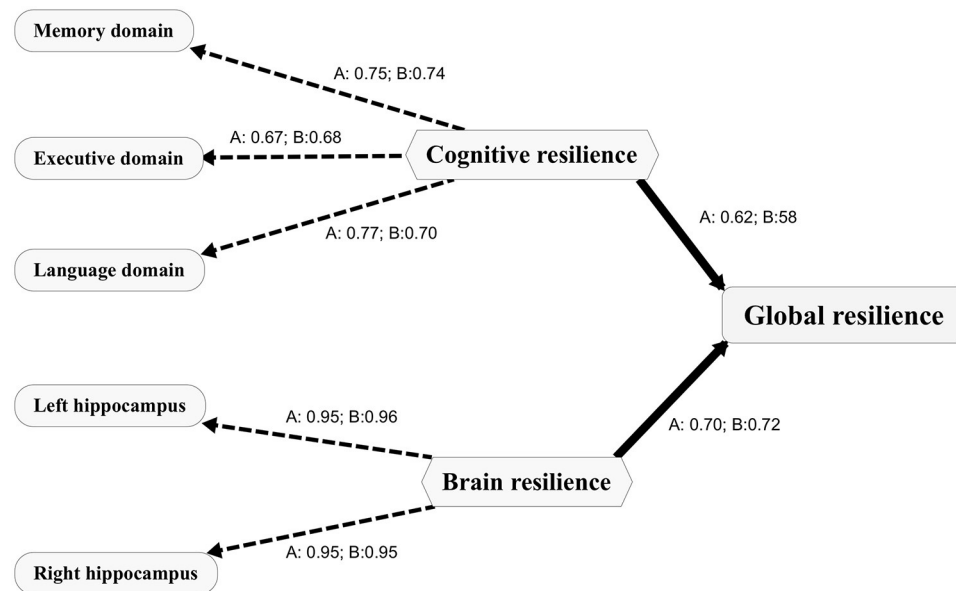

Since there is no accepted standard cut-point to determine amyloid status in relation to plasma A $\beta$ , we calculated the

cut-point to determine the amyloid status with the Gaussian mixture modeling in the SILCODE cohort. This approach was suitable since it is data-driven and does not assume similar distributions of levels of A $\beta$  across cohorts (Mormino et al., 2014; Wang et al., 2016). First, 1–5 Gaussian distributions allowing for either equal or unequal variances were fit to the data, and the number of distributions that best described the data was determined by the Bayesian information criterion (BIC) (see **Supplementary Figure 1**). We found that the optimal model contained two Gaussian distributions that reflected abnormal vs. normal A $\beta$ . Each individual was assigned a probability of belonging to either the abnormal or normal distribution. Considering the relatively high false positive rate of abnormal A $\beta$  based on only CN population and plasma A $\beta$ , CNs with  $>50\%$  probability of belonging to abnormal A $\beta$  distribution as well as smaller than 25% uncertainty corresponding to the classification were labeled A $\beta$ +. Otherwise, they were labeled A $\beta$ -. The final cut-points were 11.43 pg/ml in the SILCODE group. For the ADNI group, we used a pre-defined cut-point (980 pg/ml) to determine the amyloid status (Hansson et al., 2018).

## Statistical Analyses

Statistical analyses were performed in the R version 3.6.2 (<http://www.r-project.org/>) and R-package “pls” was used to construct the partial least squares (PLS) path models. Two multivariate PLS path models (**Figure 1**) were constructed to quantify the BR and CR and a second-order latent composite measure (GR) for each cohort. The PLS path model, which is for studying complex multivariate relationships among observed and latent variables, is the partial least squares approach to the structural equation modeling. It provides a framework for analyzing multiple relationships between a set of blocks of variables. A full path model comprises two submodels: an outer model that reflects the relationships between each latent variable and its block of indicators and an inner model that reflects the relationships between latent variables. In this study, for the outer model, memory, language, and executive domain residuals were indicators of the CR when left and right hippocampus volume residuals were indicators of the BR. For the inner model, the GR was derived from its latent variables (CR and BR). Specifically, we performed individual linear regression models between composite scores/hippocampal volumes and plasma/CSF A $\beta$  levels and used the standardized residual as an indicator of CR/BR. For example, memory domain residuals to A $\beta$  were calculated as residuals from a regression model with memory domain scores as the outcome and A $\beta$  as the predictor, representing as one of the indicators of the CR.

To evaluate which factors contribute to resilience, we performed two sets of multivariable linear regression models. In the first set, multivariable linear regression models were performed with age, sex, educational levels, APOE- $\epsilon$ 4 status, and the whole brain volume as independent variables and the respective metric of resilience as a dependent variable. In the second set, the cognitive scores and brain volumes for residuals calculation were also included as independent variables. Then,

**FIGURE 1 |** Path diagram depicting the PLS models for both cohorts. The PLS path model includes the outer model and the inner model. The outer model includes indicators presented as capsules and the first order latent variables presented as hexagons. The inner model depicts the relationships between the first order latent variables (CR and BR) and the second order latent variable (GR). The loadings between a latent variable and its indicators are presented as numbers. A, the PLS model for the ADNI; B, the PLS model for the SILCODE. CR, cognitive resilience; BR, brain resilience; GR, global resilience. PLS, partial least squares; ADNI, Alzheimer's Disease Neuroimaging Initiative; SILCODE, Sino Longitudinal Study on Cognitive Decline.

linear mixed effect models were used for longitudinal cognitive analyses. The global cognition test (MoCA) was used as the outcome variable, and fixed effects included our interested effects (i.e., the effect of resilience of interest \* time) as well as other effects that we wanted to test or control, including time (from the baseline), age, sex, education, and APOE- $\epsilon$ 4 status. The random effect included the intercept of an individual. In addition to the original mixed effect models, we also performed another set of mixed effect models adjusting the effects of the original cognitive and brain variables used to derive resilience and included the time interactions with each of these variables. To further evaluate the utility of resilience in predicting the conversion from normal controls (NCs) to MCI, the Cox analysis for each metric of resilience was performed. For visualization purposes, we dichotomized the sample according to low vs. high resilience (CR, BR, or GR) using a median split. Using these dichotomized groups, we computed three 2-level variables (CR: CR+/CR-; BR: BR+/BR-; and GR: GR+/GR-) and Kaplan-Meier survival curves were created to show the conversion rate from the baseline with respect to resilience. Finally, for evaluating the added value of resilience for predicting the longitudinal cognitive decline, we used the Akaike information criterion (AIC) and the BIC to evaluate both the predictive models with conventional indicators (MoCA/MMSE and hippocampal volume/brain volume) and the predictive models with conventional indicators plus resilience. A lower AIC or BIC value indicates a better model. The level of significance was set at  $p < 0.05$ .

## RESULTS

### Characteristics of Participants

A total of 244 participants were included in the study. From the SILCODE group, 100 participants were included [59 (59%) female; mean (SD) age, 65.38 (4.66); mean (SD) MMSE score, 28.84 (1.13)]. From ADNI group, 144 participants were included [74 (51.4%) female; mean (SD) age, 74.68 (5.65); mean (SD) MMSE score, 29.08 (1.10)]. The characteristics and clinical details of the participants are presented in **Table 1**. The average age [65.38 (4.66) vs. 74.68 (5.65),  $p < 0.001$ ] and educational level [12.6 (2.8) vs. 16.3 (2.6),  $p < 0.001$ ] of participants in the SILCODE were significantly lower than those in the ADNI.

### The PLS Path Model

The PLS path models for the SILCODE and the ADNI cohorts are presented in **Figure 1**. For evaluating the quality of the two models, we assessed three aspects of the measures of the model. Both models showed good one-dimensionality of the indicators (SILCODE: mean Cronbach's alpha = 0.67, mean Dillon-Goldstein's rho = 0.81, mean first eigenvalue = 1.79; ADNI: mean Cronbach's alpha = 0.69, mean Dillon-Goldstein's rho = 0.82, mean first eigenvalue = 1.80). Furthermore, the indicators were well-explained by its latent variable as average loading for the CR and the BR was 0.81 for the SILCODE cohort and 0.82 for the ADNI cohort. The degree to which a given construct was different from other constructs was good (all cross-loadings in two models  $< 0.26$ ). In sum, both models fit well and had a goodness-of-fit score of 0.73.

**TABLE 1** | Characteristics of the participants of the study.

	SILCODE	ADNI	P
Sample size, <i>n</i>	100	144	
Age	65.38 (4.66)	74.68 (5.65)	<0.001

MMSE, Mini-Mental State Examination; MoCA, Montreal Cognitive Assessment; AVLT-delay, auditory verbal learning test-delay recall; AVLT-recog, auditory verbal learning test-recognition; STTA, shape trail making test A; STTB, shape trail making test B; AFT, animal fluency test; BNT, Boston Naming Test; APOE, apolipoprotein E. Data are presented as mean (SD) unless otherwise indicated.

<sup>a</sup>AVLT in the Sino Longitudinal Study on Cognitive Decline (SILCODE) was HuaShan version and in the Alzheimer's Disease Neuroimaging Initiative (ADNI) was Rey AVLT version A/B.

<sup>b</sup>STT-A and STT-B in the SILCODE were Alternative Shape Trail Making Test A and B and in the ADNI were Shape Trail Making Test A and B.

<sup>c</sup>Source of amyloid- $\beta$  (A $\beta$ ) in the SILCODE was the plasma and in the ADNI was the cerebrospinal fluid (CSF).

## Factors Associated With Resilience

Multivariable models (Table 2) showed that factors contributing to different metrics of resilience were overall consistent in both cohorts. Younger age was associated with higher levels of all three metrics of resilience. Specifically, higher educational levels were related with greater CR and larger whole brain volume was related to greater BR and GR. After including the original cognitive and brain measures that resilience derived from Supplementary Table 1 the young, women, and large brain volume were associated with the BR and the GR while the CR was only related to cognitive composite scores.

## Longitudinal Cognitive Progress

Linear mixed models (Table 3) in two cohorts both showed that higher CR (SILCODE:  $\beta = 1.064$ ,  $p < 0.001$ ; ADNI:  $\beta = 0.814$ ,  $p = 0.002$ ) and higher GR (SILCODE:  $\beta = 0.677$ ,  $p < 0.001$ ; ADNI:  $\beta = 0.661$ ,  $p = 0.007$ ) were associated with better cognitive performances. We also identified a significant positive interaction between all metrics of resilience and time in the ADNI cohort and a similar trend in the SILCODE cohort, suggesting that participants with a higher level of resilience would perform better over time. After controlling the baseline cognitive performance and hippocampal volumes (Supplementary Table 2), associations between resilience and cognition were insignificant in the SILCODE cohort, whereas higher CR ( $\beta = 0.977$ ,  $p = 0.004$ ), BR ( $\beta = 0.565$ ,  $p < 0.001$ ), and GR ( $\beta = 0.420$ ,  $p = 0.036$ ) in the ADNI cohort continued

to predict slower cognitive decline in the CNs. As the results of Cox regression models and survival curves showed (Figures 2, 3), all three metrics of resilience were protective factors to clinical progression (all values of  $p < 0.05$ ). Information criteria for prediction models with and without resilience were provided in Table 4. Compared with the predictive models with conventional variables (MMSE and brain volume), models with both conventional variables and resilience showed smaller AIC and BIC values (CR: AIC $\Delta = -4.64$ , BIC $\Delta = -2.84$ ; BR: AIC $\Delta = -5.56$ , BIC $\Delta = -3.76$ ; GR: AIC $\Delta = -12.15$ , BIC $\Delta = -10.34$ ). Similar results were found in the comparison of the predictive models with another combination of conventional variables and the predictive models with conventional variables and resilience (Supplementary Table 3).

## DISCUSSION

This study provides information about different phenotypes of resilience, their associations with demographic, genetic, and neuroimaging factors in a relatively large number of CNs. Two latent variable models to quantify the metrics of resilience related to A $\beta$  in two cohorts were constructed. Results from this study suggested that younger individuals, women, and people with larger brain volumes were related to greater brain and GR when exposed to the A $\beta$  burden. All three phenotypes of resilience based on the plasma and the CSF A $\beta$  were observed to have a protective effect against cognitive decline in long-term follow-up. These metrics of resilience may capture additional information when the consequence of the clinical progression can be predicted than conventional cognitive and brain indicators.

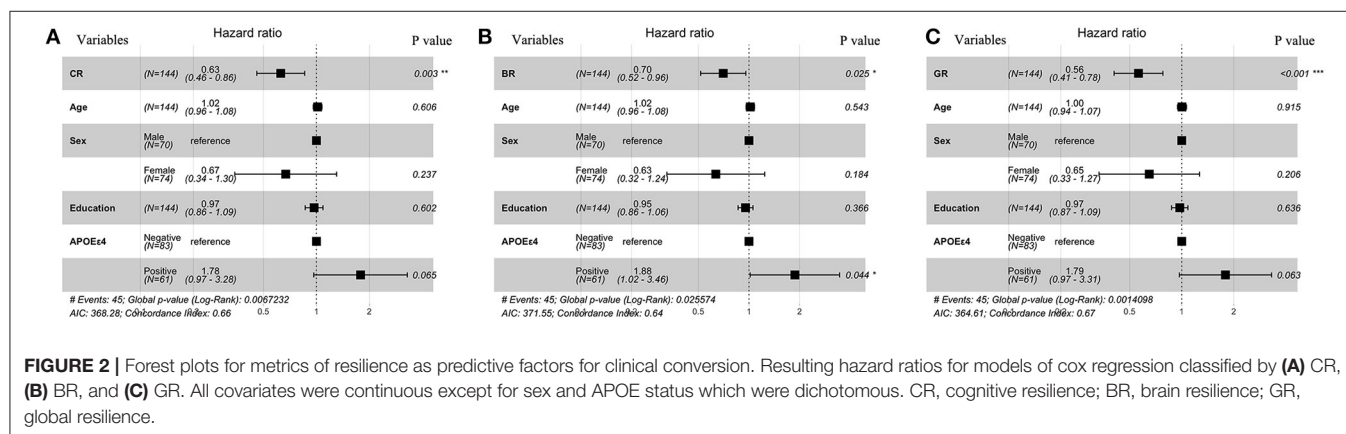

Metrics of resilience were defined with the PLS model separately in each cohort and the loadings between cognitive indicators, brain indicators, and the respective resilience as well as the loadings between the BR, the CR, and the GR were calculated. The framework and goodness-of-fit in both models were similar and consistent with the previous work, indicating to a certain extent that the residualization approach was a feasible and reliable method of quantifying the metrics of resilience. Previous literature (Jagust, 2013; Scholl et al., 2016; Jack et al., 2019) had suggested that the brains were more vulnerable to various kinds of damages in aging and the prevalence of pathologic biomarkers in AD were found to be different in women and men with respect to age. Our results had confirmed the associations of these factors and resilience and indicated that age, sex, and brain volume were important for investigating the BR and the GR. In CN individuals, women, young individuals, or larger brain volume sustained better cognitive function and the preservation of the brain structure when exposed to pathological changes. Explanations could be the neural compensation mechanism, the protective effects of sex steroid hormones before menopause, the gene expression of heterochrony, and the threshold models of brain reserve (Satz, 1993; Berchtold et al., 2008; Pike et al., 2009). Intriguingly, women displayed both higher levels of pathologic biomarkers in AD and higher resilience (Jack et al., 2019), which seems to be congruent. However, the protective effect

of resilience may diminish with age and the accumulation of pathological changes. In post-menopausal women, the depletion of sexual hormones, the gene expression changes in specific brain regions (like superior frontal gyrus), and high A $\beta$  burden accumulation would accelerate cognitive decline although they remain clinically normal (Yuan et al., 2012; Jack et al., 2017). Compared with factors associated with the BR and the GR, we found a specific association between educational levels and CR as CN individuals with higher education level could cope with more

severe pathological burden (Kemppainen et al., 2008; Pettigrew et al., 2017; van Loenhoud et al., 2019). The explanation of how education enhanced the reserve capacity and slowed down cognitive decline in individuals with accumulated pathological deposits was still unclear and was even challenged since the paradoxical results of education on modifying longitudinal cognitive decline (van Loenhoud et al., 2019; Wilson et al., 2019) though it was generally accepted that higher educational levels before progressing into the cognitive impaired stage were

AIC, Akaike information criterion; BIC, Bayesian information criterion. All models were corrected for age, sex, educational levels, and APOE-ε4 status.

<sup>a</sup> This model included MMSE as the predictor.

<sup>b</sup> This model included brain volume as the predictor.

<sup>c</sup> This model included both MMSE and brain volume as the predictor.

beneficial to our brains. However, after controlling the cognitive performance, the association between the CR and education levels disappeared, suggesting this relation was poor and more likely reflected the association between the baseline cognition and educational levels.

We found no association between the APOE genotype and the resilience at baseline in both cohorts. The dissociation of the APOE phenotype and the resilience could be caused by the dual effects on the brain of different APOE genotypes and the effect of the APOE on pathology was dominated in the later stage in AD. Consistent with this explanation, Wolk et al. (2010) reported APOE-ε4 carriers with AD displayed severe impairments in the memory domain rather than in execution and language domains. Another report (Pievani et al., 2009) found carriers were associated with greater temporal volume loss, and non-carriers were associated with greater frontoparietal volume loss.

Although previous studies exploring resilience have shown that higher resilience scores were associated with better cognitive

performances and a smaller risk of the clinical progression, many of them defined the resilience based on educational levels, reading abilities, or lifestyle (Roe et al., 2008; Kaup et al., 2015; Vemuri et al., 2017). These metrics remained stable in the elderly and hardly reflected the current level of resilience of an individual. Therefore, they may fail to reflect the individual difference in cognitive or structural brain processes over time. However, several investigators have found residual approaches based on cognitive/brain predictors and biomarkers in AD to quantify that resilience could provide more information at the individual level over time and include information from various cognitive domains and biomarkers (Reed et al., 2010; Hohman et al., 2016). With this approach, we found that all types of resilience could predict longitudinal global cognitive changes, even adjusting for the baseline cognitive performance and hippocampal volumes and considering conventional predictors. This finding suggested that resilience was not only associated with demographic, genetic, cognitive, and imaging features but also provided added information about the prognosis.

The strength of our study lies in a relatively large sample of A $\beta$ -positive CN individuals with demographic, genetic, neuroimaging, and biomarker data of AD, and a longitudinal design allowed us to inform the impact of different resilience to the clinical progression. Two cohorts provided the possibility of validating factors contributing to the different metrics of resilience and the effects of resilience on cognitive decline.

The present study has several limitations. The differences in characteristics of the participants and measurements across two cohorts led to only comparable cognitive tests with respect to the included three domains. This limitation was partly resolved by the combination of test scores and transformation. Another limitation was the different ranges of follow-up and different methods of accessing the amyloid in the two cohorts. The short follow-up period for the SILCODE cohort not only resulted in the absence of the Cox regression analysis for this cohort, as there were no sufficient clinical progression datapoints available for analysis but also may lead to the relatively poor predictive value of resilience compared to that in the ADNI cohort, though growing evidence has demonstrated that plasma A $\beta$  concentrations are highly correlated with brain amyloidosis (Nakamura et al., 2018; Risacher et al., 2019). In addition, as the false positive rate for the classification of the A $\beta$  status if only based on the CSF or the plasma was higher than those based on multiple methods or A $\beta$  PET, we, therefore, adjusted the cut-point within the SILCODE by controlling the classification uncertainty of the A $\beta$  abnormal below 25% and used a pre-defined cut-point in the ADNI that was determined to optimize the concordance with the A $\beta$  PET visual read.

## CONCLUSION

This study provides information about the associations between the resilience based on the plasma A $\beta$  and the CSF A $\beta$  and demographic, genetic, and neuroimaging factors in A $\beta$ -positive CN individuals. We found that younger individuals, women, and people with larger brain volumes were associated with higher brain and GR. Metrics of resilience based on A $\beta$  had a protective effect against the clinical progression and could provide additional information beyond the cognitive performance and imaging features in CN people.

## DATA AVAILABILITY STATEMENT

The data of SILCODE used and/or analyzed during the current study are available from the corresponding author on reasonable request. The data of ADNI can be found at the the Alzheimer's Disease Neuroimaging Initiative website ([adni.loni.usc.edu](http://adni.loni.usc.edu)).

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by XuanWu Hospital of Capital Medical University and the institutional review board at each center of ADNI. Informed written consent was obtained from all participants.

## AUTHOR CONTRIBUTIONS

LL and YH contributed conception and design of the study. LL, YS, XiaonW, XiaoqW, and YH did the clinical assessments and data acquisition. LL, YS, XiaonW, and LS did the data analysis and interpretation. All authors contributed to manuscript revision, read and approved the submitted version.

## FUNDING

This article was supported by the National Key Research and Development Program of China (2018YFC1312000) and the National Natural Science Foundation of China (61633018). Data collection and sharing for this project was funded by the Alzheimer's Disease Neuroimaging Initiative (ADNI) (National Institutes of Health Grant U01 AG024904) and the DOD ADNI (Department of Defense award number W81XWH-12-2-0012). This ADNI was funded by the National Institute on Aging and the National Institute of Biomedical Imaging and Bioengineering, and through generous contributions from the following: AbbVie, Alzheimer's Association; Alzheimer's Drug Discovery Foundation; Araclon Biotech; BioClinica, Inc.; Biogen; Bristol-Myers Squibb Company; CereSpir, Inc.; Cogstate; Eisai Inc.; Elan Pharmaceuticals, Inc.; Eli Lilly and Company; EuroImmun; F. Hoffmann-La Roche Ltd. and its affiliated company Genentech, Inc.; Fujirebio; GE Healthcare; IXICO Ltd.; Janssen Alzheimer Immunotherapy Research & Development, LLC.; Johnson & Johnson Pharmaceutical Research & Development LLC.; Lumosity; Lundbeck; Merck & Co., Inc.; Meso Scale Diagnostics, LLC.; NeuroRx Research; Neurotrack Technologies; Novartis Pharmaceuticals Corporation; Pfizer Inc.; Piramal Imaging; Servier; Takeda Pharmaceutical Company; and Transition Therapeutics. This Canadian Institutes of Health Research was providing funds to support the ADNI clinical sites in Canada. Private sector contributions are facilitated by the Foundation for the National Institutes of Health ([www.fnih.org](http://www.fnih.org)). This grantee organization was the Northern California Institute for Research and Education, and this study was coordinated by the Alzheimer's Therapeutic Research Institute at the University of Southern California. The ADNI data are disseminated by the Laboratory for Neuro Imaging at the University of Southern California.

## ACKNOWLEDGMENTS

We thank all participants and members of the SILCODE study group for their cooperation during the data collection and management, and we thank the ADNI study group for their contribution to the field and for specific use of these data.

## SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fnagi.2021.610755/full#supplementary-material>

Luo Y, Sun Y, Tian X, Zheng X, Wang X, Li W, Wu X, Shu B and Hou W (2021) Deep Brain Stimulation for Alzheimer's Disease: Stimulation Parameters and Potential Mechanisms of Action. *Front. Aging Neurosci.* 13:619543. doi: 10.3389/fnagi.2021.619543

Deep brain stimulation (DBS) is a neurosurgical technique that regulates neuron activity by using internal pulse generators to electrodes in specific target areas of the brain. As a blind treatment, DBS is widely used in the field of mental and neurological diseases, although its mechanism of action is still unclear. In the past 10 years, DBS has shown a certain positive effect in animal models and patients with Alzheimer's disease (AD), but there are also different results that may be related to the stimulation parameters of DBS. Based on this, determining the optimal stimulation parameters for DBS in AD and understanding its mechanism of action are essential to promote the clinical application of DBS in AD. This review aims to explore the therapeutic effect of DBS in AD, and to analyze its stimulation parameters and potential mechanism of action. The keywords "Deep brain stimulation" and "Alzheimer's Disease" were used for systematic searches in the literature databases of Web of Science and PubMed (from 1900 to September 29, 2020). All human clinical studies and animal studies were reported in English, including individual case studies and long-term follow-up studies, were included. These studies described the therapeutic effects of DBS in AD. The results included 16 human clinical studies and 14 animal studies, of which 28 studies clearly demonstrated the positive effect of DBS in AD. We analyzed the current stimulation parameters of DBS in AD from stimulation target, stimulation frequency, stimulation start time, stimulation duration, unilateral/bilateral treatment and current intensity, etc., and we also discussed its potential mechanism of action from multiple aspects, including regulating related neural networks, promoting nerve oscillation, reducing  $\beta$ -amyloid and tau levels, reducing neuroinflammation, regulating the cholinergic system, inducing the synthesis of nerve growth factor.

**Keywords:** deep brain stimulation, Alzheimer's disease, therapeutic effect, stimulation parameter, action mechanism

## INTRODUCTION

Alzheimer's disease (AD) is the most common type of dementia in the elderly. Its clinical manifestations are progressive cognitive decline and memory loss (Querfurth and LaFerla, 2010; Patterson, 2018). The prevalence and incidence of AD are increasing rapidly, and it is one of the major health crises facing the aging society of the 21st century (Alzheimer's Association, 2020). Clinically, only a small number of AD patients benefit from the temporary treatment effect of AD drugs. There are currently no viable medications to slow or reverse the progression of AD (Ihl et al., 2011; Arai et al., 2016, 2018; Cummings et al., 2020). The severity of AD and the limitations of drug therapy have spurred the development of research on non-drug therapies (Cummings et al., 2014; Aldehri et al., 2018). A series of physical therapy methods, including electrical stimulation and magnetic stimulation, are gradually being applied in the field of neurological diseases (Li et al., 2015; Temel and Jahanshahi, 2015; Zhou et al., 2018; Holczer et al., 2020).

Aldini first reported the use of electrical stimulation technology to improve the mood of melancholy patients in 1804, thus opening up a new field of electrical stimulation for the clinical treatment of mental illness (Aldini, 1804; Parent, 2004). Deep brain stimulation (DBS) is an invasive neuromodulation technique that involves brain stimulation and is one of the few neurosurgery methods that allows blinded research. The DBS device is mainly composed of stimulating electrodes in the brain, subcutaneous leads and pulse generators, and it directly changes brain activity in a controlled manner by using internal pulse generators to deliver electrical pulses to stimulation electrodes in specific target areas of the brain (Kringelbach et al., 2007; Lozano and Lipsman, 2013; Chen and Ponce, 2019). DBS is used for mental disorders, such as obsessive-compulsive disorder, epilepsy and depression (Zhou et al., 2018; Vazquez-Bourgon et al., 2019; Onate-Cadena et al., 2020), and for a variety of neurodegenerative diseases, such as idiopathic tremor, Parkinson's disease, and dystonia (Miocinovic et al., 2013; Chen and Ponce, 2019; Lee et al., 2019; McKinnon et al., 2019). Human clinical trials of DBS for AD began in 1984. Turnbull applied DBS to the left nucleus basalis of Meynert (NBM) in patients with a 4-years AD course but found no improvement in memory or cognition (Turnbull et al., 1985). Since then, research on treatment with DBS in AD has been vacant for more than two decades.

Research on the use of DBS in AD was restarted by a case study that used DBS to treat obese patients. The memory of a morbidly obese patient was enhanced after chronic hypothalamic/fornix DBS treatment. This enhancement may have occurred because DBS regulates marginal activity. That is, electrical activity in the medial temporal lobe is activated during DBS stimulation (Hamani et al., 2008). In the past 10 years, preliminary studies of DBS in AD have shown some positive effects of this treatment, including slowing cognitive decline and hippocampal atrophy and increasing cerebral glucose metabolism and brain connectivity in AD patients (Laxton et al., 2010; Sankar et al., 2015; Lozano et al., 2016; Aldehri et al., 2018), but there are also some controversial negative effects,

such as AD patients <65 years of age have not shown good curative effects, and some patients have postoperative side effects (Lozano et al., 2016; McMullen et al., 2016; Leoutsakos et al., 2018). These discrepant results cannot be ignored. Differences in methodology, such as DBS parameters (stimulation target, frequency, stimulation start time, duration, unilateral/bilateral treatment, and stimulation current intensity), study design and sample size may explain these differences. The exact mechanism of action of DBS in AD is unknown. At present, there is little direct research on the mechanism of action of DBS in AD, and various hypotheses (changing the electrical activity of neurons, promoting neurogenesis and neurotransmitter release, etc.) have been proposed to explain its potential mechanism of action (Hescham et al., 2013a; Laxton and Lozano, 2013; Kuhn et al., 2015a; Aldehri et al., 2018; Jakobs et al., 2019; Yu et al., 2019).

There is increasing interest in exploring DBS as a treatment method for intervention in AD. A decision analysis model of DBS in AD patients shows that DBS is more effective and more cost-effective than standard treatment in the clinical treatment of AD (Mirsaeedi-Farahani et al., 2015). To effectively promote the application of DBS in the field of AD treatment, in this review, we systematically searched the literature published in the field of DBS in AD, and explored the effect of DBS stimulation parameters on the treatment effect for AD and the potential mechanism of action of DBS in the treatment of AD.

## METHODS

### Literature Search and Selection Criteria

In the literature databases of Web of Science and PubMed (from 1900 to September 29, 2020), human clinical studies and animal studies on DBS in AD were systematically searched using the following terms, individually and combined in multiple search strategies: "Deep brain stimulation," "DBS," "Alzheimer's disease," and "AD." Literature inclusion criteria: the main purpose was to study the therapeutic effects of DBS in AD, including human clinical research and animal research; the language of the article was English only; individual case studies and long-term follow-up studies were not excluded; and duplicate studies were excluded.

### Data Abstraction

The selected articles were classified according to human clinical research and animal research to extract relevant data. The following data were extracted from human clinical studies: (1) study design; (2) basic information on the participants, including number, sex, average age, average Alzheimer's disease assessment scale-cognitive section (ADAS-Cog), average Mini-Mental State Examination (MMSE), and additional medications; (3) DBS data, including the DBS protocol and brain target; (4) follow-up; (5) main results, including the main outcome measures (average ADAS-Cog and average MMSE) and conclusion; and (6) adverse events. Various cognitive outcome measures have been used in human clinical studies, and some studies have evaluated multiple indicators. In this review, we chose the average ADAS-Cog and average MMSE as the main outcome measures. For studies that did not report averages and SDs, data were calculated from specific figures in the literature. The following data were extracted

from animal studies: (1) basic information on the animals, including number, sex, age, animal type, grouping; (2) DBS data, including DBS protocol and brain target; (3) behavioral methods; (4) follow-up; and (5) main conclusion.

## RESULTS

### Search Results

This review included 30 studies on the treatment of DBS in AD. As shown in **Figure 1**, research on DBS in AD treatment was lacking for ~25 years after 1984 when DBS was applied in AD treatment. The time on the abscissa was the publication time of the article. It was not until 2010 that there was another paper on DBS in AD. During the 10-years period from 2010 to 2020, DBS in AD papers were published every year.

### Human Clinical Studies

#### DBS Implementation

DBS is implemented in the human body and its components are surgically implanted. As mentioned earlier (Laxton et al., 2010; Mao et al., 2018), after local anesthesia is applied, the stereotaxic frame is installed on the patient's head. The position of the DBS target is ascertained by imaging. Subsequently, a drill is used to make bilateral holes in the skull, and the stimulation electrodes are implanted three-dimensionally. After the electrodes are placed, the internal pulse generator is implanted into the subclavian or subcutaneous area of the chest or abdomen under general anesthesia. The lead is implanted subcutaneously and connected to the stimulation electrodes and internal pulse generator through the head, neck, and chest. The positioning of the electrodes must be verified again by imaging after the operation.

### Therapeutic Effects

**Table 1** lists the detailed characteristics of 16 human clinical studies of DBS in AD patients. Turnbull et al. started the field of DBS in the treatment for AD in 1984 (Turnbull et al., 1985). A study by Laxton et al. (2010) showed that after DBS treatment, the memory of AD patients improved, the rate of cognitive decline decreased, and cerebral glucose metabolism increased (Laxton et al., 2010; Smith et al., 2012). Subsequently, human clinical studies of DBS in AD continued. Fontaine et al. reported that a patient with AD showed stable memory and increased metabolism in the medial temporal lobe after 1 year of DBS (Fontaine et al., 2013). Other studies have also shown that the nutritional status of AD patients remains stable, and the rate of hippocampal atrophy slows down after 1 year of DBS (Noreik et al., 2015; Sankar et al., 2015). Kuhn et al. applied DBS to 6 AD patients, and 1 year later, the ADAS-Cog scores of four participants increased or remained stable, but the scores of two participants deteriorated (Kuhn et al., 2015a). Kuhn et al. also performed DBS on two other AD patients who were 5 years younger. One AD patient had a stable ADAS-Cog score and an increase in MMSE score after 28 months. Another case showed overall improvement in the first year of treatment, but the ADAS-Cog score increased by seven points after 26 months (Kuhn et al., 2015b). The long-term follow-up results of all eight patients at 24 months showed that the ADAS-cog of young patients with mild AD remained relatively stable during the 24-months follow-up period, while the ADAS-cog of AD patients with high baseline increased (Hardenacke et al., 2016). In the two youngest patients among the eight, the repetitive inhibition of sensory gating improved (Durschmid et al., 2020). Therefore, they believed that DBS performed in the early and young ages of AD may have a beneficial effect on the progression of the disease.

AD, Alzheimer's Disease; ADAS-Cog, Alzheimer's disease assessment scale-cognitive section; B, bilateral; CDR-SB, clinical dementia rating-sum of boxes; DBS, deep brain stimulation; L, left; m, month; min, minute; MMSE, mini-mental state examination; N, number; NBM, nucleus basalis of Meynert; Sham, sham stimulation; R-, right; VC/VS, ventral capsule/ventral striatum; w, week; y, year.

and cognitive function. Baldermann et al. also showed that AD patients with less atrophy can benefit from DBS (Baldermann et al., 2018). However, the study by Lozano et al. showed different results. Lozano et al. observed an increase in cerebral glucose metabolism in 21 AD patients after 1 year of DBS, considered DBS to be safe, and proposed that DBS may benefit AD patients aged 65 years and older, while those under 65 years old may show a worsening condition (Lozano et al., 2016). Leoutsakos et al. conducted a second-year follow-up of 42 participants in the study, confirming that DBS benefits older patients with AD (Leoutsakos et al., 2018). Furthermore, McMullen et al. reported that an AD patient implanted with bilateral fornix DBS experienced asymptomatic bilateral cerebral encephalomalacia (McMullen et al., 2016). Among the current existing studies, only two studies have shown no therapeutic effect of DBS in AD (Turnbull et al., 1985; McMullen et al., 2016), and there were a few AD patients with poor performance in other studies (Lozano et al., 2016; Leoutsakos et al., 2018; Mao et al., 2018). The small sample size (case report) (Turnbull et al., 1985; McMullen et al., 2016), side effects of DBS surgery (Ponce et al., 2016), and improper use of quetiapine by patients (Lozano et al., 2016; Leoutsakos et al., 2018; Mao et al., 2018) may account for these differences, but we cannot rule out the possibility that it is due to other methodological differences. However, among most AD patients receiving DBS, DBS is a promising intervention for AD.

## Animal Studies

### DBS Implementation

For DBS in AD animal models, the stimulating electrodes are implanted, and the stimulator is connected externally. A single study implanted the stimulators subcutaneously on the backs of mice (Huang et al., 2019). Each mouse is anesthetized and fixed on a stereotaxic device; the scalp is removed, exposing the skull. An electric drill is used gently drill small holes at the target points on the skull. Then, the stimulating electrode is implanted at the target position and fixed to the skull with adhesive material. In some studies, a small number of screws are implanted in the skull to fix the electrodes (Hescham et al., 2013b; Chen et al., 2014; Zhang et al., 2015; Tsai et al., 2020). X-ray imaging or tissue staining is used to ensure that the electrode is implanted in the target position (Lee et al., 2016; Mann et al., 2018; Huang et al., 2019).

### Therapeutic Effects

In addition to human clinical research on DBS in AD, animal research on DBS in AD is also being carried out simultaneously. **Table 2** lists the detailed characteristics of 14 animal studies of DBS in AD animal models. Compared with human clinical studies, the behavioral, physiological and biochemical changes of AD model mice established by transgenic AD model or drug injection after DBS are mostly positive in the animal studies. This review later used these animal studies, combined with human clinical studies, to explore the effects of DBS stimulation parameters on the efficacy of AD treatment and the potential mechanism of action of DBS in AD.

## Adverse Events

DBS is an invasive brain stimulation technique that carries the risk of major surgery (Doshi, 2011). The main surgical complications include bleeding, infection, and hardware failure (Ponce et al., 2016; Barrett, 2017). The adverse events related to DBS that occur in AD are manifested in human clinical studies which are rarely found in animal studies. **Table 3** lists the adverse events of the human clinical study of DBS in AD. At higher voltage intensity, AD patients felt inner restlessness, warmth, flushing, sweating, increased heart rate and blood pressure, and other adverse reactions. However, after reducing the voltage intensity, AD patients had almost no adverse effects (Laxton et al., 2010; Kuhn et al., 2015a). Other minor adverse reactions, including headache, diarrhea, vomiting, and paresthesias, were almost transient and had no sequelae (Laxton et al., 2010; Kuhn et al., 2015a; Leoutsakos et al., 2018; Scharre et al., 2018). Serious adverse events, including internal pulse generator infections, skin infections, inaccurate device location, hematoma, syncope, epilepsy, etc., could almost be resolved (Ponce et al., 2016). Leoutsakos et al. conducted the largest-scale study on the safety of DBS in AD patients, which involved 42 patients with AD (Lozano et al., 2016; Ponce et al., 2016; Leoutsakos et al., 2018). Within 90 days after receiving DBS surgery, 26 patients experienced 64 non-serious adverse events related to DBS surgery, of which 5 patients experienced 7 serious adverse events. For these 64 non-serious adverse events, 57 occurred within 30 days after surgery. In the second year after receiving DBS surgery, 24 patients reported 86 non-serious adverse events, and eight patients reported 15 serious adverse events. Two statistical results showed that the shorter the time after the completion of the operation is, the greater the possibility of reported adverse events in AD patients. The occurrence of adverse events gradually decreased over time, and there seemed to be no long-term complications. The safety of adverse events was as expected. However, the case report by McMullen et al. showed that DBS has brought long-term adverse effects (McMullen et al., 2016). This might be related to both the physical state of the patients and the experience of the surgeon. Although this was only a case study, researchers should pay attention to it. In general, AD patients tolerate DBS well under the appropriate DBS parameters, which proves that DBS is a relatively safe technique for AD patients.

## DBS PARAMETERS

### Stimulation Targets

To date, the stimulation targets for DBS in the treatment of AD patients in human clinical studies have involved the fornix, NBM, and ventral capsule/ventral striatum (VC/VS) (**Table 1**). Relevant animal research also involved multiple stimulation targets, including the intralaminar thalamic nucleus (ILN), midline thalamic nuclei (MTN), mammillothalamic tract (MT), anterior nucleus of thalamus (ANT), entorhinal cortex (EC), and CA1 (**Table 2**). The selection of these stimulation targets for DBS is mainly based on the neural network of the brain. Among them, VC/VS is related to the frontal lobe neural network (Price

**TABLE 2 |** The animal study of DBS in AD.

Study (first author, year)	Base					DBS protocol	Brain target	Behavior methods	Follow up	Main conclusion
	N	Sex (male/female)	Age	Animal	Group					
Arrieta-Cruz et al. (2010)	16–20	male	8 w	TgCRND8, WT (B6C3F1)	WT, AD-DBS	Eight trains of HFS; each train of 25 Hz, 1 s duration, 300 $\mu$ A, 10 s inter-train interval, 3 d	B-MTN, [AP: $-1.1$ , ML: 0.3, DV: 2.5–3.3]	NOR	After DBS	DBS could enhance short-term memory in the CA1 region of hippocampus in TgCRND8 mice.
Heschem et al. (2013b)	21	21/0	-	An injection of scopolamine to SD rats	AD ( $n = 11$ ), AD-DBS ( $n = 10$ )	50 $\mu$ A, 100 $\mu$ A, 200 $\mu$ A, 10 Hz, 100 Hz, 100 $\mu$ s, 2 min/time	B-fornix, [AP $-1.88$ , ML 1.3, DV 8.2]	NLR, OF	After DBS	Fornix DBS reversed the memory of rats received scopolamine and it was not sensitive to stimulation frequency, but rather to current levels.
Chen et al. (2014)	32	32/0	-	An injection of A $\beta_{1-42}$ and A $\beta_{1-40}$ to SD rats	SD-PBS ( $n = 8$ ), AD ( $n = 8$ ), AD-ANT ( $n = 8$ ), AD-DBS ( $n = 8$ )	130 Hz, 60 $\mu$ s, 1.5 V	B-ANT, [AP: $-2.0$ , ML: $\pm 1.8$ , DV: $-4.7$ ]	MWM	After DBS	Bilateral ANT HFS could improve the performance of AD rats in MWM.
Zhang et al. (2015)	48	48/0	6 w	An injection of A $\beta_{1-42}$ to SD rats	ANT DBS ( $n = 8$ ), EC DBS ( $n = 8$ ), fornix DBS ( $n = 8$ ), ANT-sham ( $n = 8$ ), EC-sham ( $n = 8$ ), fornix-sham ( $n = 8$ )	500 $\mu$ A, 130 Hz, 90 $\mu$ s, 24 h	B-ANT, [AP: $-1.6$ , ML: 1.5, DV: $-5.2$ ]; B-EC, [AP: $-7.0$ , ML: 5.4, DV: $-8.2$ ]; B-fornix, [AP: $-1.9$ , ML: 1.3, DV: $-8.2$ ]	MWM, NOR, OF	4 w after DBS.	EC and fornix DBS could enhance hippocampus-independent recognition memory, and facilitated hippocampus-dependent spatial memory more prominently than ANT DBS.
Heschem et al. (2015)	63	-	-	An injection of scopolamine to SD rats	Sham ( $n = 11$ ), CA1 DBS ( $n = 10$ ), MT DBS ( $n = 13$ ), ANT DBS ( $n = 14$ ), EC DBS ( $n = 15$ )	50 $\mu$ A, 100 $\mu$ A, 200 $\mu$ A, 10 Hz, 100 Hz, 100 $\mu$ s, 24 h	B-CA1, [AP: $-3.6$ , ML: 1.8, DV: $-2.6$ ]; B-MT, [AP: $-1.8$ , ML: 1, DV: $-6.2$ ]; B-ANT, [AP: $-1.6$ , ML: 1.5, DV: $-5.2$ ]; B-EC, [AP: $-6.7$ , ML: 4, DV: $-8$ ].	NLR, OF, EZM	After DBS	CA1, EC, and fornix DBS could able to restore spatial memory-related functions and CA1 DBS increased neural activity in the anterior cingulate gyrus.
Lee et al. (2016)	25	25/0	6 w	An injection of 192 IgG-saporin to SD rats	SD ( $n = 6$ ), AD ( $n = 7$ ), AD-NS ( $n = 7$ ), AD-DBS ( $n = 5$ )	120 Hz, 90 $\mu$ s, 1 V, 1 h/d, 7 d	R-NBM, [AP: $-1.32$ , ML: $+2.8$ , DV: $-7.4$ ]	MWM	After DBS	NBM DBS improved spatial memory performance of SD rats injected 192 IgG-saporin in the MWM.
Xia et al. (2017)	98	49/49	6 w, 6 m	TgCRND8, WT (C57BL/6NTac)	WT-NS ( $n = 50$ ), AD-NS ( $n = 19$ ), AD-DBS ( $n = 29$ )	130 Hz, 90 $\mu$ s, 1 h, square wave	B-EC, [AP: $-4.0$ , ML: $\pm 3.25$ , DV: $-5.1$ ]	Contextual fear testing; Tone fear testing; MWM	1, 3, and 6 w for behavior experiments after DBS.	EC DBS rescued subsequent deficits in context fear memory, reversed spatial learning deficits in Tg mice, and reduced plaque load in young mice. But EC DBS did not produce a detectable decrease in plaque load in either the dorsal hippocampus or cortex in old mice.

**TABLE 3 |** Adverse events of the human clinical study of DBS in AD.

Study (first author, year)	Adverse events
Turnbull et al. (1985)	Did not cause epilepsy or any other untoward reactions in a personal case.
Laxton et al. (2010)	When the voltage intensity of DBS was between 6 and 8 V, AD patients would experience adverse reactions, such as warmth, flushing, sweating, increased heart rate and blood pressure. When the stimulation intensity was reduced by 50%, there was almost no adverse effect.
Smith et al. (2012)	Not involved.
Fontaine et al. (2013)	An AD patient had no complications after DBS 1 year and was fully tolerant to stimulation, except a discrete increase of irritability.
Kuhn et al. (2015a)	The DBS device was malfunctioning; an AD patient felt inner restlessness at a stimulation intensity >5 V. There were no other adverse events.
Kuhn et al. (2015b)	Both patients were well-tolerated by DBS. There were no adverse events.
Noreik et al. (2015)	Not involved.
Sankar et al. (2015)	Not involved.
Lozano et al. (2016)	Three patients had 4 adverse events, including 1 internal pulse generator infection, 1 DBS positioning error, and 2 postoperative nausea (1 patient). No neurosurgical and cognitive adverse reactions.
Hardenacke et al. (2016)	Not involved.
McMullen et al. (2016)	At 3 months after surgery, the case patient was anxious and complained that “left side of brain is asleep,” and cystic encephalomalacia appeared in the frontal lobe; at 1 year after surgery, minimal encephalomalacia appeared on the bilateral lead.
Baldermann et al. (2018)	Not involved.
Scharre et al. (2018)	Short-term side effects were resolved without sequela, including hot flashes, increased heart rate/palpitations, flushing, paresthesias, muscle twitching, non-specific discomfort, fatigue, and neuropsychiatric symptoms, mild pain at implantable pulse generator site, headache at incision site, transient visual neglect following surgery, diarrhea, vomiting, rash, rhinitis, arthralgia, fall, hematoma, and depression.
Leoutsakos et al. (2018)	Twenty-four patients experienced non-serious adverse events, common ones including neurological (including falls, headache, and muscle spasms), genitourinary (including urinary tract infections, urgency, and incontinence), and pulmonary (including upper respiratory infections and dyspnea). Seven patients had syncope and/or falls; two patients had altered mental status; two patients were involved in seizures or possible seizure; one patient was involved in agitation in a delayed; three patients were involved in a skin infection, suspected aortic valve endocarditis, and rigidity.
Mao et al. (2018)	No serious neurological adverse events occurred.
Durschmid et al. (2020)	Not involved.

AD, Alzheimer’s Disease; DBS, deep brain stimulation.

and Drevets, 2010); ILN and MTN are important components forming cortico-thalamo-cortical pathways (Saalman, 2014); NBM participates in the base forebrain cholinergic circuit; and the fornix, MT, ANT, EC, and CA1 (hippocampus) are nodes in the Papez circuit (Yu et al., 2019). **Figure 2** shows a schematic representation of these targets in the brain. AD is also considered to be a disease of the neural circuit, as neurons and neural circuits associated with cognitive function are damaged, and the Papez circuit is degraded (Lv et al., 2018). The Papez circuit is the main pathway of the limbic system and plays a vital role in the formation and storage of memory. Understanding the effects of these stimulation targets can help to select the best DBS stimulation target for AD.

**VC/VS**

DBS regulates the frontal lobe network of the brain that is involved in cognition and behavior. The ventral striatum, nucleus accumbens, and anterior limb of the internal capsule sit at the base of the frontal lobes. White matter fibers of the frontal lobe and the ventral capsule connect the dorsomedial and orbital prefrontal cortices to the ventral striatum (Price and Drevets,

2010). These neural networks have shown degeneration in AD (Lehericy et al., 1989). VC/VS DBS can affect related behavioral disorders in patients with mental disorders such as obsessive-compulsive disorder and depression (Greenberg et al., 2010; Dougherty et al., 2015). In a non-random phase I experiment, Scharre et al. first used the VC/VS of the frontal lobe network as the stimulation target for DBS in AD patients (Scharre et al., 2018). Fluorodeoxyglucose-positron emission tomography metabolism increased, and clinical dementia rating–sum of boxes (CDR-SB) performance decreased in AD patients receiving DBS. By targeting the VC/VS, DBS may adjust the frontal lobe network and affect the executive function of AD patients. This is the first report to show improved behavioral and executive defects without tracking memory targets in the treatment of AD by DBS. It provides new target options for DBS treatment in AD. This study also shows that chronic DBS with the VC/VS as a target is well-tolerated.

**ILN**

The rostral part of the ILN is connected to the medial prefrontal cortex (mPFC) and is considered to be a key component of cognitive function (Mair and Hembrook, 2008; Saalman, 2014).

**FIGURE 2 |** The schematic diagram of the stimulation targets for DBS in AD.

Although the function of the ILN in cognitive function has been proven, the effect of ILN DBS on AD-related cognitive dysfunction has not been extensively studied. Only one related study has shown that unilateral ILN DBS treatment can improve spatial learning and memory deficits in AD rat models injected with  $\beta$ -amyloid ( $A\beta$ ), reduce the expression of postsynaptic density protein 95 (PSD-95) in the mPFC and hippocampus, and maintain dendritic spine density (Tsai et al., 2020).

### MTN

The MTN connects to the medial prefrontal cortex, medial temporal lobe and hippocampus. The midline structure of thalamus is involved in memory related functions (Saalmann, 2014). An study of high-frequency MTN DBS showed that the time that TgCRND8 mice explored new objects in the object recognition task was significantly longer than that of wild type mice, and the expression of FosB protein in the hippocampus was significantly upregulated (Arrieta-Cruz et al., 2010). There is currently no other research on MTN DBS in AD.

### NBM

Acetylcholine (ACh) is essential for cognitive function and memory processing, and it is mainly derived from cholinergic neurons in the NBM (Carlsen et al., 1985). This region is mainly located below the anterior commissure and globus pallidus and on the anterior lateral part of the hypothalamus (Hedreen et al., 1984). The NBM sends a wide range of cholinergic nerve projections that dominate the cortex and hippocampus, and it represents an important cholinergic pathway in functional

networks that subserve cognition and memory (Gratwicke et al., 2013). NBM damage can lead to a decrease in cholinergic transmission and degenerative changes in mossy fibers and the dentate gyrus of the hippocampus (Bartus et al., 1982; Amenta et al., 1991). The first evidence neural network dysfunction in AD is the loss of NBM cholinergic neurons in the brain, which is evident on postmortem examination (Whitehouse et al., 1981). Turnbull et al. reported for the first time the impact of NBM DBS on AD patients, although the report found no evidence of clinical improvement (Turnbull et al., 1985). Since then, chronic NBM DBS has shown good efficacy in AD. NBM DBS performed in early AD may have beneficial effects on AD progression and cognitive function (Kuhn et al., 2015b; Hardenacke et al., 2016). AD patients receiving NBM DBS showed a substantially stabilized nutritional status within 1 year (Noreik et al., 2015). NBM DBS can also improve the spatial learning and memory of AD model mice; regulate the gamma-aminobutyric acid (GABA), glutamate system, and cholinergic systems; reduce the abundance of amyloid protein; and exert neuroprotective effects (Lee et al., 2016; Huang et al., 2019; Koulousakis et al., 2020).

### Fornix

As part of the Papez circuit, the fornix is the main inflow and outflow pathway of the hippocampus and middle temporal lobe. The fornix is an arcuate fiber bundle from the hippocampus to the mammillary body. This tract provides a direct source of input from the hippocampal structure to the anterior nucleus of the thalamus and can effectively encode and integrate memory information (Browning et al., 2010; Lovblad et al., 2014). When

the fornix of humans and animals is damaged, it can cause severe memory impairment (Tsivilis et al., 2008; Browning et al., 2010). Atrophy of the fornix can be accompanied by a transition from mild cognitive impairment to AD (Copenhaver et al., 2006). Hamani et al. reported for the first time that fornix stimulation can improve memory, although only one patient in their study received DBS to treat obesity (Hamani et al., 2008). Since then, DBS in the fornix has gradually been applied to AD. Chronic fornix DBS can stabilize or slow memory decline and increase hippocampal volume and cerebral metabolism in some patients with AD (Laxton et al., 2010; Smith et al., 2012; Fontaine et al., 2013; Sankar et al., 2015; Lozano et al., 2016) and improve spatial learning memory and recognition memory and reduce amyloidosis, the inflammatory response, the loss of neurons and the local changes in brain volume in AD model mice (Hescham et al., 2013b; Zhang et al., 2015; Gallino et al., 2019; Leplus et al., 2019). Therefore, the fornix is a good target choice for the treatment of DBS in human clinical research and animal research on AD (Senova et al., 2020).

## MT

In the Papez circuit, information related to memory is transmitted to the mammillary body through the fornix, and then to the ANT through the MT. Although the MT participates in the Papez circuit, MT DBS did not cause memory changes in patients with refractory epilepsy (Duprez et al., 2005). No beneficial memory effect of MT DBS was found in SD rats injected scopolamine (Hescham et al., 2015). Therefore, it is worth exploring whether DBS in the MT has a positive effect.

## ANT

The ANT is part of the Papez circuit, receiving information from the mammillary body via the MT and projecting it to the cingulate gyrus. The functional interaction between the ANT and hippocampus is crucial for spatial memory and conditional learning (Dumont et al., 2010). In AD model rats, ANT DBS improves impaired spatial memory (Chen et al., 2014). This is consistent with the research by Zhang et al., even though ANT DBS did not improve the recognition memory of AD model rats (Zhang et al., 2015). ANT DBS appears to be a potential treatment for AD cognitive dysfunction. However, Hescham et al. did not seem to find any beneficial memory effects of ANT DBS in SD rats injected scopolamine (Hescham et al., 2015). In addition, at high current densities, ANT DBS disrupts the acquisition of contextual fear conditions in healthy rats and impairs the performance of rats in spatially alternating tasks. In this case, ANT DBS caused a functional depolarization block near the stimulation electrode, which greatly reduced the spontaneous discharge of the local neuron population. Extracellular recordings showed that under high current ANT DBS, the discharge rate of DG cells was reduced and hippocampal activity was suppressed (Hamani et al., 2010). The differences in the results of various animal studies may have multiple causes, and further research is needed to explore the impact of ANT DBS in AD.

## EC

The EC is located in the anterior part of the parahippocampal gyrus and is a key area for information transmission to and from the hippocampus, forming a three-synapse circuit with the hippocampus. At the same time, EC is the first area affected in AD and is closely related to memory formation (Braak and Braak, 1991; Khan et al., 2014). EC DBS can enhance the spatial memory of wild-type mice, and promote the rapid proliferation of neurons in the dentate gyrus (DG) (Stone et al., 2011). Acute EC DBS can improve memory deficits induced by scopolamine, and increase the expression of c-Fos in the CA3 region (Hescham et al., 2015). Research by Zhang et al. showed that chronic EC DBS contributes to spatial memory and recognition memory deficits induced by A $\beta$ <sub>40</sub> (Zhang et al., 2015), which is consistent with research on AD transgenic mice (Xia et al., 2017; Mann et al., 2018). In addition, chronic EC DBS can significantly reduce A $\beta$  and tau in the hippocampus of AD transgenic mouse models, as well as reduce total tau and phosphorylated tau in the cortical region (Mann et al., 2018). In another study, it was been demonstrated that EC DBS can increase synaptic activity by increasing synaptophysin levels, and promote low sedimentation clearance of tau through the lysosomal pathway, thereby exerting a beneficial effect on AD (Akwa et al., 2018).

## CA1

The hippocampus is a brain area that is closely related to learning and memory functions, and is almost the central structure of memory-related circuits in the brain. The first region of the hippocampal circuit is the CA1, which mainly projects to the EC and subiculum and is very important for spatial memory (Igarashi et al., 2014). Acute CA1 DBS can improve memory deficits induced by scopolamine, and the beneficial effect of CA1 DBS is accompanied by increased expression of Fos in the cingulate gyrus (Hescham et al., 2015). No other studies related to DBS in AD have targeted the CA1 area to date.

Overall, the fornix, NBM, and EC are the preferred targets for DBS treatment in AD, even if there are other alternative targets. Currently, there are only two comparative studies of different stimulation targets for DBS in AD. Hescham et al. compared the effects of DBS in the ANT, CA1, MT, and EC in AD rat models induced by scopolamine (Hescham et al., 2015). CA1 DBS and EC DBS could improve memory deficits caused by scopolamine, and no beneficial memory effect was observed in the ANT or MT. A study had even shown that DBS in the hippocampus and entorhinal regions can impair memory (Jacobs et al., 2016). Zhang et al. investigated the effects of DBS in the ANT, EC, and fornix on the cognitive behavior of AD rat models (Zhang et al., 2015). DBS of these three targets can benefit the spatial memory of AD model rats. EC DBS and fornix DBS also improved the recognition and memory of AD model rats, but this effect was not observed in ANT DBS. In the Papez circuit, the EC and the fornix are directly connected to the hippocampus, while the ANT is connected to the fornix and the nipple body and indirectly connected to the hippocampus. This difference in neural connectivity may explain why the EC and fornix show more significant spatial and recognition memory improvements

than the ANT. The comparison of different targets of DBS in AD still needs more research.

## Stimulation Frequency

To date, the application of DBS in AD has been carried out under fixed stimulation parameters with a single frequency setting of 20, 100, or 130 Hz. The selection of frequency parameters in AD is based on the application of DBS in other diseases. The stimulation frequency of DBS, it can be divided into high frequency electrical stimulation (HFS, 25~1,000 Hz) and low frequency electrical stimulation (LFS, 0.1~25 Hz) (Schiller and Bankirer, 2007). HFS is commonly used in the treatment of mental illness. For patients with Parkinson's disease, high-frequency stimulation is beneficial for dyskinesias, and low-frequency stimulation may improve some axial movement symptoms (Baizabal-Carvallo and Alonso-Juarez, 2016). However, stimulation at a frequency that is too high can cause functional lesions (Jakobs et al., 2019). Therefore, it is critical to optimize the stimulation frequency of DBS to minimize the side effects of electrical stimulation caused by the stimulation frequency. Huang et al. implemented four DBS frequencies of 10, 50, 100, and 130 Hz in the NBM of A $\beta$  precursor protein/Presenilin1 (APP/PS1) mice and tested their spatial memory using the Morris water maze (MWM) (Huang et al., 2019). It was found that 10 Hz DBS had no effect. The latency during the learning period was significantly reduced by DBS at frequencies at 50, 100, and 130 Hz, and the number of passes and occupation time of the target quadrant and platform area in the exploration task increased significantly. Higher frequency (100 Hz, 130 Hz) stimulation was better than lower frequency (10 Hz, 50 Hz) stimulation, and a shorter latency, a larger number of times and a longer occupation time were observed at 100 Hz. Therefore, the optimal DBS frequency remains unclear. Some studies have shown that the efficacy of DBS in AD is not affected by frequency, as 10 Hz and 100 Hz show the same effect (Hescham et al., 2013b).

## Stimulation Start Time

The stimulation start time of DBS in AD is also closely related to the effect of treatment. The time from pathological appearance to clinical symptoms of AD may be as long as 20 years or more (Bateman et al., 2012; Villemagne et al., 2013; Selkoe and Hardy, 2016). It is one of the new interests in the treatment of AD to take measures to intervene the development of AD before clinical symptoms appear, and to delay or even prevent brain lesions (Alzheimer's Association, 2018; Fan and Wang, 2020). Several studies have shown that DBS intervention in the early stages of AD produces better results. Huang et al. administered NBM DBS to APP/PS1 mice at 4, 6, 9, and 12 months of age and performed MWM tests at the end of 13 months of age (Huang et al., 2019). APP/PS1 mice at 4–6 months of age are in the early stages of AD. The results showed that the escape latency of AD mice receiving DBS at 4 and 6 months of age was significantly reduced, and the occupation time of the target quadrant and the number of passes through the platform area increased significantly. DBS at 4 months of age produced the best results. However, DBS had little effect at 9 and 12 months of age. EC DBS was performed in

TgCRND8 mice at 6 weeks and 6 months of age, but a reduction in amyloid plaque was found only in mice at 6 weeks. In clinical studies, Hardenacke et al. evaluated the effects of DBS on 8 AD patients and proposed that NBM DBS in the early stage of the disease or at a younger age may have a beneficial effect on disease progression (Hardenacke et al., 2016). NBM DBS can increase blood flow by more than 50% in the cerebral cortex and nerve growth factor (NGF) expression in the parietal cortex by ~68% in healthy rats at 4–6 months of age, but in aged rats at 29–31 months of age, blood flow increased by only ~25%, with no significant change in NGF in the parietal cortex (Hotta et al., 2009). This again proves that providing DBS at a younger age has a more favorable impact. Unfortunately, in a phase II clinical study, it was suggested that fornix DBS may benefit patients with AD who are  $\geq 65$  years of age, and that patients under 65 years of age may show worsening condition (Lozano et al., 2016). This has an effect that is opposite to the impact of NBM DBS in interventions for young AD patients (Hardenacke et al., 2016). The reason for this difference may be that young patients are not in the early stages of AD, or fornix DBS alone may not be suitable for the early treatment of AD, or among other possible reasons.

## Stimulation Duration

After DBS, AD patients' disease progression slowed significantly. This may be related to the stimulation duration of DBS, and the persistence of the effect is unclear. Animal research has shown that both acute and chronic DBS can cause long-term remodeling of the mouse brain. One hour of fornix DBS improved spatial memory deficits and caused local volume differences in various regions of the brain in AD mice. These changes can last at least 45 days, suggesting that the role of DBS in AD is more than immediate (Gallino et al., 2019). The improvement of spatial memory and recognition memory caused by DBS for 24 h in the AD rat model induced by A $\beta_{42}$  can last for at least 4 weeks (Zhang et al., 2015). Chronic DBS (7 h/d) was performed on Toronto triple-transgenic (3 $\times$ Tg) AD model mice for 25 d, and the beneficial effects of DBS on recognition and memory in AD mice lasted at least 1 month. The after effects of DBS suggest that chronic DBS can also cause long-term changes in brain function (Mann et al., 2018). Huang et al. performed four durations of DBS (7, 14, 21, and 28 days for 1 h/days) in APP/PS1 mice at 4 months of age and performed the MWM and A $\beta$  detection 30 d after the end of DBS (Huang et al., 2019). However, 7 d of DBS had almost no impact. DBS for 14, 21, and 28 days all improved the spatial memory of APP/PS1 mice and significantly reduced the soluble A $\beta_{40}$  and A $\beta_{42}$  levels in the hippocampus and cortex. DBS achieved the best results after 21 consecutive days of stimulation. This shows that the therapeutic effect of DBS is not directly proportional to the duration of treatment.

## Unilateral/Bilateral Treatment

Of the human clinical studies and animal studies of DBS in AD, only 5 studies used unilateral DBS (Turnbull et al., 1985; Lee et al., 2016; Huang et al., 2019; Koulousakis et al., 2020; Tsai et al., 2020). Although researchers believe that bilateral DBS seems safe for AD, there have still been a small number of adverse events (Ponce et al., 2016; Leoutsakos et al., 2018). Preliminary

experiments by Huang et al. showed that bilateral DBS led to more severe complications and higher mortality (Huang et al., 2019). In fact, unilateral DBS can also improve the symptoms associated with AD and shows good neuroprotective effects and reversible side effects (Lee et al., 2016; Huang et al., 2019; Tsai et al., 2020). To improve the safety of DBS for AD, whether to switch to unilateral DBS in the future is worth exploring.

## Current Intensity

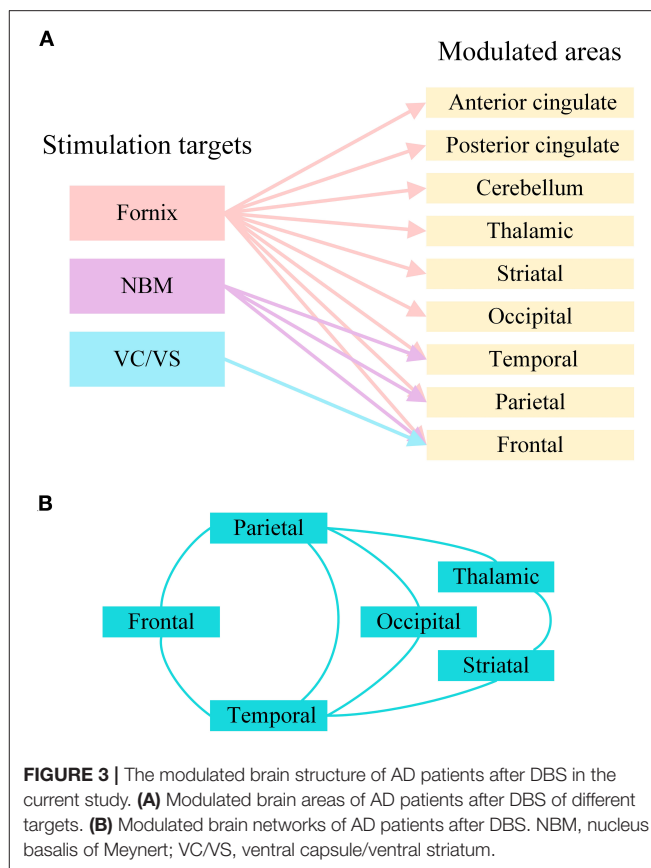

The efficacy of DBS in AD is affected by current density. Decreasing DBS current intensities of 200, 100, and 50  $\mu$ A were applied to rats receiving scopolamine to study the effects of higher, medium, and lower current densities. At low currents, there was no significant difference in the time ratio of discrimination between the displaced and familiar objects in rats receiving DBS compared with the control rats. However, the spatial memory of rats was substantially improved under DBS at 100 and 200  $\mu$ A. Therefore, it was found that a lower current intensity had no effect on DBS in AD (Hescham et al., 2013b). However, there is no other study on the effect of DBS stimulation current intensity on AD.

## POTENTIAL MECHANISMS OF ACTION

The mechanism of DBS in AD is unknown. This article will explore the potential mechanism of DBS in AD from several perspectives.

## Regulation Related Neural Networks

Due to related molecular and structural abnormalities, the memory network of patients with AD changes (Sperling et al., 2010). There is evidence that the Papez circuit and the default mode network of AD patients are impaired and that the inherent connectivity in the default network is disrupted during resting states and cognitive tasks (Raichle et al., 2001; Greicius et al., 2004; Sperling et al., 2009). DBS has been shown to play a role in the regulation of neural networks in diseases. In patients with epilepsy, fornix DBS shows an electrical effect in the upstream hippocampus (Lozano and Lipsman, 2013; Miller et al., 2015). Hamani et al. used fornix DBS in obese patients, and electroencephalogram (EEG) showed that electrical activity in the hippocampus and parahippocampus was activated during stimulation (Hamani et al., 2008). Based on this, the Hamani team further used fornix DBS in AD, and the results showed that the neural network of the default pattern network and memory circuits in AD patients' brains were activated, including the entorhinal and hippocampal regions, and the connectivity between neural networks in the brain was also increased (Laxton et al., 2010). Functional connectivity analyses revealed that cerebral glucose metabolism in AD patients increased in a frontal-temporal-parietal-striatal-thalamic network and a frontal-temporal-parietal-occipital network after fornix DBS (Smith et al., 2012). The beneficial effects of NBM DBS in AD patients are significantly correlated with the fronto-parieto-temporal pattern of cortical thickness (Baldermann et al., 2018). **Figure 3** shows the modulated brain structure of AD patients after DBS in the current study. Therefore, DBS may establish

upstream and downstream effects in related neural network circuits by targeting key nodes of the neural network in the AD brain, increasing connectivity between networks, and thereby improving AD symptoms.

## Promotion of Nerve Oscillation

Neuronal oscillations are essential for information processing and communication between different brain structures. DBS has the potential to reset the unstable mode of neuron oscillations in AD, especially  $\theta$  oscillations in the hippocampus (Hardenacke et al., 2013; Senova et al., 2018). With an approximately sinusoidal (4–10 Hz) EEG activity,  $\theta$  oscillations can be recorded in edge circuits, are related to various cognitive processes, and play an important role in learning and memory (Buzsaki, 2002; Laxton et al., 2010). Various drugs that destroy cognitive functions reduce or eliminate hippocampal  $\theta$  oscillations (McNaughton et al., 2007; Scott et al., 2012). The disruption of  $\theta$  activity leads to impaired spatial and recognition memory, and the restoration of  $\theta$  rhythm improves the learning ability of rats (Howlett et al., 2004; Hasselmo, 2006; Villette et al., 2010). Suthana et al. found that DBS caused the hippocampal  $\theta$  rhythm to reset, optimally encode input information, and improve memory function in animal models (Suthana et al., 2012). In addition, electrical stimulation of perforated pathways in rodents can trigger  $\theta$  phase reset, which creates favorable conditions for long-term memory enhancement (McCartney et al., 2004). Abnormalities

in  $\theta$  rhythm have been shown in AD patients and mouse models of AD (Klimesch, 1999; Scott et al., 2012). Based on these studies, we hypothesized that DBS may improve AD symptoms through neural oscillations that cause  $\theta$  reset.

## Reduction of A $\beta$ Levels

A $\beta$  oligomers are one of the main neuropathological signs of AD. A $\beta$  oligomers are highly neurotoxic, which may cause loss of synapses and neuronal damage (Hardy and Higgins, 1992; Perl, 2010), and affect circuit connectivity and network activities (Canter et al., 2016). Over the past decades, genetic, biochemical, and pathological evidence has revealed the importance of A $\beta$  as a neuropathological marker of AD (Sperling et al., 2011; Barage and Sonawane, 2015). Acute DBS significantly reduced A $\beta$  plaques in the hippocampus and cortex of 6-week-old TgCRND8 mice (Xia et al., 2017). Chronic DBS can also reduce A $\beta$  and APP levels in 3xTg mice. The main source of A $\beta$  production is the hydrolysis of APP. APP is hydrolyzed by  $\beta$ -secretase and  $\gamma$ -secretase to generate A $\beta$  amyloid production pathways and non-amyloid production pathways are cleaved by  $\alpha$ -secretase and  $\gamma$ -secretase (Barage and Sonawane, 2015; Chen et al., 2017; Kowalski and Mulak, 2019). Arrieta-Cruz et al. showed that high-frequency DBS can increase  $\alpha$ -secretase activity in the hippocampus of TgCRND8 AD mice by a factor of two, which significantly increases synaptic plasticity in the CA1 region but does not change  $\beta$ -secretase activity (Arrieta-Cruz et al., 2010). In addition, A $\beta$  can be cleared by internalization into glial cells (Kim et al., 2018), and DBS can regulate glial cell activity (Vedam-Mai et al., 2016; Xia et al., 2017). Therefore, DBS can reduce A $\beta$  levels and improve the pathological state of AD, possibly by reducing A $\beta$  production or increasing A $\beta$  clearance.

## Reduction of Tau Levels

Neurofibrillary tangles containing aggregates of hyperphosphorylated tau protein are also one of the neuropathological signs of AD. Tau with an abnormally high degree of phosphorylation forms toxic paired helical filaments, severely impairs synaptic function and causes cell death (Mohandas et al., 2009; Joel et al., 2015). Fornix DBS has no significant effect on hippocampal tau or phosphorylated tau in Wistar rats. However, EC DBS can reduce the total tau and Ser416-phosphorylated tau in the cortex and hippocampus of 3xTg AD mice and increase neurogenesis in the dentate gyrus (Mann et al., 2018). A study by Akwa et al. also showed that EC DBS can reduce tau phosphorylation and accumulation of tau oligomers in the CA1 region of 3xTg AD mice, and increase tau autophagy-lysosomal degradation and synaptic protein expression (Akwa et al., 2018). Therefore, DBS may affect the degradation or clearance of tau in AD to reduce tau levels. However, the specific details are not yet clear.

## Reduction of Neuroinflammation

It has been recognized that neuroinflammation plays an important role in the development and progression of AD (Von Bernhardi, 2007; Le Page et al., 2017). The development of AD is closely related to the complex cascade that leads to the death of neurons. Normally functioning glial cells can express

A $\beta$ -related degradation enzymes or bind related proteins to promote the degradation and clearance of A $\beta$  (Mulder et al., 2012; Yali et al., 2014; Kim et al., 2018). With the development of AD, glial cell malfunction can release excessive inflammatory factors and neurotoxic factors to produce neurotoxic effects, promote the cascade of A $\beta$  and inflammation, and aggravate neuronal death and the progression of AD (Bagyinszky et al., 2017). In AD, astrocytes and microglia, the two main groups of cells driving neuroinflammation, exhibit high levels of abnormal activation (Cohen et al., 2013; Lopategui Cabezas et al., 2014). Chronic fornix DBS can reduce the degree of astrocytic and microglial reactivity and the extent of neuron loss in the cortex and hippocampus (Leplus et al., 2019). DBS activates astrocytes and microglia in the early stage after implantation; the degree of glial reactivity later decreases (Song et al., 2013). Whether DBS promotes the degradation and clearance of A $\beta$  by activating additional protective glial cells, thereby reducing neurotoxicity and cascade reactions and ultimately downregulating glial cell levels and reducing neuroinflammation, is worth exploring.

## Regulation the Cholinergic System

Degeneration of the cholinergic circuit is a pathological manifestation of AD. AD patients and animal models have obvious cholinergic dysfunction involving abnormal ACh production and degradation, including choline acetyltransferase (ChAT) and acetylcholinesterase (AChE), respectively (Davies and Maloney, 1976; Perry et al., 1977; Schliebs and Arendt, 2011). Acetylcholinesterase inhibitors (donepezil, rivastigmine, galantamine) are approved by the U.S. Food and Drug Administration for the treatment of AD patients (Unzeta et al., 2016; Kaushik et al., 2018; Alzheimer's Association, 2020). High levels of ACh contribute to hippocampal  $\theta$  oscillation and enhance memory (Verdier and Dykes, 2001; Micheau and Marighetto, 2011). Supplementation of exogenous ChAT can improve memory and cognitive dysfunction in AD model mice (Fu et al., 2004; Zhu et al., 2020). Studies have shown that DBS improves scopolamine-induced learning and memory deficits in rats (Hescham et al., 2013b, 2015). Scopolamine is a muscarinic acetylcholine receptor antagonist. In APP/PS1 mice, DBS reduced the level of AChE in the hippocampus and cortex while increasing the level of ChAT, which implies an increase in ACh (Huang et al., 2019). In rats with amygdala injury, DBS treatment can effectively compensate for amygdala injury and reduce the activity of AChE (Kadar et al., 2014). Therefore, DBS can regulate the cholinergic system, which may be one of the mechanisms by which DBS improves AD. However, a large-scale study on long-term use of donepezil hydrochloride in patients with AD showed that the donepezil hydrochloride cannot help AD patients after the first 6 months. Acetylcholinesterase inhibitors are not long-term effective in the treatment of AD (Arai et al., 2016, 2018). This prompts us to consider whether DBS improves AD directly or indirectly by regulating the cholinergic system, whether this regulatory improvement is long-term effective, and how long this improvement will last. At present, there is no relevant research to solve these problems. There are still many questions to be explored about the regulation of DBS on the cholinergic system in AD.

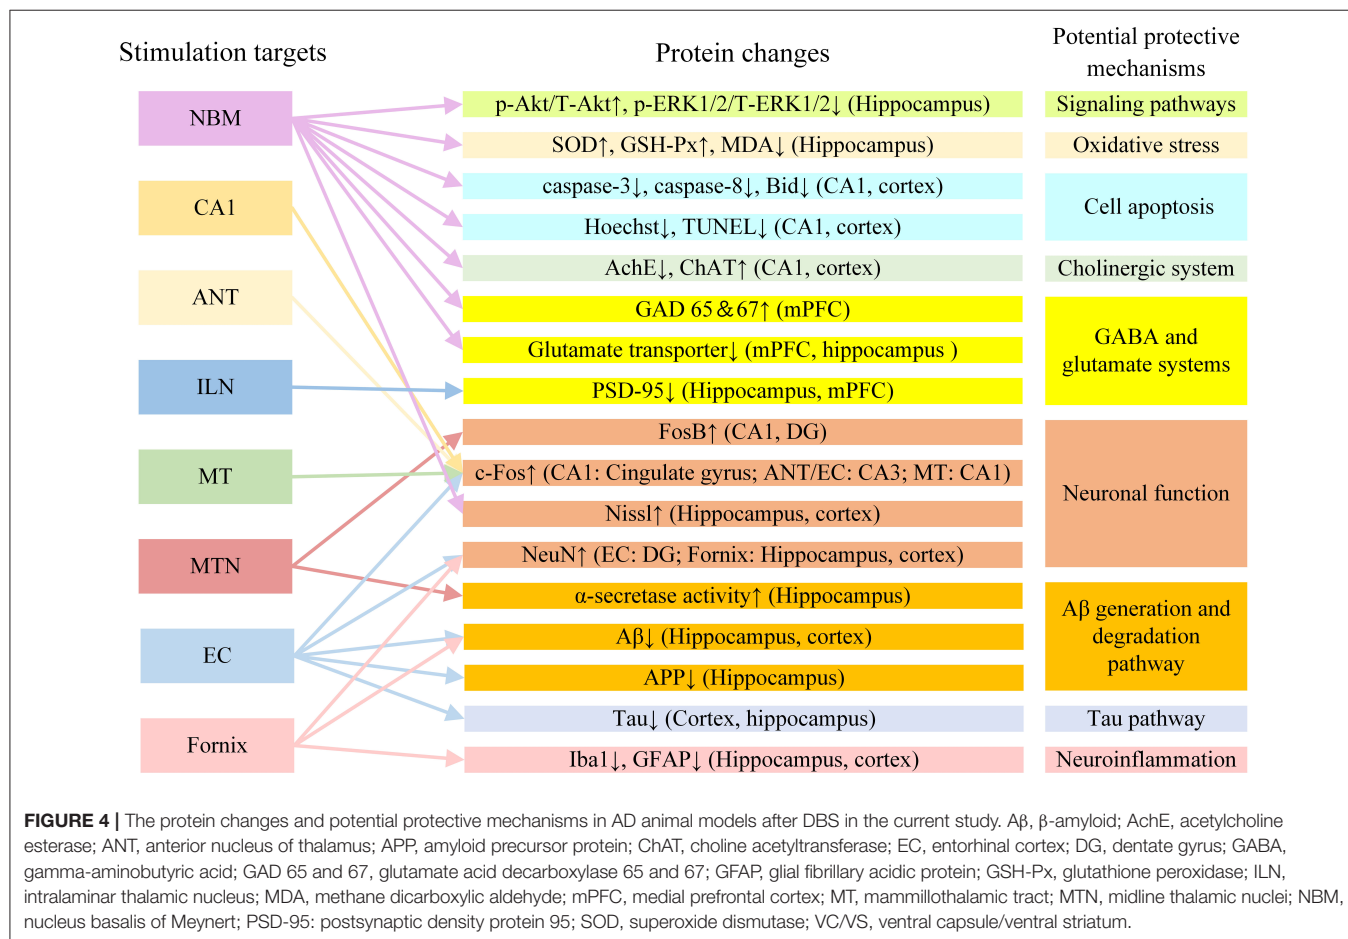

## Induction of NGF Synthesis

DBS may exert neuroprotective effects by inducing NGF synthesis in AD (Mashayekhi and Salehin, 2006; Hardenacke et al., 2013). NGF is the most typical neurotrophic peptide involved in regulating the survival and differentiation of neurons (Lindsay and Harmar, 1989; Sofroniew et al., 2001). NGF levels and metabolic pathways are clearly imbalanced in AD (Cuello et al., 2010). The decrease in NGF supply at the age-related basal forebrain cholinergic neuron cell level is similar to that observed in AD (Salehi et al., 2004). NGF gene therapy caused classic trophic responses in the brains of AD patients, including neuronal hypertrophy, axonal sprouting and activation of cell signaling (Tuszynski et al., 2015). The supply of NGF can provide long-term cholinergic nutritional support, thereby slowing or preventing cognitive decline in AD patients (Hardenacke et al., 2013). Studies have shown that unilateral NBM DBS can result in significantly higher NGF levels in healthy rats than observed before stimulation. Mecamylamine, the nicotinic blocker, can completely eliminate the secretion of NGF, which suggests that the projection of the basal forebrain may be the reason for the increase of NGF (Hotta et al., 2009). In AD disease, the ability of DBS to induce the release of NGF may be a pathway closely related to its mechanism, which also seems to be related to the cholinergic system of the basal forebrain.

## Other Potential Mechanisms

The mechanism of DBS in AD may also involve a variety of other factors. In addition to the mechanisms described above, DBS may also improve AD symptoms by regulating other neurotransmitter systems. GABA and glutamic acid are closely involved in memory function (Sivilotti and Nistri, 1991). In AD rat models, glutamate acid decarboxylase 65 and 67 and glutamate transporter levels changed after NBM DBS. This suggests that NBM DBS may regulate changes in the GABA and glutamate systems and improve memory in AD rat models (Lee et al., 2016). It is also possible that DBS can enhance synaptic plasticity, promote neuron formation, and improve memory by regulating brain-derived nerve factors, including brain-derived neurotrophic factor and vascular endothelial growth factor (Gondard et al., 2015). It has been reported that DBS can increase hippocampal neurogenesis in AD (Mann et al., 2018; McKinnon et al., 2019). The newly born neurons have normal morphology and function and can promote the normalization of functional circuits (Lledo et al., 2006). DBS may improve AD symptoms by promoting neuron regeneration. **Figure 4** shows the protein changes and potential protective mechanisms in AD animal models after DBS of different targets in the current study. The impact of DBS on AD animal models involves multiple potential protective mechanisms including signaling pathways,

oxidative stress, cell apoptosis, the GABA and glutamate systems and neuronal function. More research is still needed to explore these possibilities.

## DISCUSSION

This article reviews the published literature on DBS in AD. In patients and animal models with AD, DBS has shown some efficacy.

To provide the best parameter as a reference for the application of DBS in AD, this review summarizes and analyzes the different treatment parameters from current human clinical studies and animal studies of DBS in AD. Concerning stimulation targets, the NBM, fornix, and EC are the preferred targets for DBS treatment. This may be related to their structures and roles in the brain. They are involved in different circuit systems, including the base forebrain cholinergic system, the Papez circuit, and the trisynaptic circuit (Lv et al., 2018; Yu et al., 2019). There is currently no human clinical study of the EC as a target of stimulation in AD, and only animal studies support the EC as a target of DBS. The first area where neuropathy occurs in the AD brain is the EC, which then spreads to other cortexes and the hippocampus (Braak and Braak, 1991). The EC plays a very important role in information transmission. Whether EC DBS has a better effect than NBM and fornix DBS in AD is worthy of further investigation in animals and humans. In addition, EC DBS has been reported to improve spatial memory in patients with epilepsy by resetting the  $\theta$  rhythm on EEG (Suthana et al., 2012).

Other DBS parameters that are commonly used in AD patient studies include stimulation frequency (130/20 Hz), stimulation duration (long-term), bilateral stimulation, pulse width (90–150  $\mu$ s), and stimulation voltage (3.0–3.5 V) (Table 1); in AD animals the investigated parameters are stimulation frequency (130/100 Hz), stimulation duration (30 min–1 h, 3–42 days), bilateral stimulation, pulse width (60–100  $\mu$ s), and stimulation current (100  $\mu$ A) (Table 2). Based on the characteristics of human and animal tissues, although these DBS parameters used in AD animals cannot be directly applied for DBS in AD patients, they can provide more supporting evidence for the study of DBS in AD patients. Unilateral DBS should be popular in the treatment of DBS. After all, unilateral DBS is very likely to cause less surgical injury. Based on the long early incubation period of AD and the irreversible characteristics of neurodegenerative diseases (Selkoe and Hardy, 2016), using DBS to intervene in the early stages of AD to delay the AD process seems to be an excellent approach to treat AD (Huang et al., 2019). A number of studies have shown that NBM DBS and EC DBS have more beneficial effects in early AD (Hardenacke et al., 2016; Xia et al., 2017; Huang et al., 2019). However, in one clinical study, fornix DBS may have caused worse outcomes for AD patients at a younger age (Lozano et al., 2016). This may be related to multiple differences among different studies. In general, the preferred of DBS parameters for AD tend to be unilateral, early stage, and chronic treatment, with the NBS/fornix/EC as targets, and the pulse width, stimulation frequency, and stimulation voltage/current intensity can be individually designed in the future.

The improvement in AD caused by DBS is a multifactorial phenomenon, involving neural networks,  $\theta$  oscillations, and changes in the microenvironment in the body (Laxton et al., 2010; Smith et al., 2012; Baldermann et al., 2018; Huang et al., 2019; Leplus et al., 2019). DBS is a neural regulation technology that directly changes brain activity in a controlled manner and corrects abnormal electrical circuits in the brain (Yu et al., 2019). In AD, during stimulation, DBS may have upstream and downstream effects on related neural network circuits by stimulating targets, activating or promoting electrical activity in the brain, and resetting  $\theta$  oscillation. However, it is unclear what different upstream and downstream effects DBS has on different targets in AD. Most animal research focuses on the behavioral and biological effects in AD animals after DBS. The biological effects of DBS on AD animal models involve multiple potential protective mechanisms (Figure 4), and there may be interconnections among these fields. For example, DBS may regulate the microenvironment of AD animal models by promoting ACh release, inducing NGF synthesis, and reducing A $\beta$  and tau levels (Hescham et al., 2013a; Xia et al., 2017; Huang et al., 2019). At present, these changes are only superficial phenomena, and the mechanism underlying them has not been explored. In the future, experimental methods such as electrophysiological recording, *in vivo* and *in vitro* optogenetics, and patch clamp technology may be used to further study the mechanism of DBS in AD.

DBS has broad application prospects for the treatment of AD. However, research in this area is still in its infancy. The stimulation parameters and mechanism of DBS in AD need to be further explored. There are still limitations to applying DBS in AD. To date, most of the published studies have been performed with small sample sizes, especially human clinical studies. Some patients with AD in human clinical studies also used acetylcholinesterase medication when receiving DBS (Table 1), which may have confounding effects on the results. Compared with other electrical stimulation techniques, DBS is an invasive technique with multiple risks, including the risks of major surgery, such as bleeding, infection and other side effects (Doshi, 2011; Ponce et al., 2016; Barrett, 2017). Creating a personalized DBS treatment plan for each AD patient is a way to reduce the risk of DBS. In addition, sex is considered to be a factor related to the sex risk for AD. AD has a higher prevalence in women (Mielke et al., 2014). Most experiments in animal research are dominated by male animals. Fornix DBS can significantly improve the performance of male mice in the water maze without affecting the performance of females (Gallino et al., 2019). Human clinical studies have not considered the sex of patients with AD. Therefore, whether DBS can eventually become an effective approach for AD is still not clear. More animal studies and human clinical studies on the application of DBS in AD are needed.

## CONCLUSION

Most current research shows that DBS is a promising intervention for the treatment of AD. However, future studies of DBS therapy for AD should consider additional aspects, including individual differences, based on the diversity of DBS

parameters. The stimulation parameters need to be standardized, and the after effect and mechanism of action need to be further explored.

## AUTHOR CONTRIBUTIONS

YL and XWu were involved in study design. YL, YS, XT, and XWu contributed in literature search and review. YL and YS drafted the manuscript. XT and XZ helped with discussion

and analysis. YL, YS, and WL prepared pictures and tables. YL, XWu, BS, and WH reviewed the final version making the necessary changes. All authors read and approved the final manuscript.

A correlation between the abnormal cerebral glucose metabolism and the progression of Alzheimer's disease (AD) has been found in previous studies, suggesting that glucose alterations may be used to predict the histopathological diagnosis in AD. In this study, we investigated the dynamic changes of cerebral glucose uptake *in vivo* using MR glucose chemical exchange saturation transfer (glucoCEST) imaging in a rat model of AD with an intracerebroventricular (i.c.v) injection of amyloid A $\beta$ -protein (25–35), confirmed by Morris water maze and Nissl staining. In total, 6 rats in the AD group and 6 rats in the control group that were given an injection of sterile normal saline were included. At 28 days after injection, all rats performed a 7.0 T MR examination, including glucoCEST, diffusion tensor imaging (DTI) and hippocampus magnetic resonance spectra (MRS), to detect the possible metabolic and structural changes in the rat brain. A significantly elevated brain glucoCEST signal in the brain of AD rats was observed, and a decreased brain glucose uptake was also explored during the progression of glucose infusion compared with those in rats of the control group. In addition, there is a significant positive correlation between glucoCEST enhancement (GCE) and myo-Inositol (Ins) in the AD group and the control group ( $P < 0.05$ ). A significantly reduced number of neurons in the cortex and hippocampus in AD rats combined with the significantly longer escape and a decreased number of crossings were verified at 28 days after A $\beta$ 25–35 injection by Nissl staining and Morris water maze, respectively. Our results indicated that an abnormal brain glucose mechanism in AD rats could be detected by glucoCEST imaging, suggesting a new method to explore the occurrence and progress of diabetes-related AD or dementia.

**Keywords:** Alzheimer's disease, glucoCEST, glucose metabolism, D-glucose, magnetic resonance imaging

**Abbreviations:** CEST, Chemical Exchange Saturation Transfer; glucoCEST, glucose CEST; GCE, glucoCEST enhancement; MWM, Morris water maze; MTR, magnetization transfer ratio; DTI, Diffusion Tensor Imaging; MRS, magnetic resonance spectra; NAA, N-acetyl aspartate; Glu, glutamate; Cr, creatine; Cho, choline; mI, myo-Inositol.

## INTRODUCTION

Alzheimer's disease (AD) is a chronic progressive neurodegenerative disease characterized by the accumulation of amyloid- $\beta$  protein and a Tau-mediated neuronal injury (de Paula et al., 2009; de-Paula et al., 2012). AD affects around 50 million persons worldwide, and the number will likely increase with longer life expectancy (Abbott, 2011). Clinically, patients with AD are presented with a combination of features, such as progressive cognitive decline, dementia, and personality changes (Jack et al., 2013). The deposition of amyloid- $\beta$  peptides has been observed in AD animal models as well as post-mortem AD patients, suggesting amyloid- $\beta$  as having a key role in AD pathogenesis (Seynnaeve et al., 2018). Nevertheless, accumulated evidence shows that the pathogenesis of AD is also contributed to by multiple key players (de-Paula et al., 2012).

Glucose is a primary source of energy for almost all living organisms. Impaired glucose metabolism is associated with a wide range of pathological conditions (Mergenthaler et al., 2013) and is considered an important risk factor for AD (Duran-Aniotz and Hetz, 2016). The reduction of glucose uptake in posterior cingulate and temporal-parietal regions is the most commonly described diagnostic criterion for AD (Wang et al., 2016) with 18F-fluorodeoxyglucose (FDG) positron emission tomography (PET), and it was considered to be associated with the cognitive decline in healthy control (Gardener et al., 2016). Moreover, type 2 diabetes was shown with an increased risk of cognitive decline and developing AD (Mergenthaler et al., 2013). Therefore, the interplay between glucose metabolism and AD should be better understood, especially during the early stages of AD.

Over the last three decades, 18-FDG PET has provided important information for the diagnosis and differential diagnosis of AD in animal models and patients. Le Douce et al. (2020) found that there was a decreased glucose uptake in the amygdala, entorhinal cortex and hippocampus in 3xTg-AD transgenic mice in the early phase with 18F-FDG PET. In patients with AD, reduced glucose metabolism was also observed by 18F-FDG-PET in the temporal and superior temporal/posterior temporal regions, posterior cingulate cortex and the anterior wedge (Herholz, 2010; Kantarci et al., 2010). However, contradictory results were also found in APP/PS1 transgenic mice, indicating an increased glucose utilization in multiple brain regions at 2 and 3.5 months of age (Li et al., 2016).

Chemical exchange saturation transfer (CEST) imaging is a relatively new MR contrast technique and has been used to map exchanged protons or molecules in glucose, amide proton, glutamate or creatine *in vivo*. Based on a frequency-specific saturation pulse, the magnetization transfer effect occurred among bulk water and labile solute protons in the above metabolites and further lead to a decreased signal intensity of free water. By detecting the changes of the free water signal, the effect of glucose chemical exchange saturation transfer (glucoCEST) can be observed, which is related to the concentration of glucose and exchange environments, such as pH and temperature. GlucoCEST is considered a non-invasive alternative for the *in vivo* imaging of glucose uptake following an external administration of glucose (McMahon, 2017). Moreover,

glucoCEST enhancement (GCE) imaging was achieved by subtracting the difference glucoCEST images before and after glucose administration, which is similar to dynamic contrast-enhanced (DCE) MR perfusion by the injection of gadolinium-based contrast agent. Using glucoCEST, glucose uptake in healthy mice brains (Nasrallah et al., 2013), colorectal tumor models (Walker-Samuel et al., 2013) and healthy mice livers (Miller et al., 2015) was successfully detected. In this study, we aim to explore the dynamic changes of cerebral glucose uptake in AD model rats using both glucoCEST and GCE. The possible pathological and behavioral changes in the rat brain of the AD group were detected by Nissl staining and a morris water maze to confirm the AD model. Furthermore, the correlation between glucose metabolism, diffusion characteristics and several hippocampus metabolites was investigated for the interpretation of abnormal glucose metabolism.

## MATERIALS AND METHODS

### Animals

A total of 12 male Sprague-Dawley (SD) rats (between 16 and 18 weeks of age and weighing 250–320 g) were purchased from the Animal Center Laboratory of our Medical College. The rats were randomly divided into the control group ( $n = 6$ ) and the AD group ( $n = 6$ ). All rats were housed in plastic cages at 12 h light/dark cycle with free access to food and water. All experiments were approved by our ethics committee of Animal Care and Welfare.

### AD Rat Modeling

Amyloid  $\beta$ -Protein Fragment 25–35 (A $\beta$ 25–35; Sigma-Aldrich) was dissolved in sterile saline at a concentration of 1 mg/ml and stored at  $-20^{\circ}\text{C}$  till to be used. Before injection, A $\beta$ 25–35 was aggregated in an electronic thermostat at  $37^{\circ}\text{C}$  for 4 days (D'Agostino et al., 2012; Kim et al., 2015).

With reference to the method described by previous studies (Ohta et al., 2012; Kim et al., 2015), the AD rat model was established. Briefly, rats were anesthetized with an intraperitoneal injection of pentobarbital sodium (40 mg/kg) and placed in a stereotaxic device. Following midline incision, a dental drill was used to perforate skull over the right lateral ventricle at the coordinates (0.8 mm posterior to the bregma and 1.5 mm lateral to the midline). Rats in the AD group were transfused with 9  $\mu\text{l}$  of aggregated A $\beta$  25–35 into the right lateral ventricle using a microsyringe at a rate of 1  $\mu\text{l}/\text{min}$ , and the needle was then left in place for an additional 5 min to allow adequate diffusion. Meanwhile, the rats in the control group were injected with sterile normal saline.

### Estimation of Blood Glucose Concentration

On the 14th day after the intracerebroventricular injection of A $\beta$ 25–35, three rats in the AD and control groups were randomly selected to acquire the time-blood glucose concentration curves by continuous injection of D-glucose infusion according to

the method described previously (Chan et al., 2012). The rats were anesthetized by 1.5% isoflurane in oxygen gas during the whole experimental procedure. D-glucose (1.5 mM) was dissolved in normal saline and was continuously injected using a microsyringe pump (JMS, Japan, model SP-500) at a rate of 2.0 ml/h. The blood glucose concentration was examined in a sample obtained from the tail vein at the following time points: before injection, 10, 20, 30, 40, and 50 minutes after injection and 10 and 20 minutes after the finish of glucose infusion.

## Optimization Scan Parameters of GlucoCEST Imaging in Phantom

Firstly, seven centrifugal tubes containing the following different metabolites were scanned to acquire an optimized saturation power referenced with the method detailed previously (Haris et al., 2013). The metabolites in each tube included creatine (Cr, 10 mM), glutamate (glu, 10 mM), gamma-aminobutyric acid (GABA, 10 mM), choline (cho, 10 mM), high D-glucose concentration (200 mM), low D-glucose concentration (10 mM) as well as D-glucose and Cr mixture (5 mM each), respectively. Next, another six tubes containing D-glucose with different concentrations (6.25, 12.5, 25, 50, 75, and 100 mM) in pH of 7.4 were scanned to observe the CEST exchange signal affected by the concentration (Nasrallah et al., 2013). Finally, three tubes containing D-glucose (25 mM) with different pH (6.4, 7.4, and 8.4) were examined to observe the impact of pH on the glucose CEST exchange. All phantoms (Haris et al., 2012) were prepared in phosphate buffer solution (PBS) supplemented with 1% agarose solution.

Several important scan parameters of glucoCEST imaging, such as saturation power, saturation during and repetition time (TR), were optimized in phantom model with varying values: saturation power (1.5, 3.0, and 6.0  $\mu$ T) in the tubes with different metabolites; saturation power (1.5, 2.0, 2.5, 3.0, 3.5, and 4.0  $\mu$ T) in the phantoms with different concentration D-glucose; saturation during (4, 5, and 6 s) and TR (5, 6, 7, and 8 s), respectively (Nasrallah et al., 2013; Dai et al., 2014). In addition, the phantom model with different pH D-glucose concentrations was scanned with B1 = 1.5  $\mu$ T, saturation time 5 s.

## MRI Acquisition in Phantom and Animal Examination

In the phantom test, an echo-planar imaging (EPI) sequence with a continuous wave saturation pulse was used to perform glucoCEST imaging to explore the optimized scan parameters. The acquisition parameters were set as the following: TR 5.04 s, slice thickness 2 mm, acquisition matrix  $64 \times 64$ , field of view of  $40 \text{ mm} \times 40 \text{ mm}$ , averages 1, pre-saturation during 5 s, the saturation offset range from  $-1,500$  to  $+1,500$  Hz, the step 30 Hz and reference image without the saturation offset of 10,000 Hz. A B0 and B1 map were collected to correct the possible asymmetry and variation of magnetic field.

All rats were performed MR imaging at 28 days after the intracerebroventricular injection with A $\beta$ 25–35/sterile normal saline in the AD group/control group. Before MR examination, all rats were allowed to fast for 24 h. The rats were firstly

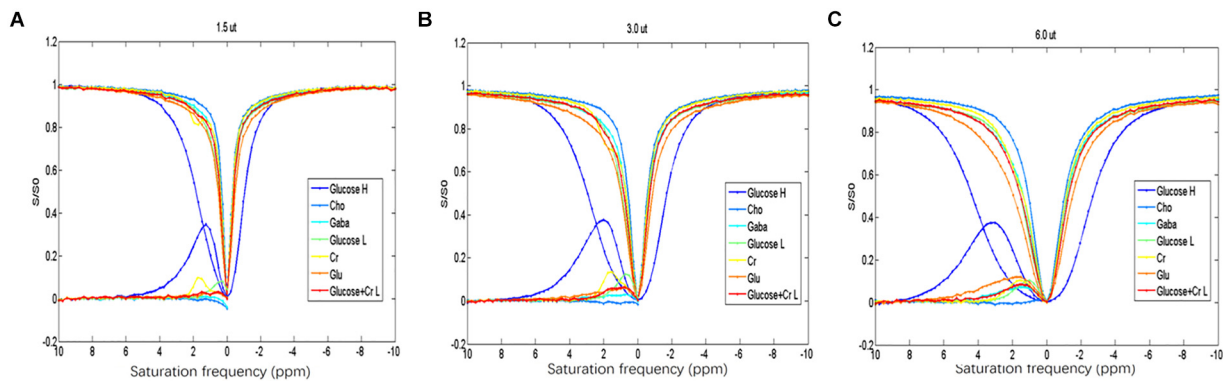

anesthetized in an induction box with 4% isoflurane in oxygen and continued to inhale the gas mixture of 1.5%/98.5% isoflurane/oxygen via a nose tube during the MRI scanning (Tang et al., 2017). The respiration rate was monitored and maintained by animal physiological monitoring and gating systems (model 1030, SAIL, United States). Then, rats were fixed on an MRI matching sampler with a bite and two ear bars to prevent the head motion.

MR imaging in phantom and animal were performed on a 7.0 T animal MR scanner (7T/160/AS Agilent Technologies, United States) with a 9,563 volume transmit/receive coil. The protocol included Axial and sagittal T2-weighted, DTI, and bilateral hippocampal MR spectroscopy and glucoCEST imaging. Axial and sagittal T2W imaging was acquired to demonstrate the morphology of rats' whole brain, and the parameters were set up as follows: TR 2,000 ms, acquisition matrix  $256 \times 128$ , field of view  $40 \times 40 \text{ mm}$ , slice thickness 2 mm, slice 6, slice spacing 0.2 mm and average 2. With the reference to T2WI, the scan layer including the middle hippocampus was selected as the area of interest. Axial Diffusion Tensor Imaging (DTI) of the rat brain was obtained with the following parameters: the scanning layer is consistent with glucoCEST imaging, TR 2,000 ms, TE 39.68 ms, FOV  $40 \text{ mm} \times 40 \text{ mm}$ , slice thickness 4 mm, matrix  $128 \times 128$ , b 1031.0  $\text{s/mm}^2$ , and the average 8. A total of seven diffusion-weighted images with S0 and six directions were obtained (b = 1031.0  $\text{s/mm}^2$ ) in a total scan time of 10 min and 41 s. Then, 1-H Magnetic Resonance Spectroscopy (MRS) was performed in the bilateral hippocampus before D-glucose infusion using a Point RESolved Spectroscopy (PRESS) pulse sequence with the following parameters: TR 4,000 ms, TE 13 ms, averages 192, and a spectral width of 4,006 KHz.

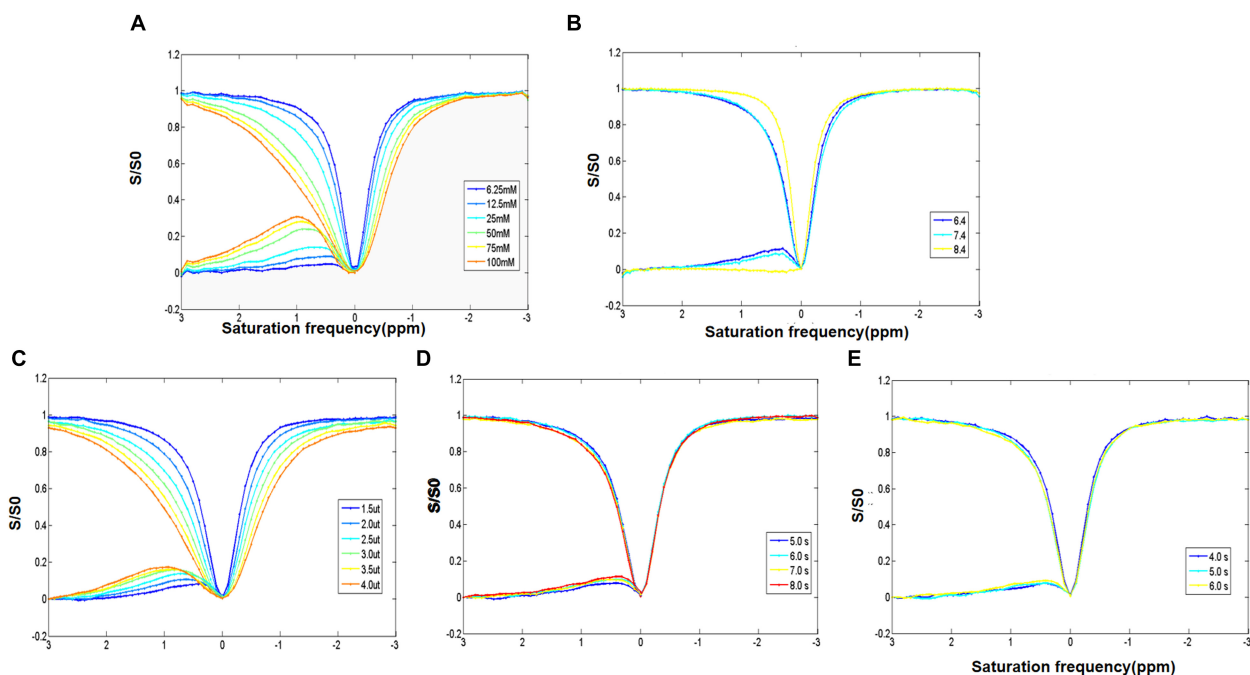

The axial glucoCEST images of the rat brain were acquired before the intraperitoneal injection of D-glucose (1.5 mM) and 10, 20, 30, and 40 min during infusion and then 10 and 20 min following the infusion. The scan parameters were: TR 6 s, slice thickness 4 mm, acquisition matrix  $64 \times 64$ , field of view of  $35 \times 35 \text{ mm}^2$ , average 1, saturation during of 5 s, saturation offset range from  $-900$  to  $+900$  Hz at intervals of 30 Hz and magnetization references at 10,000 Hz. The saturation power of 1.5  $\mu$ T was used with the minimize influence of other metabolites on glucoCEST and direct water saturation effect.

## Morris Water Maze

After MR examination, a Morris water maze (MWM) was used to evaluate learning and memory dysfunction. MWM experiments were carried out on the 14th and 28th day following A $\beta$ 25–35 administration as described previously (D'Agostino et al., 2012; Ohta et al., 2012). Rats were trained for 4 days (4 trials/day), and the swimming pattern was captured with a camera and a video track software (Noldus, Co., Ltd. Holland) for analysis. The latency to reach the platform was acquired using a computer-controlled tracking system. Rats were allowed 120 s to reach the platform then they were guided to the platform manually and left there for 5 s. On the fifth day, the platform was removed and a 120 s-spatial probe-trial was performed. The number crossing the platform position, the time of crossing from the target quadrant and the swimming speed of each rat were recorded.

**FIGURE 1 | (A–C)** Z-spectrum and MTR of the different metabolites indicating that D-glucose can be distinguished from the other metabolites at saturation energy B1 of 1.5  $\mu$ T.

**FIGURE 2 | (A)** Z-spectrum and MTR of different concentrations of D-glucose showing the direct saturation exchange rate of D-glucose and that water protons increase with the increase of D-glucose concentration. **(B)** Z-spectrum and MTR of D-glucose with different PH values examining the impact of pH. It indicates that the D-glucose effect is negatively correlated with pH. **(C–E)** Z-spectrum and MTR investigating the optimization of the saturation energy and echo and saturation time parameters. The D-glucose CEST effect increases with the increase in saturation energy and saturation and echo times.

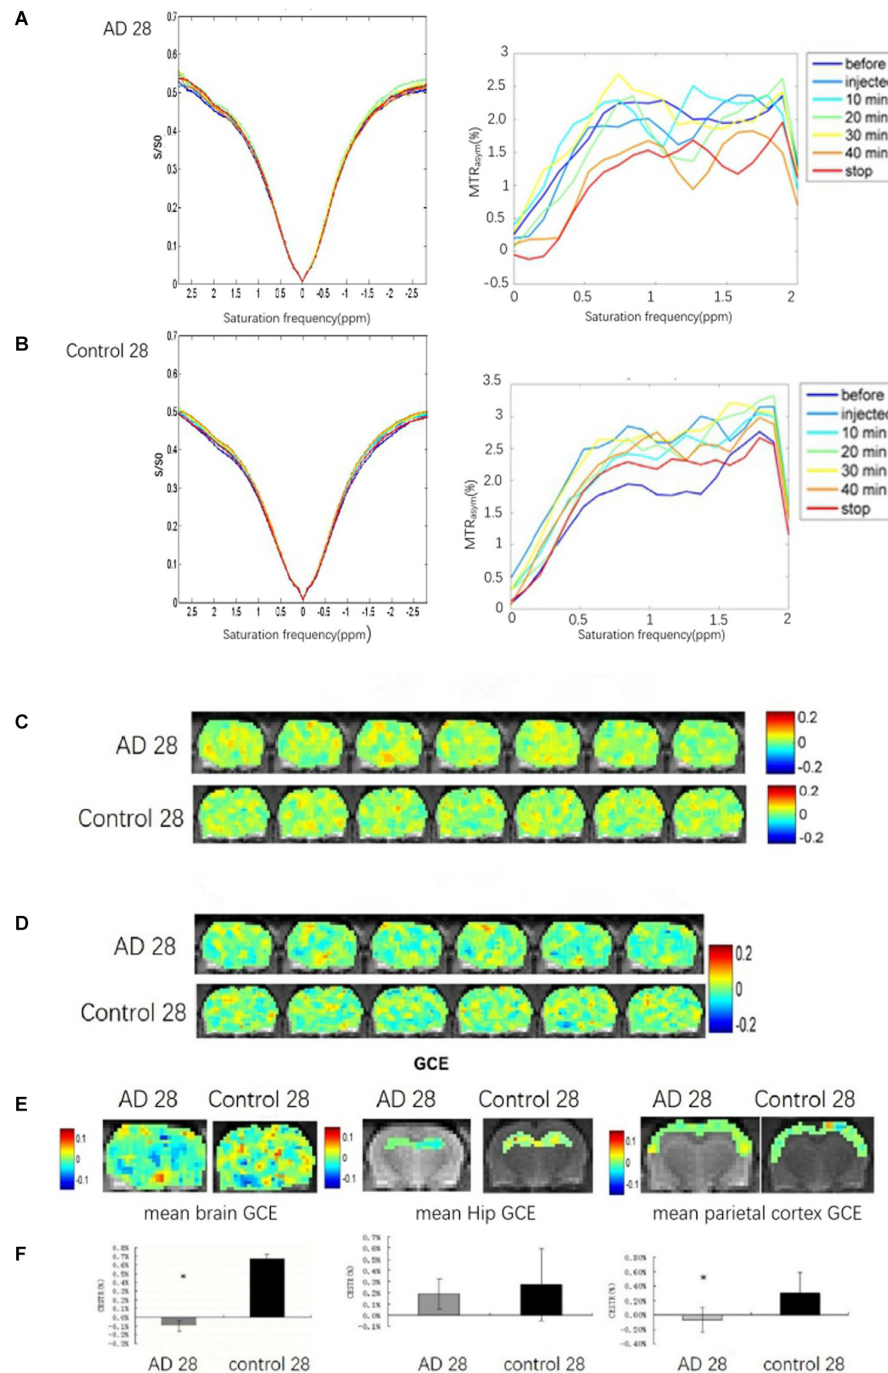

## Nissl Staining

Finally, rats were sacrificed and underwent myocardial perfusion with saline followed by 4% paraformaldehyde. The brains were removed and fixed in 4% paraformaldehyde overnight. Next, the brain tissues were dehydrated in ethanol, embedded in paraffin, subjected to coronal sectioning into 5  $\mu$ m thickness and required to undergo Nissl staining (Beyotime Co., Ltd., Shanghai, China) according to the standard protocols. The Nissl staining results were observed by an uninformed examiner. Three consecutive but non-overlapping fields of vision (magnification of 40 $\times$ ) in the hippocampal CA1 region and cerebral parietal cortex were

randomly selected from each rat brain tissue, and the neurons were counted with Image J software and showed as mean values per high-power field (HPF).

## Data Analysis

All glucoCEST images were processed using a custom MATLAB (The Mathworks, Inc., Natick, MA, United States) routine. Regions of interest (ROIs) were drawn manually based on the T2-weighted images. Total brain, bilateral hippocampal and cortex were drawn as ROI to observe the abnormal GCE in AD rats. After B0 correction, Z-spectra were obtained by

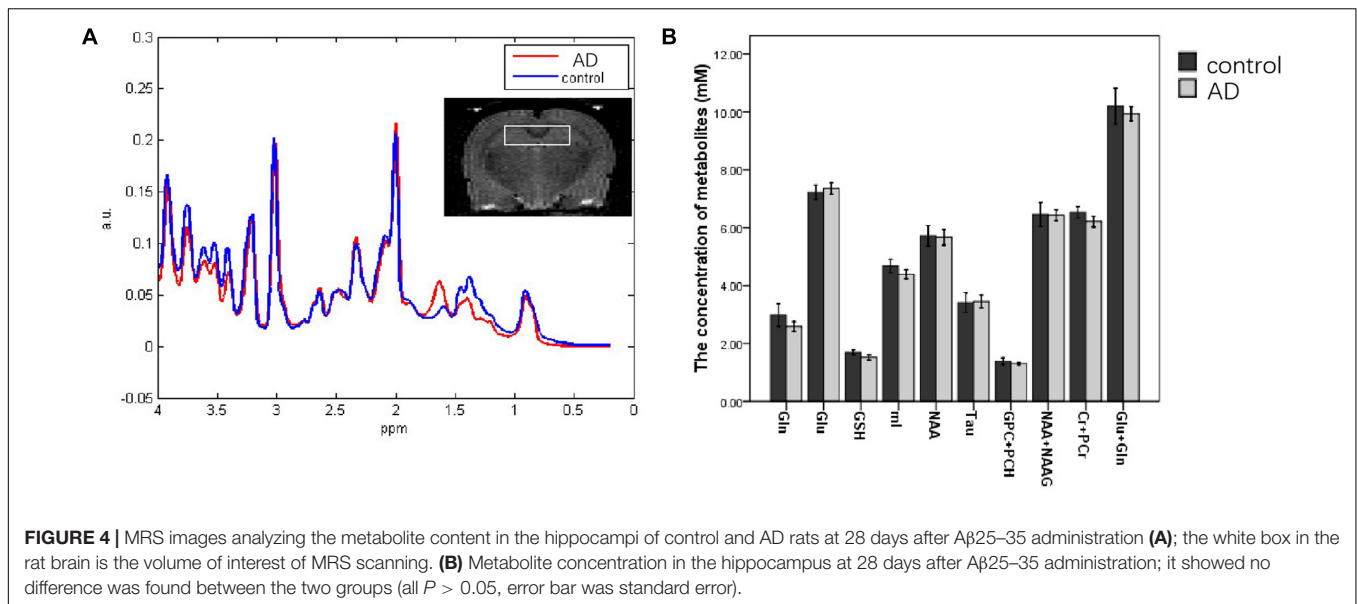

**FIGURE 3 |** The brain GCE signal of a rat in AD and control groups at 28 days after  $A\beta_{25-35}$  administration, respectively. **(A,B)** Showing Z-spectra and  $MTR_{asymp}$  of AD and control rat brains. **(C,D)** Showing glucoCEST and GCE images of AD and control rat brain at 28 days after  $A\beta_{25-35}$  administration in specific time point, respectively. **(E)** The mean GCE signal of the total brain, hippocampus and parietal cortex in AD and control rats. It indicates that the glucose uptake of the whole brain in AD rats was significantly decreased,  $P < 0.05$ ; the glucose uptake of the AD rats hippocampi is reduced, but  $p > 0.05$ ; the glucose uptake of the parietal cortex in AD is decreased,  $p < 0.05$  ( $*p < 0.05$ , error bar was standard error).

the ratio of the signals from different irradiation frequency offsets and the signal of water protons without saturation ( $S_0$ ). The magnetization transfer ratio asymmetry ( $MTR_{asymp}$ ) was

calculated as  $MTR_{asymp} (0.9 \text{ ppm}) = [S_{sat} (-0.9 \text{ ppm}) - S_{sat} (+0.9 \text{ ppm})]/S_0$ . Meanwhile, the GlucoCEST enhanced (GCE) images were calculated as the subtraction of the glucoCEST image

before D-glucose injection and the mean glucoCEST images of 40 min after injection and 10 min after the finishing D-glucose injection.

<sup>1</sup>H MRS data were analyzed with LCModel software (version 6.3, LCModel company, Canada) to acquire the concentrations of metabolites, such as N-acetyl aspartate (NAA), glutamate (Glu), glutamine (Gln), creatine (Cr), taurine (Tau), myo-Inositol (ml), glutathione (GSH), NAA + N-acetylaspartylglutamate (NAAG), glycerophosphocholine + phosphocholine (GPC + PCh), Glu + Gln, and Cr + phosphocreatine (PCr). A standard deviation (SD) value of less than 20 was accepted as being indicative of more reliable data.

In diffusion imaging, a brain apparent diffusion coefficient (ADC) map and fractional anisotropy (FA) map was acquired by VnmrJ (version 4.0, Agilent Technologies, United States) and subsequently analyzed by MATLAB software to calculate the ADC and FA in the total brain.

## Statistical Analysis

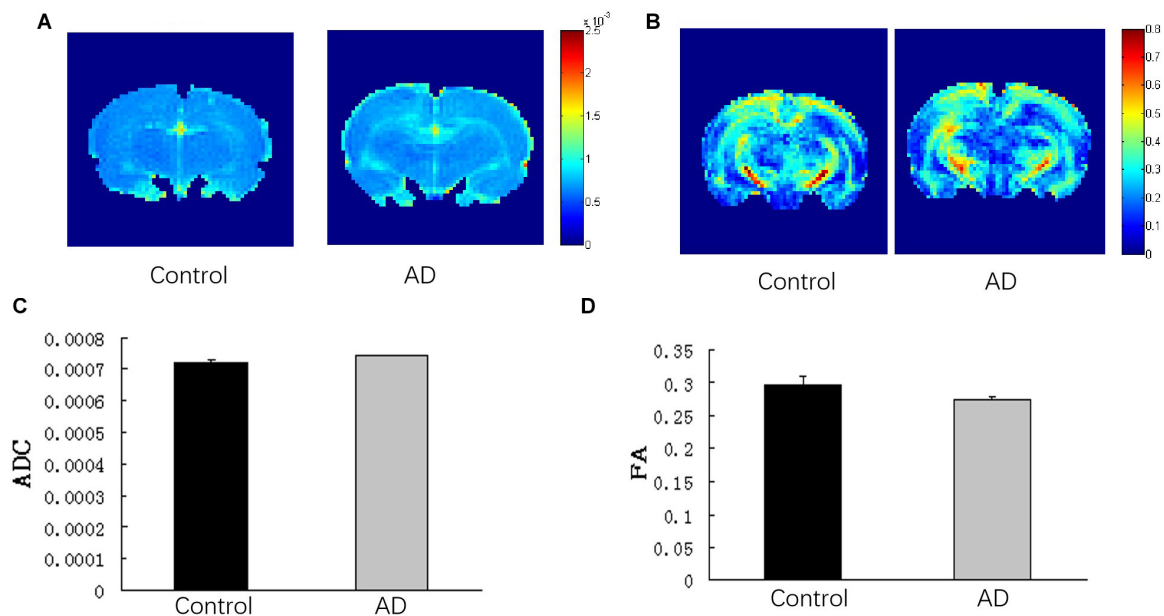

All data were analyzed statistically using SPSS 20.0 software (IBM, United States). Taking the small sample size in this study into consideration, outlier detection was firstly performed with a stem-and-leaf plot. Then normal distribution and homogeneity of variance were verified by a Shapiro-Wilk test and Levene's test, respectively. If a normal distribution and variance homogeneity tests were satisfied simultaneously, the group differences were analyzed with an independent sample *t*-test. Otherwise, a non-parametric test was used. In MWM data, square-root transformation was used to fit normal distribution and homogeneity of variance. One-way ANOVA repeated measures were performed to detect the group differences of escape latency over 4 days. The correlation among glucose metabolism and other metabolites in bilateral hippocampal were assessed using linear regression analysis. A  $p < 0.05$  was considered to be a statistically significant difference.

## RESULTS

### Optimization of Scan Parameters in Phantom

Among the different metabolites, the CEST effect of D-glucose could be better distinguished at a saturation power of 1.5  $\mu$ T (**Figure 1A**). The overlap of CEST effects of different metabolites is more serious with the increased saturation power from 1.5 to 6  $\mu$ T (**Figures 1B,C**).

**FIGURE 6 |** Analysis of DTI imaging of rat brains in the AD group and control group at 28 days after A $\beta$ 25–35 administration. **(A)** ADC images and **(B)** FA images of the control and AD rat brains. **(C)** Bar chart demonstrating the corresponding ADC value of the control and AD rats.  $P > 0.05$ . **(D)** Bar chart representing the corresponding FA value of the control and AD rats.  $P > 0.05$ , error bar was the standard error ( $n = 6$  per group).

The increase of D-glucose concentration resulted in the broadening of the glucoCEST signal in the asymmetric spectrum curve in the range of 0.5–1.0 ppm (**Figure 2A**). Moreover, a shift of the peak of D-glucose asymmetric spectrum curve (from 0.5 to 1.3 ppm) was found, and the D-glucose concentration (25–100 mM) was positively associated with the glucoCEST effect (10–25%) (**Figure 2A**).

A negative correlation was observed between the pH and the glucoCEST exchange rate. A decreased glucoCEST asymmetry signal was observed with the increase of pH value (**Figure 2B**). At a pH of 7.4, the glucoCEST exchange rate was about 10%. With the increase of saturation power from 1.5 to 4.0  $\mu$ T, there was a gradual rise in MTR<sub>asym</sub> (0.9 ppm), and the peak of the asymmetry curve shifted to a higher frequency (**Figure 2C**). Elevated MTR<sub>asym</sub> (0.9 ppm) (7.5, 9, 9.5, and 11.5%, respectively), was found with increasing repetition times (5, 6, 7, and 8 s); however, the scan time was also significantly increased (**Figure 2D**). Meanwhile, with an increase of the saturation duration from 4 to 6 s, MTR<sub>asym</sub> (0.9 ppm) increased from 7 to 11% (**Figure 2E**) with a prolonged scan time. Taken the scan time and MTR<sub>asym</sub> (0.9 ppm) into consideration, the optimal scan parameters of the glucoCEST were as follows: pH of 7.4, TR of 5.04 s, saturation power of 1.5  $\mu$ T and saturation during of 5 s.

### Decreased Brain GCE Signal in AD Rats

The brains glucoCEST asymmetric spectrum and Z-spectrum of all rats in the AD group and the control group were detected at 28 days after A $\beta$ 25–35 administration (**Figures 3A,B**). The lowest brain GCE in AD rats was observed at 40 min and

after stopping the infusion particularly in the thalamic and the hippocampal regions (**Figures 3C,D**). Additionally, in control rat brains, the change of GCE signal showed homeostasis without a downward trend.

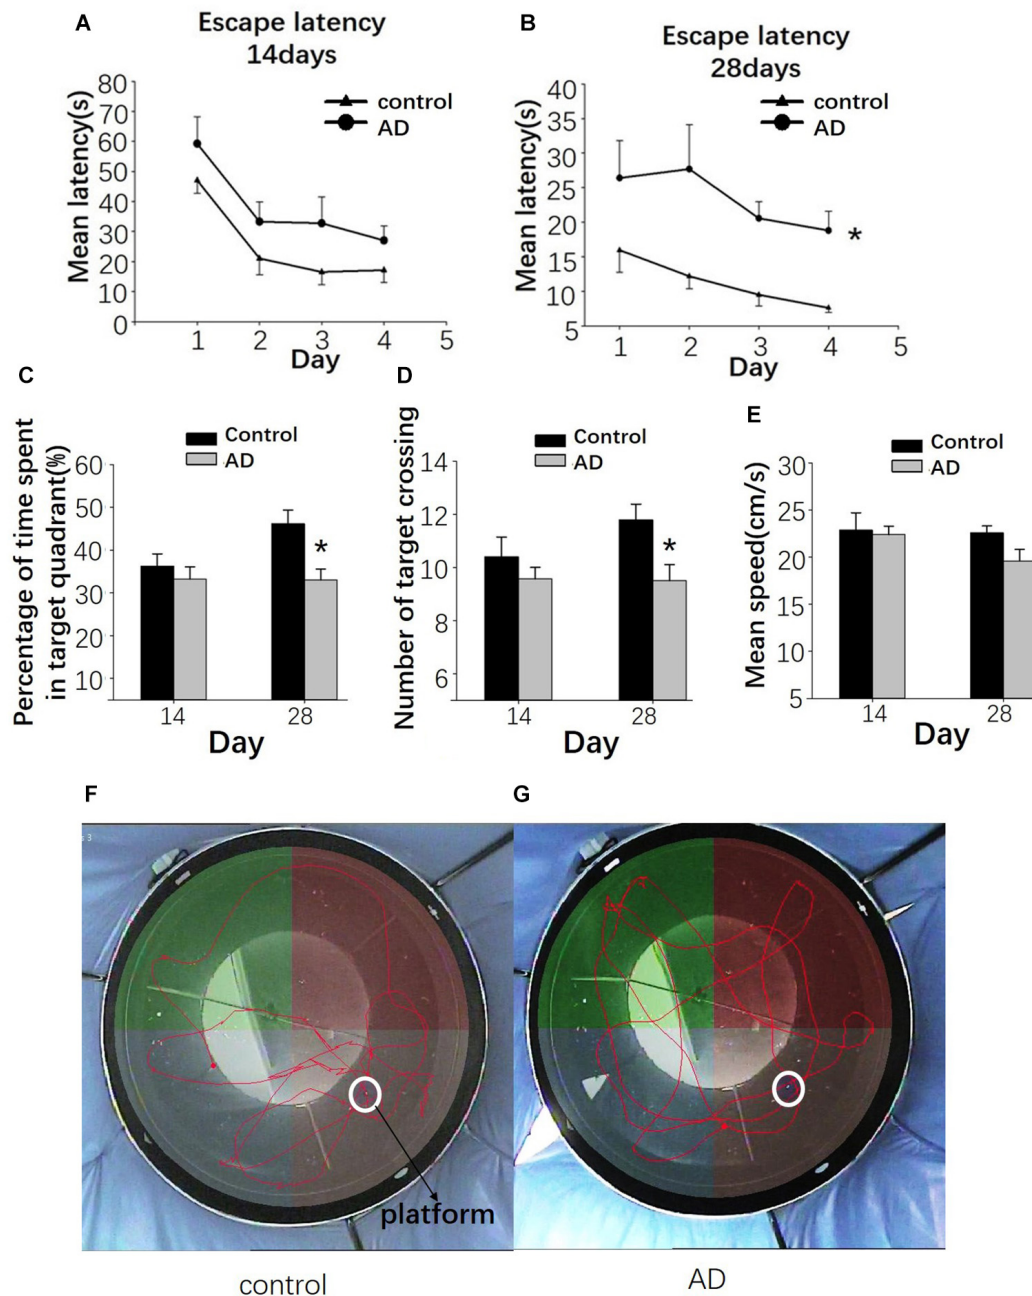

Because of abnormally elevated GCE signal, one case in the AD group was excluded. Compared to the control rats ( $n = 6$ ), significant decreases in the GCE signal of total brain and AD rats ( $n = 5$ ) were observed at continuous injection for 40 min and at 10 min after the stop of the injection ( $P < 0.05$ ; **Figures 3E,F**). The decreased GCE signal was also found in the bilateral parietal cortex of AD rats with significant statistical differences ( $P < 0.05$ ; **Figures 3E,F**), but there were no significant statistical differences in the bilateral hippocampus ( $P > 0.05$ ; **Figures 3E,F**).

### Metabolite Concentrations in the Bilateral Hippocampal

One case in the control group was cut off because of the more than 20 metabolites in the SDs. Compared to the control group ( $n = 5$ ), a descending trend of the concentrations from bilateral hippocampal in AD rats ( $n = 5$ ) was observed in the Gln, ml, Cr + PCr, and Glu + Gln at 28 days after A $\beta$ 25–35 administration. However, there was no significant difference in the concentrations of all metabolites between the AD group and the control group ( $P > 0.05$ ; **Figure 4**).

### The Correlation Between ml Concentration and GCE Signal

In rats of the control group ( $n = 5$ ) and the AD group ( $n = 5$ ), a strong positive correlation between GCE and ml ( $R^2 = 0.626$ ) was

**FIGURE 7 |** Evaluation of the learning and memory dysfunction in rats of the control and AD groups at 14 and 28 days after A $\beta$ 25–35 administration by Morris water maze (MWM). The escape latency of control and AD rats (A,B). (C) Bar charts presenting the percentage of target quadrant crossings. (D) Bar charts presenting the number of target crossings. (E) Bar chart presenting the analysis of swimming speed among rats of the control and AD groups. (F) Tracing of the swimming pattern in the control rats. (G) Tracing of the swimming pattern of the AD rats.  $n = 6$  per group, \* $P < 0.05$ , error bar was the standard error.

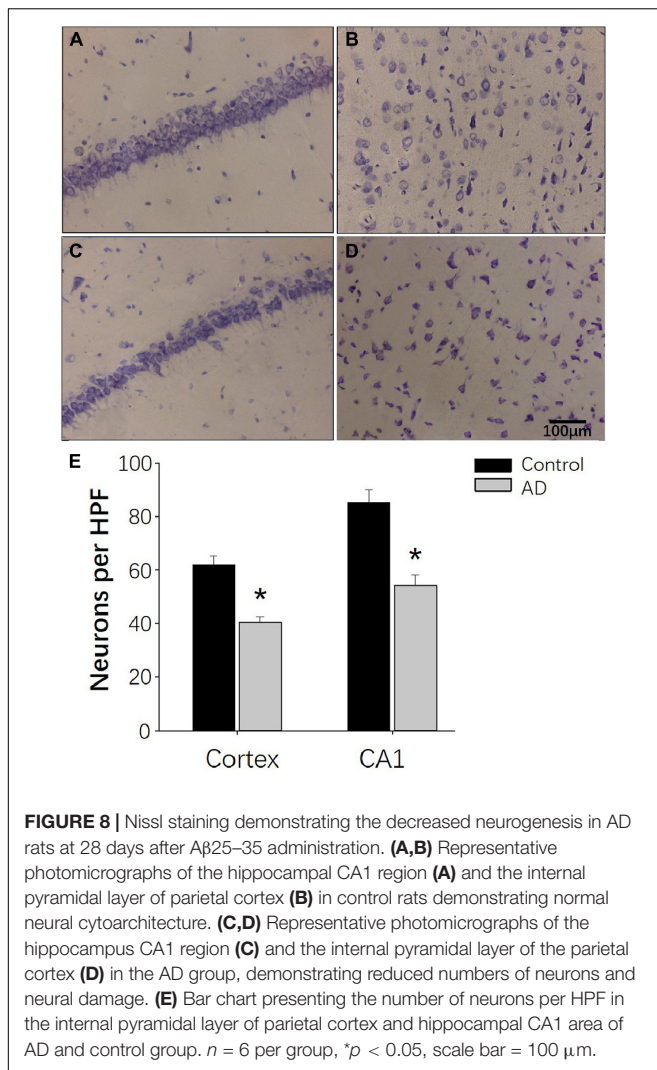

found with significant statistical differences ( $P < 0.01$ ) at 28 days after A $\beta$ 25–35 administration (Figure 5).

### Comparison of ADC and FA of Total Brain

There was no significant difference in the ADC values and FA values of the total brain between the AD and control groups ( $P > 0.05$ ; Figure 6).

### Impaired Spatial Learning and Memory in AD Rats

At 14 days after A $\beta$ 25–35 administration, the escape latency was relatively longer in the AD rats than in the control group; however, the difference was not statistically significant ( $P > 0.05$ ; Figure 7A). At 28 days after A $\beta$ 25–35 injection, a significantly longer latency to find a platform in the AD rats was found

**FIGURE 8 |** Nissl staining demonstrating the decreased neurogenesis in AD rats at 28 days after A $\beta$ 25–35 administration. **(A,B)** Representative photomicrographs of the hippocampal CA1 region **(A)** and the internal pyramidal layer of parietal cortex **(B)** in control rats demonstrating normal neural cytoarchitecture. **(C,D)** Representative photomicrographs of the hippocampus CA1 region **(C)** and the internal pyramidal layer of the parietal cortex **(D)** in the AD group, demonstrating reduced numbers of neurons and neural damage. **(E)** Bar chart presenting the number of neurons per HPF in the internal pyramidal layer of parietal cortex and hippocampal CA1 area of AD and control group.  $n = 6$  per group, \* $p < 0.05$ , scale bar = 100  $\mu$ m.

compared to those in the control rats ( $P < 0.05$ ; **Figure 7B**), indicating a slower learning pattern in the AD rats. Furthermore, fewer crossing times to the platform and the time to cross the target quadrant in AD rats were observed at the 28 days following A $\beta$ 25–35 administration, and they were statistically significant ( $P < 0.05$ ; **Figures 7C,D,E,G**), though no significant difference in the average swimming speed was found between two groups ( $P > 0.05$ ; **Figure 7E**).

### Decreased Number of Hippocampal CA1 and Parietal Nissl Body in AD Rats

Nissl staining was used to observe the neural loss and damage in the AD rat brains after 28 days of A $\beta$ 25–35 administration. Rats in the control groups showed typical Nissl staining in the hippocampus with deeper staining, regular and tighter neural arrangement and normal cytoarchitecture (**Figure 8A**). In the AD group, the hippocampal neurons had reduced numbers of Nissl bodies, lighter staining, irregular cell arrangement in the CA1 region with intact cell structure and blurred cell nuclei (**Figure 8C**). Similar observations were found in the cerebral

cortex (**Figures 8B,D**). In the control group, Nissl bodies were observed in the cortical nerve cells with typical deep staining and normal cytoarchitecture (**Figure 8B**). In the AD group, the number of Nissl bodies in the cortical neurons was decreased with a shallow staining and abnormal cytoarchitecture (**Figure 8D**). Otherwise, compared to the control group, the numbers of neuronal cells per HPF of hippocampal CA1 and parietal cortex neurons in the AD group were decreased ( $P < 0.05$ ; **Figure 8E**).

## DISCUSSION

In this study, we investigated the changes in the cerebral glucose metabolism with GlucoCEST in a rat model of AD. A significantly decreased mean GCE signal of total brain and bilateral parietal cortex of AD rats was observed after 40 min of continuous injection of D-glucose and 10 min after the stop of injection. Moreover, there is a strong positive correlation between GCE and mI in the rats of the control group ( $n = 5$ ) and the AD group ( $n = 5$ ), suggesting the presence of abnormal glucose metabolism in the brain of AD rats.

Different from previous animal AD studies with transgenic mice models, we chose the AD rat models for acquiring the brain glucoCEST images with high SNR. The method of AD rat modeling is based on a previous study (Lu et al., 2009), and the water maze test and pathological examination were performed to verify the abnormal behavioral and pathological changes in rats with the intracerebroventricular injection of aggregated A $\beta$ 25–35 (9  $\mu$ l). The injection of 9  $\mu$ l A $\beta$ 25–35 was demonstrated to cause severe neurotoxicity leading to impaired learning and memory function, the release of inflammatory mediators and impairment of neuronal cells (Lu et al., 2009). Indeed, in our study, rats in the AD group had a reduced number of neurons in the cortex and the hippocampus with altered neural architecture after A $\beta$ 25–35 injection. These results are consistent with previous studies (Maurice et al., 1996). Moreover, AD rats had significantly longer escape latency and a decreased number of crossing times compared to rats in the control group at 28 days after the injection of A $\beta$ 25–35. These results indicate that the capacity for space exploration was impaired in AD rats, and the same was true for their learning and memory abilities. Taken together, our results confirm the feasibility of single A $\beta$ 25–35 administration in inducing AD symptoms in rats (Kim et al., 2015).

D-glucose is a glucose metabolite produced by the body's metabolism that can pass through the blood–brain barrier (Nasrallah et al., 2013). GlucoCEST is based upon the fact that each glucose molecule contains five hydroxyl groups that can be chemically exchanged with hydrogen protons in the free-water molecule (Walker-Samuel et al., 2013). Consequently, this reduces the strength of the MRI free-water signal that can reflect the content of D-glucose. Therefore, D-glucose can be used as an MRI contrast agent to increase the imaging sensitivity. Walker-Samuel et al. (2013) indicated the presence of an intracellular origin of glucoCEST using D-glucose, and Nasrallah et al. (2013) reported that most of the glucoCEST signals seen in the brain after injecting 2DG are of an intracellular origin. In this study, the GCE technique was used

to detect the uptake of exogenously administered D-glucose in the brain.

Previous studies used glucoCEST to examine the glucose metabolism in tumors, and the brain sugar content was mainly examined with  $^{18}\text{F}$ FDG-PET (Coleman et al., 2017). In the few AD relative studies using glucoCEST imaging, Wells et al. (2015) explored the glucose metabolism in AD and found that elevated CEST signal in the cortex of AD mouse, which is consistent with our results. But the quality of glucoCEST images in Wells' study needs to be improved. In this study, an EPI sequence with a continuous-wave saturation pulse was used, and it had been proven to be able to improve the CEST contrast ratios and the quality of glucoCEST images (Sun et al., 2008). Furthermore, the important scan parameters of glucoCEST imaging, such as saturation power, saturation duration and TR were optimized in phantom to improve the quality of brain glucoCEST images.

The glucose tolerance test was performed in fasted rats in this study using intraperitoneal glucose injections. To prolong the time window of blood glucose peaks and maintain a higher concentration of glucose in the brain, we used a syringe pump to continue the small dose supplementation. In the control group, the brain GCE signal continued to rise and was consistent with the trend of blood glucose monitoring, confirming the reliability of our method. The GCE signals, however, were significantly reduced in the AD group, and these results were in accordance with the previously reported  $^{18}\text{F}$ FDG-PET studies (Waldron et al., 2015; Coleman et al., 2017).

In glucoCEST images before D-glucose injection, we found more elevated MTRasym (0.9 ppm) signals in the total brain of AD rats than in the control group. Except for technical issues such as B0/B1, direct water saturation and MT, the CEST signal is considered related to the concentration of exchanged protons or molecules, T1 relaxation time of tissues and the exchanged environment, including pH and temperature. Although elevated glucose/Cr in the AD brain was reported (Mullins et al., 2018), the effect of other issues was not excluded. Further experiments are thus needed to confirm the elevated MTRasym (0.9 ppm) signal mainly comes from elevated glucose concentration. As for the molecular mechanism of abnormal glucose metabolism and AD, the insulin receptor substrate 2 (IRS2) and Glycogen Synthase Kinase-3 (GSK-3) may play important roles in the insulin signaling in the brain and AD processes (reviewed by Daniëlle et al., 2018). We will also explore the relationship between molecular signals and glucoCEST signals in further studies.

A decreased concentration trend of the metabolites (Gln, mI, Cr + PCr, and Glu + Gln) from the bilateral hippocampus in AD rats was observed in this study. Although there were no statistical differences, we think the group differences may be observed with increased sample size. Decreased NAA/tCr and Glu/tCr ratios were also reported in previous animal studies with mice models of AD (von Kienlin et al., 2005). However, those changes were age-dependent index observed in 24-month-old animals instead of 12-month-old animals. Interestingly, an increased mI/tCr ratio was also reported in 20-month-old APP-PS1 mice (Marjanska et al., 2005) and amyloid-positive healthy elderly (Voevodskaya et al., 2016) in the cortex, though this is still a matter of controversy. We found a decreased mI in the bilateral

hippocampus of an AD rat at 28 days after modeling, and it was related to GCE in this study. As a second messenger glucose isomer, mI is involved in glucose and insulin metabolism and promotes muscle glucose uptake (Chukwuma et al., 2016). We thus believe that decreased mI may mainly contribute to elevated MTRasym (0.9 ppm) signals and decreased GCE in AD rats. This is also abnormally increased in old age, and this may be as a compensation mechanism.

This study had some limitations: (1) the relatively small number of examined animals, which could impact the significance of our results; (2) the total scan time was too long, and in future studies, we need to use a more efficient method to increase brain glucose uptake; and (3) we used the A $\beta$ 25–35-induced AD rat instead of a double transgenic AD mouse model. Therefore, we will improve our experimental condition and enquire with a mouse head coil with a high channel in future studies.

## CONCLUSION

In this study, we found a reduced GCE signal of glucose in the whole brain and parietal cortex of AD rats *in vivo*, and reduced GCE in the total brain is associated with decreased concentrations of mI in the bilateral hippocampus of AD rats and control rats. Therefore, CEST-based MRI GCE can be a potentially valuable tool to explore the early pathogenesis and pathological mechanisms of many diseases, such as diabetes-related AD and other kinds of dementia as well as neurodegenerative diseases.

An active lifestyle as well as cognitive and physical training (PT) may benefit cognition by increasing cognitive reserve, but the underlying neurobiological mechanisms of this reserve capacity are not well understood. To investigate these mechanisms of cognitive reserve, we focused on electrophysiological correlates of cognitive performance, namely on an event-related measure of auditory memory and on a measure of global coherence. Both measures have shown to be sensitive markers for cognition and might therefore be suitable to investigate potential training- and lifestyle-related changes. Here, we report on the results of an electrophysiological sub-study that correspond to previously published behavioral findings. Altogether, 65 older adults with subjective or objective cognitive impairment and aged 60–88 years were assigned to a 10-week cognitive ( $n = 19$ ) or a 10-week PT ( $n = 21$ ) or to a passive control group ( $n = 25$ ). In addition, self-reported lifestyle was assessed at baseline. We did not find an effect of both training groups on electroencephalography (EEG) measures of auditory memory decay or global coherence ( $p \geq 0.29$ ) and a more active lifestyle was not associated with improved global coherence ( $p = 0.38$ ). Results suggest that a 10-week unimodal cognitive or PT and an active lifestyle in older adults at risk for dementia are not strongly related to improvements in electrophysiological correlates of cognition.

**Keywords:** coherence, lifestyle, dementia, mismatch negativity, cognitive training, physical training, electrophysiology

**Abbreviations:** AD, Alzheimer's disease; ADAS, Alzheimer's Disease Assessment Scale; ANOVA, analysis of variance; CT, auditory cognitive training; DMN, default mode network; EEG, electroencephalography; fMRI, functional magnetic resonance imaging; ISI, interstimulus interval; MCI, mild cognitive impairment; MMN, mismatch negativity; MMSE, Mini-Mental State Examination; MVGT, Münchner Verbaler Gedächtnistest; PT, physical training; SL, synchronization likelihood; SOA, stimulus onset asynchrony; WLC, wait-list control;  $\Delta$ MMN, difference score between MMNs to short and to long ISIs;  $\Delta$ MMN-Dur, index for automatic auditory memory, amplitude difference between the MMN after duration deviant in the Memory Trace paradigm and Optimum-1 paradigm, higher values indicating better automatic auditory memory or less pronounced automatic auditory memory decay.

## INTRODUCTION

The number of people with cognitive deficits and dementia is growing due to increasing life expectancy and demographic change. Thus, the meaning of the detection of pathological cognitive decline as well as its prevention and slowing down became an increasingly important issue. For decades the assessment of cognitive decline in healthy aging and in dementia had been mainly based on neuropsychological data. However, recently surrogate biomarkers in cerebrospinal fluid and neuroimaging have evolved. In our recent studies we described two sensitive electroencephalography (EEG) markers for cognition. These are resting-state global coherence (Laptinskaya et al., 2019) and a novel mismatch negativity (MMN) index for auditory memory decay, namely  $\Delta$ MMN (Laptinskaya et al., 2018).

Resting-state global coherence cognition was defined as the coherence over the whole skull at rest in the frequency range between 4 and 30 Hz. Coherence represents functional coupling between brain regions or single electrode pairs. A wide range of studies reported alterations in resting-state EEG coherence in dementia (e.g., Knott et al., 2000; Stevens et al., 2001; Adler et al., 2003). The most prominent change is attenuated coherence in the alpha and beta frequency range in fronto-parietal and the temporo-parietal coupling (see Babiloni et al., 2016 for a review). Recent studies suggest that these changes might already occur in mild cognitive impairment (MCI; Michels et al., 2017). In line with previous study results investigating frequency- or region-specific coherence, we found global coherence to be a sensitive EEG marker for global cognition (Laptinskaya et al., 2018).

The MMN is one of the most widely investigated ERP components and is elicited when a presentation that has been automatically predicted by the central nervous system is violated (Näätänen et al., 1978, 2011). In an auditory paradigm the MMN can be evoked when in a sequence of equal tones a deviant tone is presented. The MMN represents two, closely linked, processes: auditory discrimination ability and auditory memory. With increasing interstimulus interval (ISI, the distance between the standard and the deviant tone) MMN provides more information on the auditory memory trace (for a review see Bartha-Doering et al., 2015). Many previous studies have shown attenuated MMN amplitude, especially after long ISIs in dementia (Pekkonen et al., 1994; Schroeder et al., 1995; Papadaniil et al., 2016) as well as in MCI as a possible prodromal stage of dementia (Lindín et al., 2013; Ji et al., 2015; Papadaniil et al., 2016). However, no MMN marker for cognition has been established yet. This might be due to the fact that the comparability between study results is difficult because of the methodological difference, such as different deviant types and ISI lengths. To address this challenge, we built a difference score between MMNs after short and after long ISIs. The difference score (hereafter referred to as  $\Delta$ MMN) takes individual differences in auditory discrimination ability as well as auditory memory into account and has been shown to reflect

cognition or even the cognitive decline over a period of 5 years (Laptinskaya et al., 2018).

Beneath new diagnostic tools for cognition, intervention methods which are capable to prevent or slow down cognitive decline are of great clinical and scientific interest. Previous studies suggest that cognitive and physical activity may benefit cognition or even delay dementia (Livingston et al., 2020). Regarding the impact of physical and cognitive activity on cognition, specific training programs and an active lifestyle can be distinguished. The last one is often defined as the number of regularly performed activities. While some studies reported positive training effects on cognition (e.g., Hess et al., 2014; Lampit et al., 2014; Edwards et al., 2016; Groot et al., 2016), others failed to find beneficial effects (e.g., Williamson et al., 2009; Barnes et al., 2013). Training factors such as the combination of cognitive and physical training (PT) aspects (e.g., Fissler et al., 2013; see Gheysen et al., 2018 for a review and a recent meta-analysis), longer training periods, and variability in training tasks (cf., Fissler et al., 2013) seem to be important determinants for training success. Results regarding active lifestyle are more consistent than results on training interventions: the majority of studies reported a positive association between an active lifestyle and cognition. But the comparability between training and lifestyle studies is limited. Training effects on cognition often refer to time limited experimental designs. In contrast, lifestyle cognition studies are associative in nature and consider longer time periods. Furthermore, lifestyle cannot be experimentally manipulated. To fill this scientific gap, we systematically investigated the effects of specific training programs with lifestyle cognition associations for 10 weeks in older adults with increased risk of developing dementia (cf., Küster et al., 2016). We found that persons with a more active lifestyle showed benefits in cognitive performance post-training when compared to persons with a less active lifestyle. In contrast, neither a 10-week auditory cognitive training (CT) nor a 10-week PT showed beneficial effects on cognition. We concluded that the lifestyle might be beneficial for cognition more than the short-term training programs by higher variability in cognitive demands, enjoyment, fun, and intrinsic motivation.

Until now the biological mechanisms of positive effects of cognitive and physical activity on cognition are not well understood. Understanding the mechanisms of treatment is decisive to develop individualized treatments that specifically target brain changes that underlie cognitive symptoms. In the present study, we examine the association between lifestyle and changes in EEG markers for cognition as well as the effect of a 10-week auditory CT and a 10-week PT on the two EEG parameters. The results might give further insights into electrophysiological mechanisms which underlie the positive link between cognitive and physical activity and changes in cognition. In the long term, this knowledge could be used for individualized therapies that are based on biomarker profiles of patients with cognitive impairment. The aim of the present study was to investigate the association between lifestyle and EEG markers for cognition. Furthermore, we tested the hypothesis,

whether specific training programs are suitable to enhance global cognition and  $\Delta$ MMN.

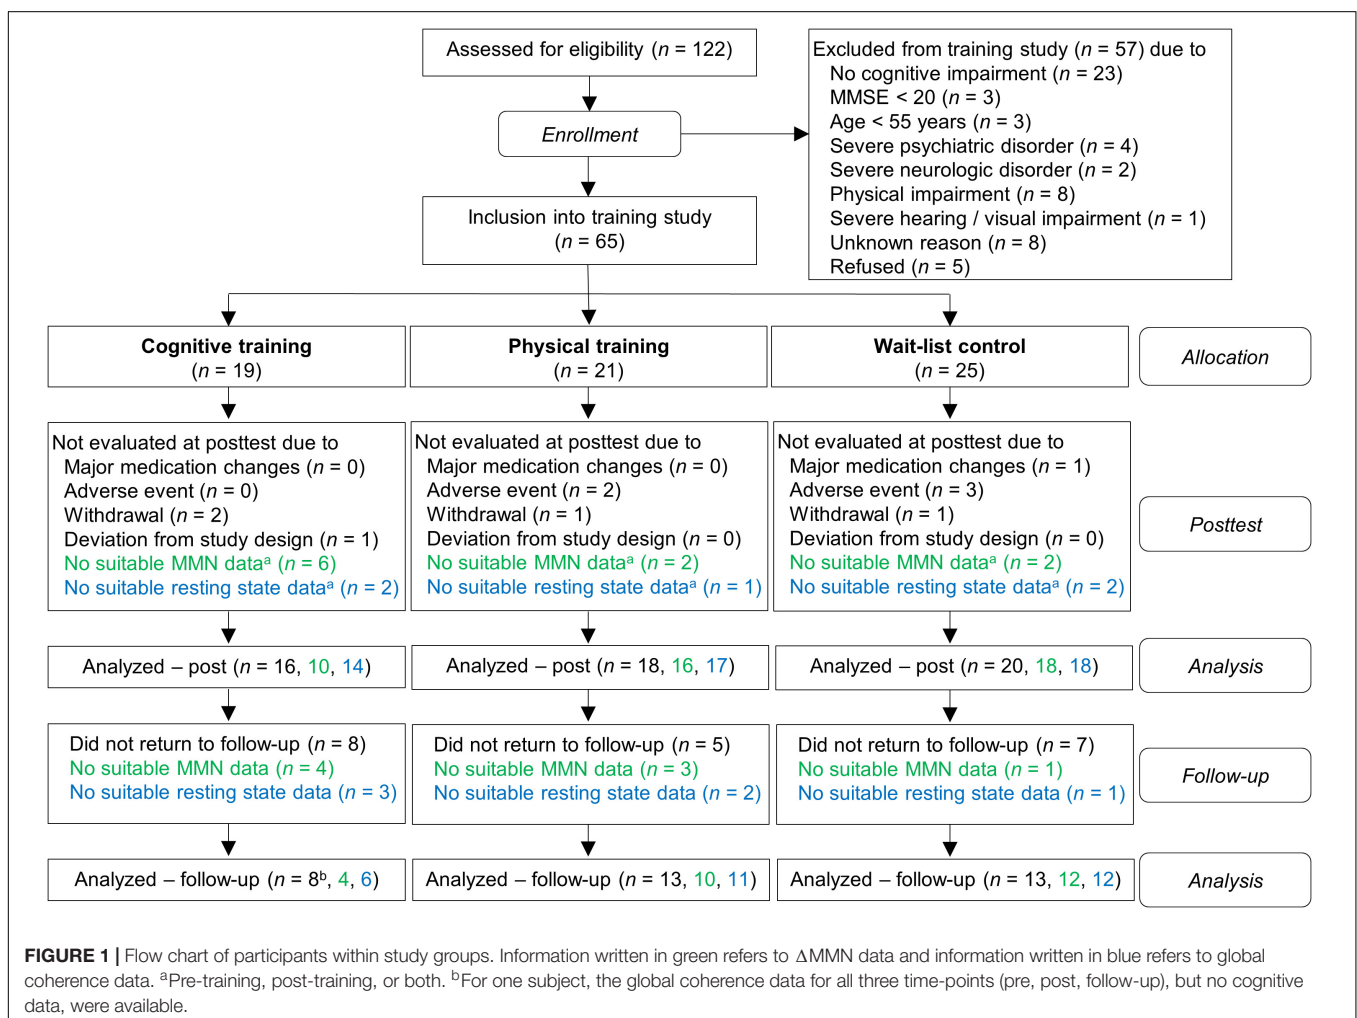

## MATERIALS AND METHODS

### Participants

The study was approved by the ethics committees of both study centers, the University of Konstanz and Ulm University, Germany. The study was part of a controlled clinical trial investigating the effect of physical exercise and auditory CT on cognition as well as on electrophysiological and biological parameters (Küster et al., 2016, 2017; Fissler et al., 2017; Laptinskaya et al., 2018, 2019). Prior to the study, all participants provided written informed consent. Subjects were recruited in the Memory Clinic of Ulm University Hospital, Germany and the Center for Psychiatry Reichenau, Germany, or via public advertisements. The detailed description of the inclusion and exclusion criteria can be found in Küster et al. (2016). In brief, inclusion criteria were: 55 years of age or older and subjective or objective memory

impairment, fluency in German language, stable anti-dementia and antidepressant medication, and independent living. Exclusion criteria were as follows: probable moderate or severe dementia [Mini Mental State Examination; MMSE (Folstein et al., 1975) < 20] and history of other neurologic or psychiatric disorders (except mild to moderate depression). Furthermore, participants with severe hearing or visual impairment, and physical impairment which could restrain the participation in the training programs were also excluded.

Out of 122 participants who were screened for eligibility, due to exclusion and drop-outs 65 subjects were included in the study (for the detailed flow of participants see **Figure 1**). Subsequently, the participants were assigned into one of the three groups: auditory CT ( $n = 19$ ), PT ( $n = 21$ ), and wait-list control (WLC;  $n = 25$ ). In order to minimize differences in age, gender, education, and cognitive status (MMSE) between groups, we used a minimization approach. The investigators were blind to the subjects' group allocation. In rare cases this was not maintained because the participants disclosed their group assignment during neuropsychological assessment. Notably, because of drop-outs, the number of evaluated training

data sets varied for MMN and for coherence analysis (for drop-out reasons see **Figure 1**).

According to classification criteria (see **Supplementary Presentation 1**) the participants were classified as having subjective memory impairment (SMI,  $n = 12$ ), amnesic cognitive impairment (aMCI,  $n = 23$ ), non-amnesic cognitive impairment (naMCI,  $n = 14$ ), or probable dementia (AD<sub>p</sub>,  $n = 5$ ).

## Procedure

Four weeks prior to the commencement of the intervention and within a slot of one or two appointments, details of sociodemographic, cognitive and lifestyle data, as well as electrophysiological recordings were collected. Prior to the beginning of EEG recordings, individual hearing thresholds were assessed using in-house software PyTuneSounds (Hartmann, 2009). The training or the waiting period started 1–4 weeks after the pre-training test and lasted 10 weeks. Post-training tests were carried out 1–4 weeks after the end of the intervention. Potential long-term effects were examined in follow-up tests 3 months after the post assessment.

## Neuropsychological Assessment

All participants completed the following assessments: the Alzheimer's Disease Assessment Scale–cognitive subscale (ADAS; Ihl and Weyer, 1993), phonemic and semantic word fluency as well as TMT part A and B of the Consortium to Establish a Registry for Alzheimer's Disease–plus test battery, the subtests digit span and digit-symbol coding of the Wechsler Adult Intelligence Scale (Tewes, 1991). Furthermore, an adapted German version of the California Verbal Learning Test [German: Münchner Verbaler Gedächtnistest [MVGT, Munich Verbal Memory Test]; Ilmberger, 1988] was conducted. Additionally, everyday cognition in an ecologically valid task was assessed using the working-memory subtest of the Everyday Cognition Battery (ECB computation span, Allaire and Marsiske, 1999). Verbal Knowledge Test (German: Wortschatztest) was used to assess crystallized abilities.

To reduce multiple testing and thus  $\alpha$ -inflation and in order to assess latent cognitive function scores, a principal component analysis using the oblique rotation technique was performed across all participants. Using the Kaiser criterion (Eigen values  $\geq 1.0$ ) two components were extracted. One component showed high loadings of episodic memory scores, namely MVGT encoding, MVGT long-delay recall, and ADAS-free recall. The second component showed high loadings of attention and executive function scores, i.e., TMT part A and B, digit span forward and backward, digit-symbol, phonemic and semantic fluency, and ECB computation span. All variables were  $z$ -standardized and two component scores were built, one representing memory functions and the one representing attention and executive functions. The components represent the weighted average of those  $z$ -standardized variables with loadings of at least  $a_{ij} = 0.40$  on the respective component. Additionally, a global cognition component score was calculated as the average of the two component scores. A more detailed description of the principal component analysis can be found in Küster et al. (2016).

## EEG Assessment

### EEG Recording and Data Processing

The EEG was recorded using a high-density 256-channel HydroGel Geodesic Sensor Net (HCGSN; Electrical Geodesics, Inc.; Eugene, OR, United States). During data acquisition Cz served as reference and the data were sampled with 1,000 Hz. Resting state EEG as well as MMN EEG were collected in the same session after neuropsychological assessment, starting with the resting state EEG recording. During EEG recordings participants were seated comfortably in an electrically shielded room. To avoid drowsiness artifacts during resting state EEG, participants were instructed to keep their eyes open and to fixate on a chosen mark approximately at eye level on the opposite wall. Furthermore, to avoid blink and muscle artifacts, the participants were instructed to relax and to reduce blinking during both EEG recordings. There was a 5 min break between the recordings. During MMN EEG recording participants watched silent Charlie Chaplin videos while auditory stimuli were presented binaurally through stereo headphones at 50 dB above the individual hearing threshold. Since the MMN is elicited automatically without participants' attention and it is preferable to keep attention effects low during MMN recording, participants were instructed to watch the video carefully and not to pay any attention to the sounds.

After recording the EEG, the data were imported into MATLAB (version 2015b; The MathWorks, 2015); the FieldTrip toolbox (version 20151012) was used for preprocessing.

### Global EEG Coherence Analyses

Data were bandpass filtered in the range of 1–30 Hz (24 dB/octave), noisy channels were rejected, and the data were re-referenced to the average of all channels marked as good. For a better comparison between assessments, the noisy channels were compared between recordings and the same channels were used for coherence analyses for the pre-post ( $M = 220.65$ ,  $SD = 20.76$ , range: 170–246) and the pre-follow-up comparison ( $M = 220.93$ ,  $SD = 20.88$ , range: 170–246), respectively. Artifact-contaminated epochs were manually rejected. To avoid trial bias, 20 trials were randomly selected from clean epochs for each subject and assessment. Spectral coherence analyses were calculated as an index for functional connectivity assuming a linear coupling in brain activity. Spectral coherence analyses were applied using the *bsmart* implementation for MATLAB (Cui et al., 2008). As an index for global coherence, we calculated the spectral coherence for all pairs of electrodes and averaged all values for the 1–30 Hz frequency range as an index for global coherence.

### $\Delta$ MMN Analyses

#### Procedure and paradigms

We used two different passive MMN paradigms. The paradigm order was counterbalanced between subjects. The Optimum–1 paradigm (Näätänen et al., 2004) focuses on auditory discrimination ability. Stimuli were presented with a constant SOA of 0.5 s. The Optimum–1 paradigm is suitable to detect MMN after five deviant types: duration, frequency, intensity, location, and a gap deviant. The paradigm presents 1,845 stimuli

in three 5 min blocks. Every second tone was a standard tone. Thus, the probability for the standard tone was 50% and the probability for each deviant type was 10%. For the formation of a standard tone as such, a sequence of 15 standard tones was presented at the beginning at each block.

The Memory Trace paradigm (in accordance to Grau et al., 1998) uses long 3 s ISI and was developed to investigate the auditory memory trace. A total number of 462 stimuli are presented within three blocks of 6 min each. The same standard tone, duration and frequency deviant as in the Optimum-1 paradigm were used in the Memory Trace paradigm. As in the Optimum-1 paradigm 15 standard tones were presented at the beginning of each block for the standard tone formation. One to three standard tones were presented between two deviant tones. The number of standard stimuli and the ISI between standard tone (0.5, 1.5, or 3 s) were assigned pseudo randomly. The ISI between standard stimuli and deviant tone was constantly 3 s. Standard stimuli were presented with 66.2% probability and each deviant tone with a probability of 16.9%.

#### **Detailed description of the stimuli**

The standard tone was a harmonic tone of three sinusoidal partials of 500, 1,000, and 1,500 Hz with the second partial being 3 dB and the third being 6 dB lower in intensity than the first partial. The standard tone was 75 ms in duration including 5 ms rise and fall times. The duration deviant was 50 ms shorter in comparison to the standard tone. The gap deviant comprised a 7 ms silent gap (including 1 ms fall and rise times) in the middle of the tone. One half of all frequency deviants were 10% higher (partials: 550, 1,100, and 1,650 Hz) and the other half 10% lower in frequency than the standard tone (partials: 450, 900, and 1,350 Hz). Intensity deviants were 10 dB louder or lower than the standard tone (50% each). The location deviants had an interaural time difference of 800  $\mu$ s to the left or to the right ear (50% each).

#### **MMN analysis**

For both paradigms the EEG data were bandpass filtered in the range of 1–35 Hz (24 dB/octave) and noisy channels were interpolated using the average method. Artifact-contaminated epochs were manually rejected. Finally, the data were re-referenced to the linked mastoids. As the largest MMN is often assessed at fronto-central EEG electrodes, and the averaging of electrodes with similar activity has been demonstrated to show more reliable results than the measure of single separate electrodes (Huffmeijer et al., 2014), the average voltage at FCz, Fz, and Cz was computed as mean MMN amplitude for all further analyses.

The number of averaged trials can influence the signal-to-noise ratio. Thus, to avoid these confounding effects, main analyses were repeated by building the  $\Delta$ MMN from 50 randomly selected artifact-free trials for each assessment and each subject.

#### **Calculation of $\Delta$ MMN**

The difference score  $\Delta$ MMN was defined by subtracting MMN after long ISI from MMN after short ISI, with higher values indicating less automatic auditory memory decay (cf., Laptinskaya et al., 2018). Thus, for the calculation of  $\Delta$ MMN the

MMN in both Optimum-1 and Memory Trace paradigms needed to be available. Since no MMN was observed after the frequency deviant in the Memory Trace paradigm in a previous study (Laptinskaya et al., 2018), we restricted the  $\Delta$ MMN analyses to the duration deviant. The dataset of one person was excluded from analyses, as no Optimum-1 data were available.

### **Assessment of Lifestyle**

For the assessment of lifestyle we used the Community Healthy Activities Model Program for Seniors (CHAMPS) Physical Activity Questionnaire for Older Adults (Stewart et al., 2001). The questionnaire describes 40 daily life activities, each assigned to a cognitively challenging (e.g., solving crossword puzzles, reading), physical (e.g., swimming, running), or social domain (e.g., meeting friends and family, calls with friends and family). Each activity was rated by three of the authors (PF, OCK, DL) on a five-point rating scale from 1 (*no demands*) to 5 (*high demands*). Activities with a rating score above three points were categorized to the respective domain (see **Supplementary Table 1**). Cronbach's  $\alpha$  for authors' ratings was very good:  $\alpha_{\text{Cronbach}} = 0.92$  for physical domain,  $\alpha_{\text{Cronbach}} = 0.86$  for cognitive domain, and  $\alpha_{\text{Cronbach}} = 0.95$  for social domain. The categorization was validated by ratings of 39 independent healthy older adults (MMSE  $\geq 26$ , aged 64–90). The comparison between authors' and seniors' ratings revealed very high correlations for all domains:  $r = 0.87$  for physical domain,  $r = 0.89$  for cognitive domain, and  $r = 0.84$  for social domain. If the chosen categories differed between authors and seniors the classification was adapted to the seniors' opinion. Finally, the cognitive domain comprised 14 activities, the physical domain 17 activities, and the social domain 13 activities. Twelve activities could not be assigned to any domain because of an overall loading under three points.

Study participants were asked which typical activities they perform within a 4-week span. For each domain the number of performed activities was divided by the number of potential activities in this domain. Subsequently, the domain values were averaged and the final average value was regarded as the index for lifestyle activity.

### **Training Interventions**

#### **Auditory Cognitive Training**

As CT we employed the German adapted version of the Brain Fitness software provided by the Posit Science Corporation (San Francisco, CA; for more detailed training tasks description see Küster et al., 2016). It consists of six tasks which target working memory and auditory processing. Each exercise lasted approximately 15 min. One training session included four out of six training tasks and took 1 h in duration. The training difficulty was automatically adapted according to the participant's task performance. Participants were asked to perform the 1-h session once a day, 5 days per week for a period of 10 weeks. Thus, the participants completed 50 training hours in total.

## Physical Training

The PT was carried out in groups consisting of 5–10 participants and involved aerobic, strength, flexibility, coordination, and balance elements. The training was based on a training program that has shown positive effects in nursing home residents (Thurm et al., 2011). Each group met twice a week for a 1-h session over a period of 10 weeks. The difficulty of the training was adapted by two instructors. Furthermore, the participants completed three fixed homework sessions per week of about 20 min each with the same exercise elements as the main training. Homework sessions were documented and regularly checked by the instructors. Thus, in total the participants completed 20 training hours in the group setting and 10 training hours at home.

## Wait-List Control Group

Participants in the WLC were asked to continue their daily routine as usual. After study participation, we offered them the participation in one of the training programs.

## Statistical Analyses

### General Procedure and Descriptive Statistics

All statistical analyses were carried out with *R* (version 3.2.3; R Core Team, 2016) in *RStudio* (RStudio Team, 2015). In group comparisons, all model residuals were normally distributed according to the Shapiro-Wilk normality test; therefore, parametric tests were applied. Baseline group differences in continuous variables (demographics and outcome measures) were evaluated with univariate analysis of variance (ANOVA) models with intervention group (CT, PT, and WCT) as between group factor. Differences in gender distribution were analyzed with Pearson's Chi-square ( $\chi^2$ )-test. Normal distribution of all models' residuals was confirmed using the Shapiro-Wilk test (*W* statistic) and visual inspection (Q–Q plots). The statistical significance level ( $\alpha$ ) was set to 0.05 for all analyses.

### Cognitive Progression of the Sample

These analyses were performed in accordance to Küster et al. (2016, p. 6, 8) and are repeated here to show the cognitive progression for the sample. The overall cognitive change was demonstrated for the cognitive component scores as well as for single test values. For this purpose, comparisons between post- and pre-training were performed. To adjust for possible retest effects, we calculated *z*-values based on baseline assessment for pre- and for post-training, respectively. Subsequently, the standardized post-value was subtracted from the pre-value and 95% confidence intervals were calculated. Finally, Group (CT vs. WLC and PT vs. WLC)  $\times$  Time (pre vs. post) as well as Lifestyle (continuous)  $\times$  Time interactions were performed for each cognitive outcome to test for possible differences in cognitive progression in dependence on group allocation or lifestyle. Training effects on cognitive progression were indicated by a significant Group  $\times$  Time interaction, while positive associations between lifestyle and cognitive change were indicated by a significant Lifestyle  $\times$  Time interaction.

## Lifestyle Global Coherence Association and Training Effects on Global Coherence

We evaluated the association between active lifestyle and change in global coherence as well as training effects on global coherence by employing linear mixed-effects models using the nlme package 3.1.119 (Pinheiro et al., 2011). The model included Group (CT vs. WLC and PT vs. WLC)  $\times$  Time (pre vs. post) as well as Lifestyle (continuous)  $\times$  Time interactions as fixed effects in the same model, and Subject as random intercept with Global coherence as dependent variable. Significant Group  $\times$  Time interactions reflected a training effect on global coherence, and significant Lifestyle  $\times$  Time interactions demonstrated an association between lifestyle and global coherence. Hedges' *g* was calculated by comparing the difference scores in the auditory cognitive or PT group and the control group, respectively. As secondary analyses, *t*-tests were carried out for pre-post comparison in global cognition for each group separately.

Nowadays, the most prominent coherence change has been reported for the fronto-temporal and fronto-parietal area. Thus, as supplemental analyses, the same linear mixed-effects model was used to assess training-induced effects and lifestyle-associated changes in fronto-temporal and fronto-parietal coherence.

### Training Effect on $\Delta$ MMN

As for global coherence, to explore training effects on  $\Delta$ MMN, a linear mixed-effects model was modeled. It was restricted to Group (CT vs. WLC and PT vs. WLC)  $\times$  Time (pre vs. post) as fixed effect with  $\Delta$ MMN as dependent variable because we focused on the effect of auditory CT on  $\Delta$ MMN and did not expect a positive effect of PT or a positive association between lifestyle and  $\Delta$ MMN. Significant lifestyle associations for the period of 10 weeks were revealed by a significant Lifestyle  $\times$  Time interaction, while training effects on EEG indices were indicated by a significant Group  $\times$  Time interaction. Hedges' *g* was calculated to show effect sizes for the training programs. Therefore, the *z*-standardized difference score between pre- and post-training was built for the two interventions as well as for the control group. Hedges' *g* was calculated by comparing the difference scores in the auditory cognitive or PT group and the control group, respectively. Positive effects indicate beneficial effects of the intervention.

The main analysis was repeated with  $\Delta$ MMN calculated from constant 50 trials (for rare exceptions see **Supplementary Presentation 1**) for each subject.

Again, as secondary analyses, *t*-tests for paired samples were performed for pre-post comparisons in  $\Delta$ MMN within each group.

### Follow-up-Assessment

In a final step, all linear mixed-effects models were repeated, including the follow-up analysis as a third time point in the model (pre vs. post and pre vs. follow-up) to account for possible long-lasting training effects.

**TABLE 1 |** Baseline characteristics and group comparisons for and between study groups.

SMI, subjective memory impairment; naMCI, non-amnesic mild cognitive impairment; aMCI, amnesic mild cognitive impairment; AD<sub>p</sub>, probable dementia; y., years; f., female; m., male; cs., component score. ΔMMN, the difference score between MMN for long and for short ISI for duration deviant. The data refer to complete sample without the exclusion of ΔMMN and global coherence missing data (see **Figure 1**). Data analyses accounting for the missing data did not change the results.

## RESULTS

### Mismatch Negativity Analysis

The number of trials was left for averaging in the Optimum-1 paradigm as well as in the Memory Trace paradigm can be found in the **Supplementary Material**.

### Group Comparisons at Baseline

At baseline, the three study groups (CT, PT, and WLC) did not differ in demographic variables, cognitive data, lifestyle data, and in EEG parameter (see **Table 1**).

### Cognitive Progression of the Sample

As already shown by Küster et al. (2016, p. 8), no positive training effects on cognition were found neither for the auditory cognitive nor for the PT program,  $ps \geq 0.08$  (see **Table 2**). In turn, participants who reported a more active lifestyle had a significantly better progression in global cognition and in memory functions over a period of 10 weeks in comparison to their less active counterparts,  $ps < 0.01$  (see **Table 2**).

### Lifestyle Global Coherence Association and Training Effects on Global Coherence

The mixed-effects model comprising Group × Time and Lifestyle × Time as fixed effects and Subject as random intercept with Global coherence as dependent variable revealed no significant associations between lifestyle and global coherence changes over a period of 10 weeks,  $F_{(1,43)} = 0.78$ ,  $p = 0.38$  (see **Figure 2**). The same model revealed no significant training effects on global coherence,  $F_{(2,43)} = 1.13$ ,  $p = 0.33$  (see **Figure 3**). Likewise, in comparison to the control group the Hedges' *g* was

negative for the cognitive, Hedges'  $g = -0.40$ , 95% CI [−1.14, 0.33],  $p = 0.29$ , as well as for the PT, Hedges'  $g = -0.32$ , 95% CI [−1.01, 0.37],  $p = 0.34$ . The secondary analyses did not show a significant change in global coherence over time within groups (see **Table 3**). The supplemental analysis with ΔMMN calculated from a constant number of 50 trials did no change the main results. The analyses regarding the fronto-parietal and fronto-temporal area did not reveal significant training-induced effects and lifestyle-associated changes in coherence (see **Supplementary Table 2**).

### Training Effect on ΔMMN

Also, for ΔMMN no significant auditory CT effect was found,  $F_{(2,39)} = 0.10$ ,  $p = 0.90$  (see **Figure 3**). In comparison to the control group the auditory CT did not show beneficial impact on ΔMMN, Hedges'  $g = 0.14$ , 95% CI [−0.67, 0.95],  $p = 0.79$ . The 50 trials' analyses for ΔMMN did not change the results. The *t*-test as secondary analysis did not reveal a significant pre-post change for ΔMMN (see **Table 3**).

Also, the *t*-test analyses did not reveal significant alterations in global coherence and ΔMMN within the 10-week period in any of the groups (see **Table 3**).

### Follow-Up-Assessment

No significant relationships between lifestyle and change in global coherence as well as significant training effects were found after including the follow-up assessment into the model.

## DISCUSSION

This study aimed at investigating the association between an active lifestyle and changes in global coherence in a sample at-risk

**TABLE 2 |** Cognitive changes and group effects on cognition as well as lifestyle cognition associations over time (cf. Küster et al., 2016, p. 8).

Depicted are the mean differences in cognitive measures between pre- and post-training within the three groups and 95% confidence intervals in brackets, as well as statistics for Group × Time and Lifestyle × Time interactions. cs., component score; ADAS, Alzheimer's Diseases Assessment Scale; MVGT, German adaptation of the California Verbal Learning Test; ECB, Everyday Cognition Battery; TMT, Trail Making Test (part A and B).

Values are z-standardized on the basis of baseline cognitive assessment.

for developing dementia. Furthermore, we examined the effects of a cognitive and a PT program on global coherence and the effects of auditory CT on  $\Delta$ MMN-Dur as an index for automatic auditory memory decay.

## Lifestyle Association With Global Coherence

We did not find an association between self-reported lifestyle and changes in global coherence during a period of 10 weeks in older adults at risk for developing dementia. Thus, there is no evidence that global coherence is an underlying mechanism of lifestyle-related cognitive benefits, which were previously reported by several studies including our working group. This finding is not

in line with studies reporting positive effects of an enriched environment on neuronal plasticity in animals (e.g., Fabel and Kempermann, 2008; for a review see Kramer et al., 2004), as changes in functional connectivity have been attributed to neuronal structural and functional changes. Notably, the majority of studies investigating the effects of an enriched environment on neuroplasticity reported positive effects for separate areas, while in the present study global changes in functional connectivity were considered. Thus, a possible explanation for the discrepancy in results might be the fact that lifestyle-dependent functional neuroplasticity takes place in individual brain regions or in separate frequency bands and is not reflected by a global coherence score. Finally, the observation period of 10 weeks might have been too short to show significant effects.

## Training Effects on Global Coherence

Contrary to previous results reporting positive training effects on functional connectivity (Voss et al., 2010; Anguera et al., 2013; Klados et al., 2016; Zilidou et al., 2018), we did not find any effects of cognitive or PT interventions on global coherence. So far, only few studies investigated training impacts on functional connectivity. Even if the aforementioned results by previous studies are promising, several methodological differences in investigation tool (functional magnetic resonance imaging, EEG), study sample (healthy adults, cognitively impaired adults), regions of interest (separate regions vs. global connectivity), and training programs make the comparison of study results difficult.

One important factor might be the duration of training. In a functional magnetic resonance imaging study Voss et al. (2010) investigated the effect of aerobic walking training on the default mode network in healthy older adults. Interestingly, the authors reported enhanced coherence in several regions of the default mode network only after a 12-month training period, while the effects were not significant after 6 months. Stronger DMN connectivity was associated with better executive control after training. Consequently, the training period in the present study might have been too short to tap functional neuroplasticity.

In recent years, there is a growing interest in combined training interventions (e.g., Fissler et al., 2013;

**TABLE 3 |** Electroencephalography raw data comparisons between pre- and post-training.

	<i>n</i>	Pre-training	Post-training	<i>t</i> statistic	<i>p</i>
<b>Global coherence</b>					
Cognitive Training	14	0.36 $\pm$ 0.12	0.35 $\pm$ 0.18	$t_{(13)} = 0.08$	0.93
Physical Training	17	0.29 $\pm$ 0.18	0.31 $\pm$ 0.17	$t_{(16)} = -1.04$	0.31
Wait-list control	18	0.29 $\pm$ 0.10	0.36 $\pm$ 0.14	$t_{(17)} = -2.21$	0.04
<b><math>\Delta</math>MMN</b>

The *t*-values represent the results of paired samples *t*-tests.

$\Delta$ MMN, the difference score between MMN for long and for short ISI for duration deviant.

Herold et al., 2018). Styliadis et al. (2015) found positive effects on MMSE scores only for the combination of an 8-week physical and auditory CT and not for interventions of physical or auditory CT alone. Furthermore, the cognitive improvement was associated with an elevated power in delta and theta band activity which has been shown to be positively associated with neurodegeneration (e.g., Stevens et al., 2001; Adler et al., 2003; Babiloni et al., 2009). Using low resolution brain electromagnetic tomography, Klados et al. (2016) examined the same combined training program used by Styliadis et al. (2015) on EEG coherence and found a widespread training induced elevated beta band activity to enhanced neuroplasticity (Styliadis et al., 2015; Klados et al., 2016). Enhanced functional connectivity as a result of neuroplasticity has also been supported by other authors (e.g., Frantzidis et al., 2014; Zilidou et al., 2018). Oswald et al. (2006) offer an explanation for the effectiveness of the combination of physical and auditory CT and conjectured that physical activity drives neuroplasticity induced by cognitively demanding activities through improved metabolic processes. Therefore, the combination of both of the training programs used in the present study might have yielded significant effects, especially because Styliadis et al. (2015) and Klados et al. (2016) used the adapted Greek version of the same auditory CT program that was applied in the present study. Furthermore, similarly to the results for lifestyle, it is also possible that particular brain networks, such as the DMN, and separate frequency bands, such as the beta band, are more sensible to training effects than the global scores (cf., Klados et al., 2016).

### Training Effects on $\Delta$ MMN-Dur

In contrast to our hypothesis, we did not find significant auditory CT effects on  $\Delta$ MMN-Dur. We based our expectation on previous results reporting positive associations between MMN as an index for automatic discrimination ability and the persons' ability to discriminate changes between sounds or sound sequences. For instance, musicians, who are more capable to discriminate tones in comparison to non-musicians, also showed a larger MMN; their automatically elicited MMN-amplitude was associated with better discrimination performance. Furthermore, an enhanced MMN has been shown to be associated with linguistic skills in young subjects (Tremblay et al., 1997; Kujala et al., 2001; Cheour et al., 2002). It has to be noted that learning a new instrument or a new language might be more intrinsically motivating as exercising an auditory training program. Furthermore, studies on musicians focused on long lasting exercise periods; therefore the comparison to the present 10-week training period is limited. As for the MMN as a marker for linguistic skills, the corresponding studies have been conducted with children or very young adults. Even if the human brain has been shown to stay neuroplastic up to old age (e.g., Gutchess, 2014), neuroplasticity becomes more difficult in advanced age due to age-associated neuronal changes, for example, the neuronal atrophy or hemispheric asymmetry reduction (Oberman and Pascual-Leone, 2013).

While, to our best knowledge, no study exists that investigated the effects of auditory CT on MMN in the field of cognitive aging, more research exists for subjects with schizophrenia or schizophrenia-spectrum illnesses. Persons with schizophrenia-spectrum illnesses show pronounced cognitive deficits. Similar

to AD, cognitive deficits in schizophrenia have been shown to be associated with a decreased MMN (e.g., Hermens et al., 2010) and furthermore with functional disability (e.g., Hamilton et al., 2018). Recent studies examined whether auditory training might improve cognition in subjects with schizophrenia and whether the positive changes are accompanied by an improved MMN. In line with the missing training-induced results in the present study, the authors did not find any positive training effects on MMN using the adapted version of the same training as applied in the present study (Kärgel et al., 2016; Biagiante et al., 2017). Some authors even report an attenuated MMN after auditory training in schizophrenia patients (Perez et al., 2017).

These results indicate that some other factors than the auditory training per se might be responsible for the intervention's success. In this context, Chandrasekaran and Kraus (2010) noted that we learn best about things that we care about, thus the intrinsic motivation, enjoyment, and fun of the training might be of high relevance (cf. also, Küster et al., 2016). These factors might be higher for learning a new instrument or language than for a computer-based relative monotonous training program. Furthermore, the training duration in the aforementioned studies ranged between a single 1-h session (Perez et al., 2017), 2-week training period (Kärgel et al., 2016), 8-week training period (Biagiante et al., 2017), and 10 weeks of training intervention in the present study. Thus, besides the training's contents and motivational aspects, the missing effect of training in the present study might be explained by the training's duration.

## STRENGTHS AND LIMITATIONS

Since global coherence is a global marker measured over the whole skull, it is more reliable as the measure of EEG coherence for separate pairs of electrodes.  $\Delta$ MMN-Dur as a difference score between MMN for long and for short interstimulus interval is a novel EEG marker which takes different auditory processing aspects into account, such as auditory discrimination ability as well as the automatic auditory memory trace (Näätänen et al., 2012) and is correlated with cognitive performance (Laptinskaya et al., 2018).

Also, the following limitations have to be considered: in our previous research we found a positive lifestyle cognition association but no positive training effects on behavioral measures of cognition. Thus, training-induced electrophysiological changes might be difficult to detect. However, other authors reported positive training effects despite the missing of significant benefits in neuropsychological testing (cf., Miró-Padilla et al., 2020). Random allocation is the best method to prevent selection bias. Due to logistic issues, a randomized allocation to the groups was not feasible. Thus, we chose the minimization approach in order to control for bias regarding age, gender, education, and cognitive status reflected by MMSE. Although, selection bias cannot be excluded, we assume that it was unlikely: there were no differences in sociodemographic data, cognition, or EEG parameters

between groups. Finally, the small sample size might be a further limitation.

In the coherence analyses as a measure for functional connectivity, the interactions between brain regions are considered as linear connections, although there are indications that at least some of the interactions between brain regions may have a non-linear component (Rombouts et al., 1995). An often-used non-linear measure for functional connectivity is the synchronization likelihood (SL). In a magnetoencephalography study, Gómez et al. (2009) compared the accuracy of coherence as well as SL to discriminate healthy older adults without cognitive deficits from subjects with MCI. Interestingly, the authors reported a better accuracy for the linear coherence measure. Thus, we assume that coherence analysis is a suitable method to investigate functional connectivity in the present sample at-risk for developing AD.

## CONCLUSION

In the light of the results of the present study as well as the review of the previous literature, we conclude that training interventions focusing on only one training aspect are not very powerful to generate positive effects on global EEG coherence. Instead, multimodal interventions taking physical and cognitive as well as motivational and emotional aspects into account seem to be more promising. Notably, this sort of intervention is very similar to an active lifestyle, which has been shown to be related to positive cognitive change.

Since, the auditory training did not reveal positive effects on  $\Delta$ MMN-Dur as an index for automatic auditory memory decay, we suggest that other training parameters such as longer training periods and more intrinsically motivating as well as joyful approaches might be more suitable to tap the automatic auditory memory trace in EEG.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ulm University and the University of Konstanz. The participants provided their written informed consent to participate in this study.

## AUTHOR CONTRIBUTIONS

DL contributed to the study conception and design, organized the study procedures and acquired the data, analyzed and interpreted the data, and wrote the first draft of the manuscript. FT contributed to the study conception and design,

organized study procedures, acquired the data, contributed to the data analysis, and critically revised the first draft of the manuscript. PF and OK contributed to the study conception and design, organized the study procedures and acquired the data, contributed to the data interpretation and critically revised the manuscript. CA and I-TK conceptualized the study, obtained funding, supervised all phases of the study as principle investigators and critically revised the manuscript. All authors read and approved the final manuscript.

## FUNDING

This research was funded by the Heidelberg Academy of Sciences and Humanities, Germany. During the data collection, I-TK was a fellow (now alumna) of the Zukunftscolleg of the University of Konstanz, Germany. The funders had no role in study design, data collection, analysis and interpretation of the data, writing the manuscript, or decision to submit the manuscript for publication.

Alzheimer's Disease (AD), the leading cause of senile dementia, is a progressive neurodegenerative disorder affecting millions of people worldwide and exerting tremendous socioeconomic burden on all societies. Although definitive diagnosis of AD is often made in the presence of clinical manifestations in late stages, it is now universally believed that AD is a continuum of disease commencing from the preclinical stage with typical neuropathological alterations appearing decades prior to its first symptom, to the prodromal stage with slight symptoms of amnesia (amnestic mild cognitive impairment, aMCI), and then to the terminal stage with extensive loss of basic cognitive functions, i.e., AD-dementia. Positron emission tomography (PET) radiotracers have been developed in a search to meet the increasing clinical need of early detection and treatment monitoring for AD, with reference to the pathophysiological targets in Alzheimer's brain. These include the pathological aggregations of misfolded proteins such as  $\beta$ -amyloid ( $A\beta$ ) plaques and neurofibrillary tangles (NFTs), impaired neurotransmitter system, neuroinflammation, as well as deficient synaptic vesicles and glucose utilization. In this article we survey the various PET radiotracers available for AD imaging and discuss their clinical applications especially in terms of early detection and cognitive relevance.

**Keywords:** PET, neuroimaging, Alzheimer's disease, radiotracer, clinical research

## INTRODUCTION

Alzheimer's Disease (AD), the leading cause of senile dementia, is a progressive neurodegenerative disorder affecting millions of people worldwide and exerting tremendous socioeconomic burden on all societies (Goedert and Spillantini, 2006; Querfurth and LaFerla, 2010). AD is neuropathologically characterized by deposition of senile plaques and neurofibrillary tangles in the brain tissue. Excessive aggregation of misfolded  $\beta$ -amyloid ( $A\beta$ ) and hyperphosphorylated tau proteins leads to cytotoxicity and disruption of cytoarchitecture, and subsequent neuronal death and brain function decline. Neuroinflammation activation, cholinergic deficit, impaired glucose utilization and synaptic dysfunction are also outstanding characteristics of AD. Functional neuroimaging using positron emission tomography (PET) is able to reveal these *in vivo* pathological/pathophysiological alterations. With increasing viewpoint of AD as a continuum from asymptomatic preclinical stage, to prodromal stage with mild cognitive impairment (MCI), and finally to the advanced stage of dementia, integrated early diagnostic and differentiation paradigms with the help of PET imaging has been well-acknowledged in multiple diagnostic criteria (Dubois et al., 2007, 2014; Jack et al., 2011). In this review article, we describe the various PET radiotracers

available for AD imaging and discuss their clinical applications especially in terms of early detection and cognitive relevance. Literature evidence on the predictive ability of PET imaging with various PET tracers for prodromal stage conversion and monitoring of disease progression will also be reviewed. Finally, comments on emerging biomarkers and their prospects in early detection of AD will be provided.

## PET TRACERS FOR IMAGING A $\beta$

### Overview

The disturbance of homeostasis between the accumulation of neurotoxic A $\beta$  peptides and its clearance in the brain is believed to be the core event in AD etiology (Hardy and Allsop, 1991; Hardy and Higgins, 1992). The A $\beta$  peptides are derived from the breakdown of amyloid precursor protein (APP) through cleavage by  $\beta$ - and  $\gamma$ -secretase. The soluble oligomers, believed to be the perpetrator of cytotoxicity, are aggregated by longer species of the A $\beta$  peptides such as A $\beta_{40}$  and A $\beta_{42}$  released into the extracellular space. The accumulation of A $\beta$  peptides, from neurotoxic oligomers to further aggregated insoluble  $\beta$ -sheet fibrils and dense fibrillary plaques, is believed to underlie subsequent neurofibrillary tangle formation and neuronal loss, which precede the onset of clinical symptoms by more than 10–15 years (Hardy and Gwinn-Hardy, 1998; Hardy et al., 1998). However, confirmation of AD neuropathology has long relied on immunohistochemical staining of A $\beta$  aggregates in postmortem autopsy tissues. Since the early 2000s, the availability of antemortem *in vivo* PET imaging with A $\beta$  radiotracers has greatly advanced our knowledge on the time course and correlation of A $\beta$  aggregation, AD progression, and cognitive decline, and revolutionized AD diagnosis.

### Tracer Development

The search for A $\beta$  imaging tracers dated back to the mid-1990s, culminated in the first *in vivo* imaging of A $\beta$  in an AD patient in 2002 with the  $^{11}\text{C}$ -labeled Pittsburgh compound B ( $^{11}\text{C}$ ]PIB, **Figure 1**), which is derived from the A $\beta$  staining agent thioflavin-T (Klunk et al., 2004).  $^{11}\text{C}$ ]PIB has a relative high selectivity for A $\beta$  of all forms from soluble oligomers to insoluble fibrils and plaques over other pathological proteins such as tau and

$\alpha$ -synuclein. Both visual inspection and quantitative analysis demonstrated higher cortical retention in AD patients than in cognitively intact subjects, especially in the orbitofrontal cortex, inferior parietal cortex, posterior cingulate cortex and precuneus, which resembled the pattern found in immunohistochemical studies (Rowe and Villemagne, 2011). To date,  $^{11}\text{C}$ ]PIB is still the best and most widely used A $\beta$  PET tracer and regarded as the gold standard.

The short radioactive half-life of  $\sim 20$  min for the carbon-11 nuclide limits the use of  $^{11}\text{C}$ ]PIB to institutions with on-site cyclotrons, thus inspiring the development of  $^{18}\text{F}$ -labeled A $\beta$  radiotracers. Three of such tracers with favorable binding and imaging properties,  $^{18}\text{F}$ ]florbetapir ( $^{18}\text{F}$ ]AV-45),  $^{18}\text{F}$ ]florbetaben ( $^{18}\text{F}$ ]AV-1,  $^{18}\text{F}$ ]BAY-94-9172), and  $^{18}\text{F}$ ]flutemetamol ( $^{18}\text{F}$ ]GE-067) (**Figure 1**), have since been approved by the United States Food and Drug Administration (FDA) for clinical diagnosis and differential diagnosis of AD (Barthel et al., 2011; Lister-Jones et al., 2011; Curtis et al., 2015).  $^{18}\text{F}$ ]NAV4694 ( $^{18}\text{F}$ ]AZD4694), another promising  $^{18}\text{F}$ -labeled tracer with rapid pharmacokinetics and lower non-specific binding in the cerebral white matter, is now in clinical trials (Cselenyi et al., 2012; Theriault et al., 2021). These tracers, with longer radioactive half-life of  $\sim 110$  min, are suitable for long-distance distribution and thus can be more widely used in the clinics. They are presumed to yield less noisier images and therefore more precise quantitation of minute cerebral A $\beta$  accumulation in the early stage of the disease, due to more abundant radioactivity counts in the later period of scan. Notably, imaging protocols provided for each tracer are quite different from one another in terms of scanning window as well as visual interpretation and quantitative analysis of the images (Mallik et al., 2017).

### Imaging Research Findings and Clinical Relevance

In general, cortical A $\beta$  retention detected by PET imaging is in good correlation with immunohistochemical staining of amyloid plaques at autopsy or biopsy brain samples (Clark et al., 2012; Rinne et al., 2012; Curtis et al., 2015; Sabri et al., 2015a). This qualifies the application of A $\beta$  PET imaging as a non-invasive tool for *in vivo* detection of cortical A $\beta$  deposition

**FIGURE 1** | Structures of representative PET radiotracers for A $\beta$  imaging.

in the living brain. In the clinical daily-routine context, A $\beta$  PET imaging provides plenty valuable information for the purpose of differential diagnosis between AD dementia and dementia disorders associated with non-A $\beta$  pathologies such as frontotemporal lobe dementia (FTLD), which is sometimes indistinguishable from AD by neuropsychological assessments and conventional structural imaging modalities only (Rowe et al., 2008).

On the other hand, it has been emphasized that an amyloid-positive PET merely reflects the existence of amyloid neuropathology *in vivo* and does not necessarily guarantee a diagnosis of AD, concerning the fact that many otherwise cognitively normal subjects (even young healthy volunteers) have been found to be amyloid-positive judging from PET results, and that cognitive decline is more likely due to factors other than amyloid pathology in dementia with Lewy bodies (DLB) or in some co-morbid situations (Johnson et al., 2007; Ossenkoppele et al., 2015; Petrou et al., 2015). It has also been debated whether a negative amyloid scan could exclude the possibility of AD (Jack et al., 2016), since evidence of neurodegeneration in the absence of amyloid pathology challenges the proposed AD progression scheme (Sperling et al., 2011).

The ability of PET imaging with A $\beta$  tracers to predict conversion from MCI due to AD, the prodromal stage of the disease defined by different diagnostic guidelines (McKhann et al., 2011; Dubois et al., 2014), to AD dementia has also been extensively investigated. Roughly 70% of amyloid-positive MCI patients converts to AD dementia within 3 years (Okello et al., 2009a). As compared to [ $^{18}$ F]FDG PET, amyloid PET has higher sensitivity but relatively lower specificity (Teipel et al., 2015), which is consistent with the finding that amyloid accumulation commences at least a decade before the worsening of synaptic activity and brain function to a clinically significant level where amyloid deposition reaches a plateau (Jack and Holtzman, 2013; Jack et al., 2013a). Correlation of A $\beta$  retention to cognitive performance has been shown to be greater in MCI and cognitively intact subjects than in AD dementia patients (Pike et al., 2007, 2011; Villemagne et al., 2008), which could also be explained by the hypothesized plateau model. Therefore, it is not surprising that regional hypometabolism and amyloid deposition in the temporoparietal regions are closely associated with each other whereas those in the frontal lobe, a region affected only in advanced AD, are not (Edison et al., 2007; Cohen et al., 2009).

The significance of A $\beta$  PET in subjects without objective evidence of cognitive decline is emerging most recently. Large-scale comprehensive studies have shown that A $\beta$  positivity is linked to high progression risk in subjective cognitive decline (SCD) and is associated with age and family history other than sex, education, marital or retirement status and self-reported lifestyle factors (Papp et al., 2020; Sperling et al., 2020). Longitudinal follow-up studies suggest that the duration of A $\beta$  existence might be more important than age or binary result in affecting both deteriorating rate and the final status of cognition through elevated entorhinal tau burden (Hanseeuw et al., 2019; Kosciak et al., 2020). Even if A $\beta$  burden detected by PET is below threshold, its value is still positively correlated to the subject's future risk of cognitive decline (Guo et al., 2020).

## The Centiloid Scaling Project

As the utilization of amyloid PET in clinical trials and research expands and multiple tracers are available for such imaging applications, the urgent need for inter-tracer standardization and for multi-center collaboration and longitudinal comparison drove the launch of the centiloid scaling project (Klunk et al., 2015). According to the concept of the project, one institute can follow a multi-step regime to create a scaling from 0 (young healthy controls) to 100 (typical AD patients) using its own amyloid PET data (Rowe et al., 2016). In this way a universal cutoff value could then be directly or indirectly applied in multi-center imaging and/or longitudinal studies to allow for inter-site/inter-tracer comparisons. The study group of the centiloid project has now made progress in the derivation and verification of converting formula, enabling the translation of non-[ $^{11}$ C]PIB A $\beta$  PET semi-quantitative values to standardized [ $^{11}$ C]PIB counterparts (Rowe et al., 2017; Battle et al., 2018; Bourgeat et al., 2018; Navitsky et al., 2018). The authenticity of the centiloid approach has been confirmed neuropathologically (Amadoru et al., 2020).

## Discussion

The amyloid cascade theory has been the predominant theory of AD etiology and drove the development of anti-A $\beta$  therapeutics in the last 3 decades. The availability of A $\beta$  PET imaging tracers and its applications in AD imaging have indicated that amyloid pathology may be a high risk factor for future cognitive decline. However, increasing evidence also indicates that cortical amyloid is not specific for the presence of cognitive symptoms, thus affecting the positive predictive value of A $\beta$  PET imaging. Among populations without dementia, the prevalence of cerebral amyloid pathology as determined by A $\beta$  PET imaging or cerebral spinal fluid (CSF) A $\beta$  measurement is associated with age (Jansen et al., 2015), e.g., 33% of healthy elderly individuals have significant levels of A $\beta$  deposition without apparent clinical symptoms (Rowe et al., 2010). Therefore, A $\beta$  deposition alone cannot explain AD pathogenesis and progression. Repeated failures of clinical trials for many anti-A $\beta$  drug candidates have dampened the hope for their efficacy as disease-modifying therapeutics. Nonetheless, it should be kept in mind that A $\beta$  PET imaging will still remain the gold standard to investigate disease mechanisms as it provides information regarding the topography of A $\beta$  lesions. Although there have been no successful anti-A $\beta$  drugs up to date, A $\beta$  PET imaging has provided useful outcome measures for anti-A $\beta$  therapeutics in clinical trials (Salloway et al., 2014; Honig et al., 2018; Wessels et al., 2020).

## PET TRACERS FOR IMAGING TAU TANGLES

### Overview

In addition to the  $\beta$ -amyloid peptides, microtubule-associated protein tau (MAPT), or simply tau protein, together with its misfolded products, has been more thoroughly studied in recent years to explore its relationship with AD. Similar to the case of senile plaques formed by A $\beta$ , the formation of neurofibrillary tangles (NFTs) by paired helical filaments (PHFs)

is also a neuropathological hallmark of AD (Braak and Braak, 1997). PHFs are aggregated by misfolded hyperphosphorylated tau protein whose binding affinity with the microtubules is weakened, causing neuronal cytoarchitecture breakdown and dysfunction (Hoover et al., 2010; Spillantini and Goedert, 2013).

With the repeated failures of anti-A $\beta$  therapeutics in large scale clinical trials, the focus was shifted from A $\beta$  to tau on the development of AD therapeutics and imaging agents (Giacobini and Gold, 2013). However imaging tau *in vivo* is more challenging than imaging A $\beta$ . Tau protein has six unique isoforms characterized by the number of repeats of its microtubular binding domains, and multiple secondary/tertiary structures differentiated by the shape of the filaments (Spillantini and Goedert, 2013). In addition to its much lower abundance compared to A $\beta$  peptides in the brain, MAPT's intraneuronal property demands the qualified tracer to cross neuron cell membrane in addition to the blood brain barrier. These factors collectively hamper the screening and identification of sensitive and specific compounds. Nevertheless, substantial progress has been made in overcoming these inherent obstacles, and preliminary studies have shown encouraging results worthy of the efforts (Hall et al., 2017; Leuzy et al., 2019).

## Tracer Development

PET imaging of fibrillary tau traced back to about the same time for amyloid, with [ $^{18}\text{F}$ ]FDDNP arguably as the earliest tracer (Agdeppa et al., 2001). Indeed, this tracer labels both amyloid plaques and fibrillary tau tangles *in vivo*, but this property is also its biggest disadvantage, as it has comparable affinity for both amyloid and tau proteins, i.e., a lack of selectivity for either

target. The first selective tau tracer [ $^{18}\text{F}$ ]THK523 was developed by Tohoku University of Japan in 2005 (Okamura et al., 2005). Later structural modifications led to the development of other tracers in the THK family: [ $^{18}\text{F}$ ]THK5105, [ $^{18}\text{F}$ ]THK5117, [ $^{18}\text{F}$ ]THK5317, and [ $^{18}\text{F}$ ]THK5351, with improved binding and *in vivo* pharmacokinetic properties (Okamura et al., 2013; Chiotis et al., 2016; Betthausen et al., 2017). However, tracers in this family were later found to have notable off-target binding to monoamine oxidase-B (MAO-B), which greatly limited their utility in imaging of tauopathies including AD (Ng et al., 2017).

[ $^{18}\text{F}$ ]Flortaucipir ([ $^{18}\text{F}$ ]AV1451, or formerly [ $^{18}\text{F}$ ]T807) is currently the most applied and the only FDA-approved tau radiotracer (Figure 2) (<https://www.fda.gov/drugs/drug-approvals-and-databases/drug-trial-snapshot-tauvid>). It has a 25-fold higher affinity for tau than A $\beta$ , as well as favorable kinetics for both uptake and washout in the brain without radioactive metabolites penetrating the blood-brain-barrier (Xia et al., 2013). [ $^{18}\text{F}$ ]flortaucipir has higher affinity to PHFs over straight filaments (SF), and to combined 3-repeat (3R) and 4-repeat (4R) isoforms over 3R or 4R isoforms alone, making it more suitable for imaging AD pathology than non-AD tauopathies such as progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD) (Lowe et al., 2016). It is noted that suspected minor off-target binding to MAO-A in the basal ganglia and substantia nigra would limit the application of [ $^{18}\text{F}$ ]flortaucipir in imaging Parkinsonian tauopathies (Ono et al., 2017).

[ $^{11}\text{C}$ ]PBB3 is another selective tau tracer that has also been thoroughly studied in various tauopathies including AD (Figure 2). [ $^{11}\text{C}$ ]PBB3 binds to both 3R and 4R tau isoforms

FIGURE 2 | Structures of representative PET radiotracers for tau imaging.

and its affinity for tau is over 40 times higher than that for amyloid, making it suitable for imaging of various tauopathies *in vivo* (Kimura et al., 2015). Minor structural modifications then afforded [ $^{18}\text{F}$ ]APN-1607 (PM-PBB3) and [ $^{18}\text{F}$ ]AM-PBB3, the next generation members of the PBB3 family. [ $^{18}\text{F}$ ]APN-1607, (**Figure 2**) has recently been reported to possess more favorable pharmacokinetics and provide higher gray-matter/white-matter contrast (Hsu et al., 2020; Su et al., 2020; Tagai et al., 2021).

The clinical development of several newer, second generation selective tau tracers are ongoing, including [ $^{18}\text{F}$ ]PI2620, [ $^{18}\text{F}$ ]MK6240, [ $^{18}\text{F}$ ]GTP1, [ $^{18}\text{F}$ ]RO-948 (RO6958948), [ $^{18}\text{F}$ ]JNJ-311 (JNJ64349311), and [ $^{18}\text{F}$ ]JNJ-067 (JNJ-64326067) (**Figure 2**). Designers of these new generation tracers are focusing on improving *in vivo* characteristics such as higher selectivity, faster brain penetration/washout, and less off-target binding. Preliminary studies for these newer tracers have shown promising results (Declercq et al., 2017; Kuwabara et al., 2018; Guehl et al., 2019; Rombouts et al., 2019; Teng et al., 2019; Schmidt et al., 2020).

Off-target binding has been a universal concern for tau tracers since the early [ $^{18}\text{F}$ ]FDDNP was found to be non-selective to both amyloid and tau (Thompson et al., 2009). In PET imaging of neurodegeneration, selectivity of tau tracers over other pathological proteins such as A $\beta$ ,  $\alpha$ -synuclein, and TDP-43 would always require validation. Similarity of the secondary/tertiary structures of the binding sites of these proteins makes it difficult to find a truly selective and specific probe, not to mention the complexity introduced by potential comorbidity of the neurodegenerative disorders. In addition, off-target binding in the central nervous system (CNS) has been widely examined across the tau tracers. It is now known that MAO-A and MAO-B are the most frequent off-targets whose secreting neurons are highly overlapped with Parkinsonism-related brain regions (Lowe et al., 2016; Bischof et al., 2017; Okamura et al., 2018). Choroid plexus is frequently found to be a tissue with apparent off-target binding, the mechanism of which is yet unclear (Ikonovic et al., 2016). It is postulated that melanin, neuromelanin, mineralized structures and hemorrhagic lesions can also cause off-target binding of tau tracers in various locations. There is also debate that the suspected “off-target” binding may be reflecting true tau-binding, or binding to some specific targets yet to be identified (Ikonovic et al., 2016; Passamonti et al., 2017). These characteristics pose substantial difficulties to clinical differentiation and potential post-treatment evaluation (Passamonti et al., 2017).

Recent cryo-electron microscopic structure discoveries of AD tau filaments may provide new insights for the binding interactions between various tau tracers and tangles, and spur refinements on the design of novel, subtype-selective tau tracers (Fitzpatrick et al., 2017).

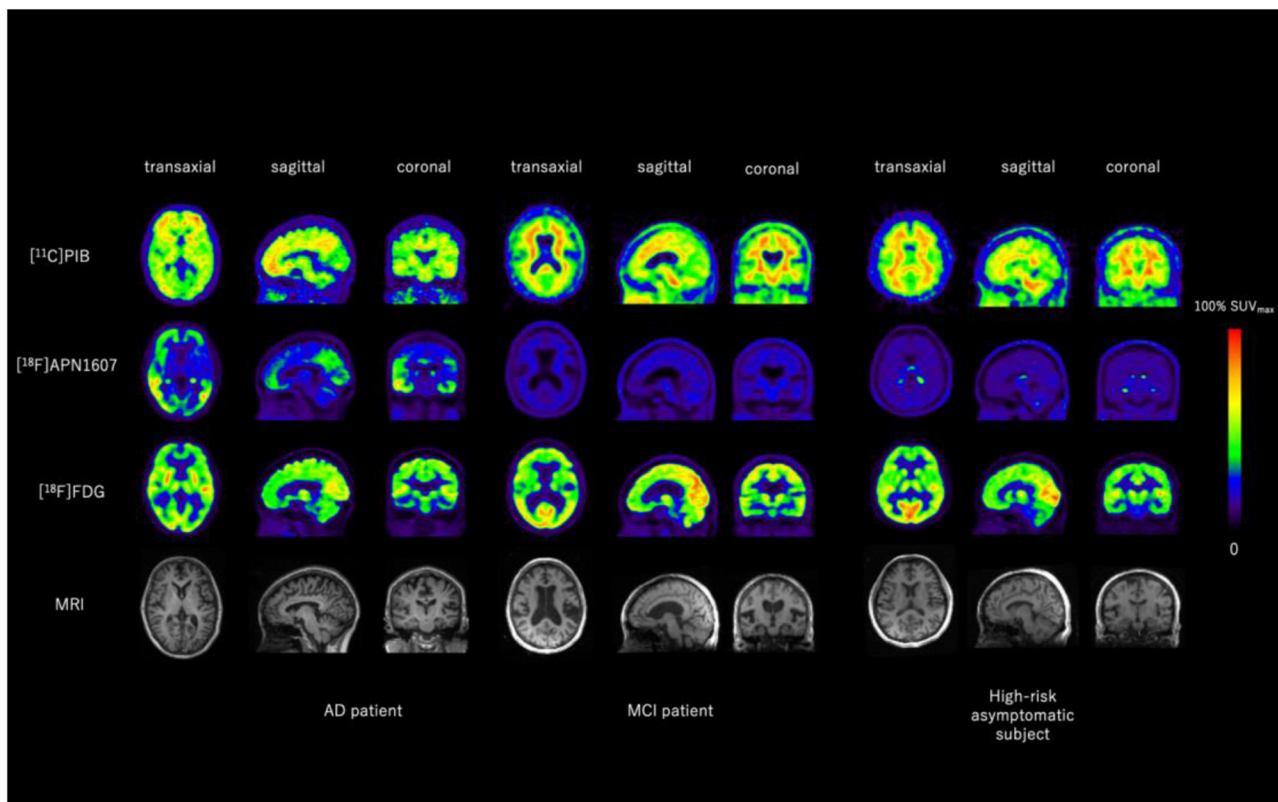

## Imaging Research Findings and Clinical Relevance

According to the amyloid cascade hypothesis, neurodegeneration characterized by misfolded tau tangle aggregation is the downstream event secondary to major amyloid deposition (Jack

et al., 2013b). In contrast to the globally elevated pattern seen in brain amyloid PET of AD dementia patients, the spatiotemporal distribution of tau tracers follows a typical neuropathological sequence of spreading (Braak's stage), as have been demonstrated in both cross-sectional and longitudinal studies in a wide-range of subjects from advanced AD dementia patients to cognitively intact elderly controls (Rabinovici and Jagust, 2009; Johnson et al., 2016; Wooten et al., 2017; Villemagne et al., 2018). This quantitative and sequential connection indicates that this *in vivo* tangle spreading trajectory may reflect not merely neuronal dysfunction but also disease progression. In parallel to postmortem immunohistochemical findings, *in vivo* tau deposition varies amongst the brain regions, starting from the medial temporal lobe, i.e., hippocampus and entorhinal cortex (Braak stage I–II), to the adjacent neocortices (Braak stage III–IV), and finally to the entire brain (Braak stage V–VI) (Cho et al., 2019; Leuzy et al., 2019; Baek et al., 2020; Fleisher et al., 2020). As expected, clinical manifestation of AD is closely related to tau retention in the responsible brain regions. For instance, while temporal lobe deposition correlates well with memory performances, frontal lobe retention strongly correlates with execution and global cognition (Ossenkoppele et al., 2016; Bejanin et al., 2017; Shimada et al., 2017).

According to current experience with all the available tau tracers, AD is not likely to be the diagnosis of a tau-negative individual, while non-tauopathies can be basically excluded from the cause of cognitive decline for a tau-positive individual (Bischof et al., 2017). Non-AD tauopathies such as FTL, PSP and CBD, however, manifest different distribution patterns and trajectory from AD involving different sub-regions in the brain stem and basal ganglia as well as cortical regions, which could be of additional differential diagnostic value in the clinical context (Bischof et al., 2017; Leuzy et al., 2019). Recently, tau deposition in cognitively intact healthy elderly subjects has also been revealed by PET and confirmed by autopsy results. This phenomenon is coined primary age-related tauopathy (PART) and believed to produce only minute, if any, clinical symptoms (Crary et al., 2014). In the absence of amyloid, PART alone is believed to be insufficient to develop memory decline (Harrison et al., 2019). Its relationship to suspected non-amyloid pathology (SNAP) has also been proposed, which presumably underlies the preclinical abnormalities during the development of AD (Jack, 2014).

Hypometabolism in brain regions that are commonly affected in advanced AD, including posterior cingulate cortex, precuneus and temporoparietal association cortex, represents synaptic dysfunction of the neurons in the course of AD (see below section on FDG imaging of glucose metabolism). Cortical tau tracer deposition can be seen in the same areas, establishing a typical topographic “yin-yang” offset between the two biomarkers. Further, correlation between these two imaging findings grows stronger as tau burden increases (**Figure 3**) (Whitwell et al., 2018; Lu et al., 2020). These unique phenomena demonstrate outstanding pathophysiological coherency of excessive MAPT retention and subsequent destruction of cytoarchitecture, resulting in synaptic metabolic deficit. On the other hand, multi-modality studies also reveal that the correspondence between

**FIGURE 3 |** Representative images of [ $^{11}\text{C}$ ]PIB, [ $^{18}\text{F}$ ]APN1607, and [ $^{18}\text{F}$ ]FDG PET and MRI of an AD patient, an MCI patient and a high-risk asymptomatic subject. A $\beta$  was positive for the AD patient and equivocal for the MCI patient and the high-risk asymptomatic subject. Typical Braak Stage V–VI tau deposition was seen in the AD brain, whereas no tau deposition was seen in the brain of the MCI patient or the high-risk asymptomatic subject. Typical AD-like glucose-hypometabolism was seen in AD brain including posterior cingulate cortex, parietal, temporal, and pre-frontal cortices, whereas most of these regions are relatively spared in the brain of MCI patient and high-risk asymptomatic subject. Images provided by PET Center, Huashan Hospital, Fudan University.

frontal hypometabolism and medial temporal tau retention is present independent of amyloid deposition, which can be interpreted as aging-related.

The relationship between tau aggregation and cortical atrophy as demonstrated by structural MRI is similar to that between tau aggregation and hypometabolism. However the former was found to be weaker than the later, especially in conditions other than mild AD (Sepulcre et al., 2016; Iaccarino et al., 2018). In addition to local correlation, tau deposition in the parietal lobe and precuneus can also be correlated to medial temporal lobe atrophy (Shimada et al., 2017). These observations seem plausible due to the fact that substantial structural alterations often relate to the later stage of the disease.

In general, CSF phosphorylated tau (p-tau, representing misfolded tangle formation) and total tau (t-tau, representing neurodegeneration) levels parallel *in vivo* tau tracer binding (Mattsson et al., 2018; Leuzy et al., 2019; Okafor et al., 2020). However, discordant results have also been found in small subgroups, possibly due to varying detectability around the CSF threshold and uneven rate of tau tangle formation in different disease stages (Murray et al., 2015; Thal et al., 2015). Although it is believed that elevated CSF tau levels precede tau imaging

manifestation, tau PET has the advantage of visualization and topographic quantitation capacity, as well as relative non-invasiveness (Wolters et al., 2020).

## Discussion

The research and development of tau PET tracers has gained undeniable progress in the last few years. Although some issues remain, especially isoform selectivity and other potential off-target binding, the applications of these tracers in AD imaging have provided, and are expected to continue to provide valuable information on the time course and topography of tau tangles in AD, and the correlation with cognitive dysfunction. Longitudinal and cross-sectional multi-target and multi-modality studies are encouraged to further elucidate the role of tau in the course of AD, as well as its interaction and relationship with A $\beta$  deposition, synaptic dysfunction, brain atrophy, and other pathological biomarkers. Another important application of tau imaging is its utility for patient selection and endpoint measurements in phase 2 and phase 3 clinical trials of disease-modifying anti-tau treatments that have been gaining increasing impetus (Giacobini and Gold, 2013).

Coming from different compound families, the currently available tau tracers have different affinities for the various MAPT

isoforms or tangle structures, hence distinctive topographic binding patterns in the same tauopathy. Selectivity to isoforms and structures could be a future direction to design new probes as 3R-specific or 4R-specific. We could therefore foresee a future tau imaging landscape where different tracers “rule” their own pieces of territory (i.e., specific tauopathy characterized by specific isoform or structure) in case that the correlation of tau imaging results similar to the “A $\beta$  centiloid” is not achievable.

## PET TRACER FOR IMAGING GLUCOSE METABOLISM: [ $^{18}\text{F}$ ]FDG

### Overview

As a radionuclide-labeled analog of glucose, the major metabolic substrate of neurons, [ $^{18}\text{F}$ ]fluorodeoxyglucose ([ $^{18}\text{F}$ ]FDG, or FDG) has long been used in the investigation of CNS disorders to reflect neuronal degeneration and injury. In fact the first report of this most widely used tracer was a brain imaging study (Phelps et al., 1979), although now the majority of its clinical application is for oncological purposes. The characteristic AD pathology (McGeer et al., 1986) and neurodegenerative changes (Mielke et al., 1996; Scholl et al., 2011) are associated with cortical hypometabolism demonstrated in pre-mortem FDG PET imaging. Clinical application of FDG PET in AD lies mainly in differential diagnosis from other causes of dementia, as well as treatment effect evaluation of disease-modifying or progression-slowing therapies. Clinical value of FDG PET has also been investigated for its predictive ability for conversion to AD dementia of high-risk subjects assumed to be in the prodromal or asymptomatic stage.

### AD Dementia Patients

The characteristic manifestation of FDG PET in AD dementia is hypometabolism in the posterior part of cerebrum including the posterior cingulate cortex (PCC), precuneus (PrC), and parietotemporal association cortices such as the angular gyrus. These regions are the most discriminating components of AD-specific cerebral hypometabolic pattern as well as strong indicators of disease severity and progression. It is of significant differential value that PCC and PrC are substantially spared in other minor causes of senile dementia including frontotemporal lobe dementia (FTLD), dementia with Lewy bodies (DLB), Parkinson’s Disease dementia (PDD), and vascular dementia (VaD). The hippocampus and entorhinal cortex are involved in the earliest stages of AD according to neuropathological findings based on NFT formation (Braak and Braak, 1997), however glucose metabolism in these areas cannot be readily distinguished between AD patients and normal controls. This is largely due to the frequent presence of medial temporal hypometabolism even in normal aging, and the partial volume effect (PVE) correlated with regional cortical atrophy. Frontal lobe hypometabolism is often associated with advancement, executive dysfunction, or atypical behavior in AD cases, although it could also be observed in normal aging. Occipital lobe hypometabolism is related to the posterior cortical atrophy (PCA) subtype of AD, but care should be taken when differentiating dementia types because this is also a prominent sign of DLB.

### MCI Patients

Early differentiation of MCI due to AD is crucial since early therapeutic intervention is indicated to be beneficial at least in slowing disease progression (Vellas et al., 2007; Molinuevo et al., 2011). It should be noted, though, that the etiology of MCI is heterogeneous, meaning that approximately half of the patients convert to dementia other than AD, or do not convert at all (Rowe et al., 2010; Bennett et al., 2012; Frisoni et al., 2017). Therefore, whether FDG PET has discriminative and predictive ability for MCI patients is of great clinical relevance.

Hypometabolism revealed by FDG PET in typical AD-affected brain regions including the inferior parietal lobe, precuneus and posterior cingulate cortex is present early in prodromal AD, namely MCI stage. In a meta-analysis comparing the accuracy of 3 different imaging modalities, FDG PET (sensitivity = 88.8%, specificity = 84.9%) exhibits higher sensitivity and higher specificity than cerebral blood flow SPECT (sensitivity = 83.8%, specificity = 70.4%) and structural MRI (sensitivity = 72.8%, specificity = 81%) in terms of predicting short-term conversion to AD dementia (Yuan et al., 2009). Interestingly, FDG PET performs better in excluding non-converters than [ $^{11}\text{C}$ ]PIB A $\beta$  PET (specificity: 74.0 vs. 56.2%), while its sensitivity is lower (sensitivity: 78.7 vs. 93.5%) (Zhang et al., 2012). This could be explained by the compensatory mechanism of preserved cerebral synaptic function against amyloid burden. Aside from the advantage of accurate short-term predictive ability, FDG PET can also exclude other potential etiology underlying MCI such as FTLD and DLB, in contrast to other biomarkers including CSF A $\beta_{1-42}$  and t-tau/p-tau assays (Arbizu et al., 2018).

The value of FDG PET in MCI has been acknowledged in existing diagnostic criteria (Albert et al., 2011; Dubois et al., 2014). Meanwhile, future researches in this field are encouraged to overcome the various current limitations in terms of methodology normalization, gold standard verification, and effectiveness/economy evaluation (Arbizu et al., 2018).

### High-Risk Asymptomatic Subjects

People with subjective cognitive decline (SCD) rather than objective evidence of cognitive impairment, subjects burdening amyloidosis, and family members of AD patients expressing PSEN1/2 or APP mutation were reported to have higher tendencies to develop to AD dementia (Bateman et al., 2011; Villemagne et al., 2011; Wolfgruber et al., 2016). It is hypothesized that neurodegenerative alterations could have been silently undergoing in these subjects.

Various confounding factors lead to heterogeneity of the underlying etiology for SCD, leaving controversy in the regional metabolic manifestation of typical AD-affected areas in this subgroup (Scheef et al., 2012; Brugnolo et al., 2014; Van Der Gucht et al., 2015). Although amyloid-positive asymptomatic subjects, as defined by CSF A $\beta_{1-42}$  or amyloid PET, will have higher risk of converting to AD in a life-long period, the utility of FDG PET reflecting neurodegeneration in this population is still not comparable to that in MCI patients, due to its poor performance in prediction of short-term conversion (Villemagne et al., 2011). Glucose metabolic abnormalities prior to the onset of clinical symptoms were observed in

asymptomatic carriers of mutated APP and PSEN1/2 genes (Mosconi et al., 2008; Benzinger et al., 2013), who theoretically would suffer from dementia eventually. Nonetheless, the relationship between cerebral hypometabolism and time-to-conversion cannot be easily concluded in the absence of well-designed longitudinal studies.

In view of the above-mentioned facts, it is not recommended to clinically apply FDG PET to asymptomatic subjects with only one risk factor for diagnostic or prognostic purposes. Further investigation is needed to verify whether FDG PET is useful for individuals with multiple risk factors (Mosconi et al., 2008; Vannini et al., 2017).

## Treatment Monitoring

FDG PET has been used as an imaging biomarker for outcome assessment in multiple clinical trials of AD therapeutics (Hoyer, 2002; Landau et al., 2011; Herholz, 2012). Global as well as sub-global or regional FDG uptake alterations following medication or surgical treatment has been observed in multiple clinical research studies (Nordberg et al., 1992; Heiss et al., 1994; Mega et al., 2001; Potkin et al., 2001; Tune et al., 2003; Schmidt et al., 2008; Tzimopoulou et al., 2010; Craft et al., 2012; Smith et al., 2012).

## Discussion

FDG PET has been most widely used in dementia research and as an important adjunct imaging tool in the diagnosis of AD. On the whole, FDG PET enables early diagnosis of AD and thus early therapeutic intervention, as well as treatment strategy optimization in a large proportion of cases (Laforce et al., 2010; Elias et al., 2014). Delaying of disease progression and prevention of life quality deterioration as instructed by FDG PET can help lessen the overall healthcare expenditure (Banerjee and Wittenberg, 2009; Getsios et al., 2012).

Although quite a few critical issues in the utility of FDG PET for AD diagnosis have already been resolved, there are still many others that require verification with larger cohorts and better-designed trials (Garibotto et al., 2017).

## PET TRACERS FOR IMAGING NEUROINFLAMMATION

### Overview

Increasing evidence has helped with the formation of neuroinflammation hypothesis of AD etiology (McGeer and McGeer, 2010; Morales et al., 2014). Similar to the cases in other systems of the human body, it is now believed that the impact on CNS under different phases of the inflammatory process could be different. While acute inflammation could be protective to the brain against the harmful effects of invading pathogens and traumatic injuries, consistent stimulation by inflammatory factors could, on the other hand, be detrimental to the neurons and eventually induce neurodegeneration and loss of cognitive functions (Wyss-Coray and Mucke, 2002; Mrak and Griffin, 2005). It is also suggested that the neuroinflammation underlying AD starts from the earliest stages without any obvious clinical symptoms, and lasts to the end stage of the disease (Vehmas

et al., 2003; Hoozemans et al., 2005). Therefore it is hypothesized that the clinical onset of AD dementia could be partly prevented or postponed by anti-inflammation interventions, which is based on results from retrospective observation studies and prospective trials (McGeer et al., 1996; Hoozemans et al., 2011). Multiple pathophysiological factors can trigger the process of immunoactivation in the CNS, in which complements, cytokines, growth factors, reactive oxygen species, microglia and astrocytes participate (Barger and Harmon, 1997; Akiyama et al., 2000). PET radiotracers have been developed to image these neuroinflammatory targets *in vivo* (Zimmer et al., 2014; Varley et al., 2015).

## Tracer Development

The 18-kDa translocator protein (TSPO) is a mitochondrial protein. Under normal circumstances, it is low-expressed in specific brain regions in the microglia, the monocyte-macrophage-dendritic cell family member majorly active in the CNS and comprising ~15% of the non-neuronal cells within. TSPO is found to participate in amino acid and cholesterol transportation, and to serve as a “switch” in activating microglia from the resting state in response to various stimuli including infection and traumatic injury (Streit et al., 2004). Pro-inflammatory cytokines and neurotoxic substances are released by significantly proliferated microglia after the induction of soluble or fibrillary A $\beta$  and subsequent TSPO regulation, which could be related to the fact that amyloid plaques are found to be colocalized with activated microglia *in vivo* in the brain where massive neuronal destruction and brain atrophy occur (McGeer et al., 1988; Venneti et al., 2009; Schilling and Eder, 2011). These characteristics made TSPO the predominant target for imaging *in vivo* inflammatory process in AD.

[<sup>11</sup>C]PK11195 was the first successfully developed TSPO tracer for human PET imaging (Figure 4) (Cagnin et al., 2001), but it remains controversial whether its binding is correlated with amyloid deposition, probably due to its low specific binding signal and hence low sensitivity to detect small changes in TSPO under disease conditions (Edison et al., 2008; Wiley et al., 2009; Yokokura et al., 2011). To overcome the shortcomings of [<sup>11</sup>C]PK11195, a series of 2nd generation TSPO tracers were developed and evaluated, including [<sup>11</sup>C]PBR28, [<sup>11</sup>C]DAA1106, [<sup>18</sup>F]DPA713, [<sup>18</sup>F]DPA714, [<sup>18</sup>F]FEPPA, [<sup>18</sup>F]FEMPA, and [<sup>18</sup>F]FEDAA1106 (Figure 4; Varley et al., 2015; Calsolaro and Edison, 2016; Edison et al., 2018). Though the majority of these radioligands are more sensitive than [<sup>11</sup>C]PK11195, subsequent studies found that their brain uptake are regulated by the TSPO gene rs6971 polymorphism, thus requiring phenotyping of individual subjects to match imaging results to their TSPO affinity status (Owen et al., 2012). More recently, 3rd generation, putative “phenotype-insensitive” TSPO probes such as [<sup>11</sup>C]ER176 (Figure 4) are being developed and evaluated (Wadsworth et al., 2012; Ikawa et al., 2017).

Similar to the paradigm of TSPO imaging of microglial activation, MAO-B is found to be elevated in reactive astrocytes and chosen as the target for *in vivo* imaging of neuroinflammation. The selective MAO-B tracer [<sup>11</sup>C]deuterium-L-deprenyl ([<sup>11</sup>C]DED) has been applied

**FIGURE 4** | Structures of representative PET radiotracers for TSPO imaging.

to studies of neurodegenerative disorders including AD (Carter et al., 2012). Type-2 imidazoline receptor, a newly discovered target for imaging astrocyte, is now being evaluated for its potential in differentiating AD and control using  $[^{11}\text{C}]$ BU99008 under ongoing trial (Wilson et al., 2019).

## Imaging Research Findings and Clinical Relevance

*In vivo* TSPO imaging is generally able to discriminate between AD dementia patients and normal control subjects (Cagnin et al., 2001; Yasuno et al., 2008; Suridjan et al., 2015; Varrone et al., 2015; Hamelin et al., 2016; Kreisl et al., 2016a). The majority of the multi-modality studies report that regional TSPO binding correlates to  $[^{11}\text{C}]$ PIB retention positively, and FDG uptake as well as cortical volume negatively (Edison et al., 2008; Yokokura et al., 2011; Kreisl et al., 2013, 2016b) (**Figure 5**). In most cases the extent of TSPO binding is associated with not only baseline cognitive performance, but also its deterioration over time (Edison et al., 2008; Okello et al., 2009b; Yokokura et al., 2011; Kreisl et al., 2013, 2016a). Elevated TSPO binding in advanced AD dementia patients is seen in various cortical regions following an anticipated distribution pattern (Cagnin et al., 2001; Hamelin et al., 2016). Apart from global discrimination, regional TSPO binding is correlated to attenuated corresponding brain function. One study uncovered an inverse correlation between visuospatial function and  $[^{18}\text{F}]$ FEPPA binding in the parietal and posterior internal capsule, as well as correlation between language ability and binding in the latter region (Suridjan et al., 2015). Interestingly, early-onset AD (EOAD) is reported to be associated with higher TSPO binding than late-onset AD (LOAD), especially in the frontal and parietal cortices, suggesting greater microglial activation in the former condition (Kreisl et al., 2013). In addition, a longitudinal study revealed that TSPO

**FIGURE 5** | Single subject images from a patient with posterior cortical atrophy (top row), a patient with amnesic Alzheimer's disease (center row), and a healthy control subject (bottom row). The posterior cortical atrophy subject showed focal occipito-temporal  $[^{11}\text{C}]$ PBR28 binding, with FDG hypometabolism in the same region (arrows). While the posterior cortical atrophy subjects showed occipito-temporal PIB binding, PIB binding was also found in frontal cortex. The subject with amnesic Alzheimer's disease showed more diffuse  $[^{11}\text{C}]$ PBR28 binding, with occipital sparing on PIB and classic bilateral temporo-parietal hypometabolism on FDG imaging. The control subject showed low amounts of diffuse  $[^{11}\text{C}]$ PBR28 binding and absence of cortical  $[^{11}\text{C}]$ PIB binding. Courtesy from Kreisl et al. (2016b).

binding in MCI converters to AD dementia is drastically different from that of non-converters (Kreisl et al., 2016a). These results are concordant with previous finding that chronic microglia participation may be associated to the brain in AD progression (McGeer and McGeer, 2010; Morales et al., 2014).

However, conflicting results are also present in various aspects. Absence of the expected correlation between TSPO binding and cortical amyloid retention or neuronal metabolism has been repeatedly reported (Okello et al., 2009b; Wiley et al., 2009; Schuitemaker et al., 2013). There are also studies showing the inability of TSPO tracers to discriminate healthy subjects from patients with MCI or even advanced dementia (Okello et al., 2009b; Wiley et al., 2009; Schuitemaker et al., 2013; Golla et al., 2015). Likewise, significant association between TSPO binding and memory performance or disease severity is not always found (Yasuno et al., 2008; Schuitemaker et al., 2013). Single-nuclide polymorphism of rs6971 has been discovered to regulate TSPO binding *in vivo* and may partly contribute to the conflicting findings so far, since binding adjusted to individual phenotyping shows increased discriminating accuracy (Suridjan et al., 2015). In addition to doubts about the sensitivity of current TSPO tracers to detect subtle alterations in the prodromal stages of AD, there are data relating higher binding of [<sup>18</sup>F]DPA714 to slower cognitive decline, suggesting a neuroprotective role of microglial activation perhaps in the early phase of the disease (Hamelin et al., 2016).

According to a collective study with both [<sup>11</sup>C]DED and [<sup>11</sup>C]PIB, astrocytosis is most profound in amyloid-positive MCI subjects, followed by advanced AD patients as well as amyloid-negative MCI subjects and healthy controls (Carter et al., 2012; Rodriguez-Vieitez et al., 2016). This PET finding suggests that astrocytic reaction diminishes after prodromal AD converts to dementia, and is supported by postmortem autoradiographic study showing highest binding of MAO-B radioligand in the earliest Braak stages (Gulyas et al., 2011).

## Discussion

It is universally acknowledged that neuroinflammation plays an active part in the course of AD. PET imaging of neuroinflammation targets have, in part, confirmed the correlation between A $\beta$  deposition and elevated microglia/astrocyte activation/neuroinflammation. Nonetheless, in light of the complexity of both the process and components, questions such as “Is neuroinflammation beneficial at the beginning and harmful thereafter?” and “Is TSPO imaging and MAO-B imaging reflecting true activation of microglia and astrocytes?” remain to be answered. In order to obtain a clearer picture of the various aspects of inflammation in the CNS, further exploration is needed with some of the clues now at hand. First, microglia can be polarized to either M1, releasing neurotoxic substances, or to M2, releasing neuroprotective cytokines (Mosser and Edwards, 2008). Highly selective radioligands discriminating the two opposing activations will help answer these questions. Further, longitudinal studies, ideally tracking from the very early stage to the end stage of the disease across subjects, will be more informative than cross-sectional studies in mapping the time course and topography of microglia activation in disease progression. In addition, genotype-insensitive TSPO tracers under development require verification and validation in large-sample cohorts (Wadsworth et al., 2012; Zanotti-Fregonara et al., 2014; Ikawa et al., 2017). Finally, multi-modality imaging

approaches will be helpful in revealing the interactions between neuroinflammation and various pathologic/pathophysiological components in AD.

## PET TRACERS FOR IMAGING TARGETS IN THE CHOLINERGIC SYSTEM

### Overview

The basal/rostral forebrain cholinergic pathways are believed to play an important role in a variety of neuropsychological functions including attention, consciousness and memory processing (Perry et al., 1999). Cholinergic replacement countering the loss of cholinergic neurotransmission in neurodegeneration is the theoretical basis of AD-treatment strategies using clinically approved medications (Bartus et al., 1982; Schliebs and Arendt, 2011). Cholinergic depletion and the resulting deficit in neuronal compensatory plasticity are confirmed in autopsy studies of AD patients (Bierer et al., 1995; Craig et al., 2011). PET imaging tracers targeting various aspects of cholinergic neurotransmission and metabolism can help us to better understand the role of cholinergic neuropathy and its interaction with other pathologic/pathophysiological components in the course of AD.

### Tracer Development

Acetylcholinesterase (AChE) is the major target of AD medications, most of which are acetylcholinesterase inhibitors (AChEIs). These therapeutic agents, including galantamine, rivastigmine, tacrine and donepezil, block AChE to inhibit hydrolysis of ACh, thus increasing ACh level in the synaptic cleft. *N*-[<sup>11</sup>C]methyl-4-piperidiny propionate ([<sup>11</sup>C]PMP) and *N*-[<sup>11</sup>C]methyl-4-piperidyl acetate ([<sup>11</sup>C]MP4A) are two selective substrates for AChE that have been successfully brought to *in vivo* human imaging research (Figure 6). Another presynaptic cholinergic PET tracer [<sup>18</sup>F]FEOBV, selective to the vesicle ACh transporter (VACHT), is reported to have been assessed in humans (Aghourian et al., 2017). Postsynaptic acetylcholine receptors can be classified into nicotinic acetylcholine receptors (nAChRs) and muscarinic acetylcholine receptors (mAChRs). While most of the previous human PET studies used  $\alpha_4\beta_2$  or non-selective nAChR tracers including [<sup>11</sup>C]nicotine, 2-[<sup>18</sup>F]F-A-85380 ([<sup>18</sup>F]2-FA), [<sup>18</sup>F]AZAN, and [<sup>18</sup>F]flubatine (also known as [<sup>18</sup>F]NCFHEB) (Figure 6) (Nordberg et al., 1990; Sabri et al., 2008, 2015b; Wong et al., 2013), successful development of selective tracers for new targets such  $\alpha_7$  nAChR and M1 and M4 mAChR has been reported recently. Recent imaging evaluations in humans indicated that [<sup>18</sup>F]ASEM, [<sup>11</sup>C]LSN3172176, and [<sup>11</sup>C]MK-6884 (Figure 6) have appropriate kinetics and imaging properties and are promising tracers for their respective targets  $\alpha_7$  nAChR and M1 and M4 mAChR (Hillmer et al., 2017; Wong et al., 2018; Masdeu et al., 2020; Tong et al., 2020; Naganawa et al., 2021b). [<sup>18</sup>F]ASEM and [<sup>11</sup>C]MK-6884 have been used in preliminary studies of  $\alpha_7$  nAChR and M4 mAChR in AD (see below), while evaluation of M1 mAChR in AD is ongoing with [<sup>11</sup>C]LSN3172176 in our laboratories.

**FIGURE 6 |** Structures of representative PET radiotracers for cholinergic targets.

## Imaging Research Findings and Clinical Relevance

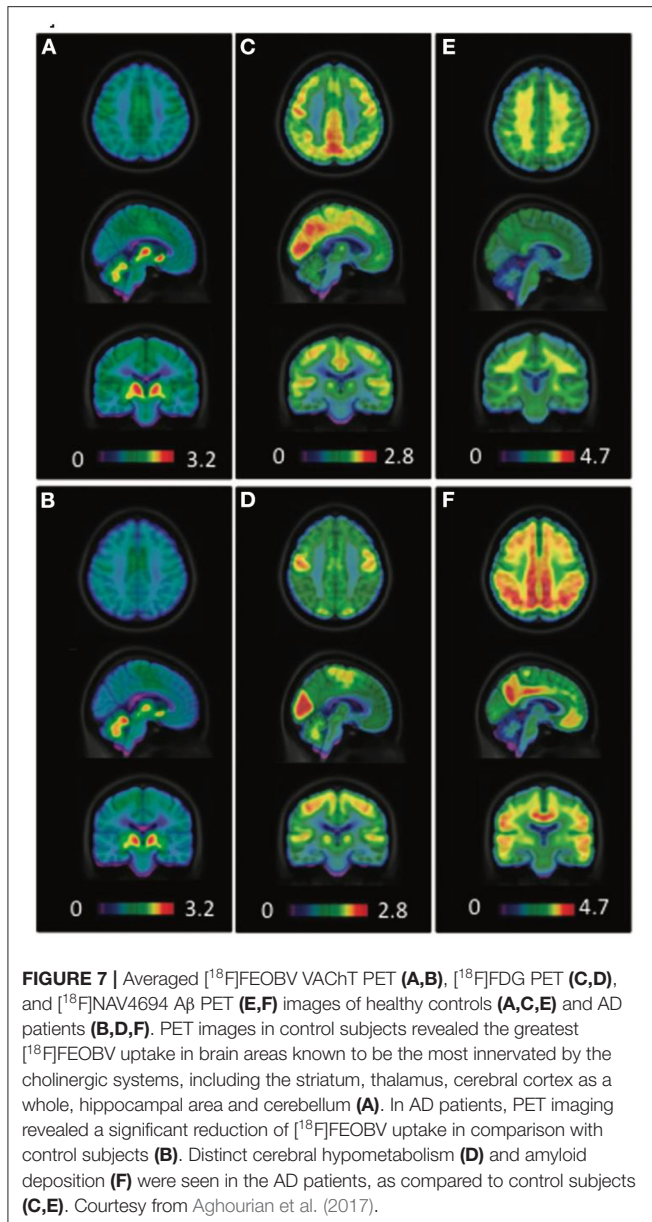

AChE imaging using  $[^{11}\text{C}]\text{PMP}$  and  $[^{11}\text{C}]\text{MP4A}$  showed reduced cortical binding in AD patients than in healthy controls, especially in regions innervated with cholinergic projections (Iyo et al., 1997; Kuhl et al., 1999). AChE binding is lower in AD patients than in healthy controls, in parallel with VACHT reduction, and is further decreased by treatment with AChE inhibitors donepezil, rivastigmine and galantamine (Kuhl et al., 1999, 2000; Shinotoh et al., 2001; Kaasinen et al., 2002; Kadir et al., 2008). However this induced inhibition is absent for nAChR binding, suggesting that allosteric modulation effect maintains ACh signaling by up-regulating nAChR but not AChE (Maelicke et al., 2001). The degree of treatment-induced decline in AChE binding is more prominent in the frontal cortex than in the temporoparietal cortices, and correlated to improvement in frontal lobe functions such as execution and attention rather than episodic memory. Correlation between AChE hydrolysis and hypometabolism in the posterior cingulate cortex is also absent, while a connection between higher hydrolysis rate and APOE4 positivity exists (Kuhl et al., 1999; Eggers et al., 2006).

The binding of novel VACHT tracer  $[^{18}\text{F}]\text{FEOBV}$  is found to be lower in AD than in healthy controls in a recent multi-tracer study involving  $[^{18}\text{F}]\text{FDG}$  and  $[^{18}\text{F}]\text{NAV4694}$  as well (Aghourian et al., 2017).  $[^{18}\text{F}]\text{FEOBV}$  PET is shown to have higher sensitivity than  $[^{18}\text{F}]\text{FDG}$  in discriminating AD from

healthy controls (Figure 7). There is also a positive correlation of  $[^{18}\text{F}]\text{FEOBV}$  binding to minimal mental state examination (MMSE) and Montreal cognitive assessment (MoCA). A more recent study attributed basal forebrain degeneration in AD to the loss of cortico-amygdalar cholinergic input, as demonstrated by  $[^{18}\text{F}]\text{FEOBV}$  binding decline (Schmitz et al., 2018).

Nicotinic AChR binding reduction is not only lower in AD and MCI subjects than in cognitively-intact volunteers, but also in MCI converters to AD dementia than in non-converters (Nordberg et al., 1990, 1995; Kendziorra et al., 2011). Binding quantitation of the AD-affected brain regions is significantly responsible for their coupling cognitive functions (Ellis et al., 2008; Sabri et al., 2008; Kendziorra et al., 2011; Okada et al., 2013). Frontal  $[^{11}\text{C}]\text{PIB}$  retention is found to be inversely correlated with  $[^{18}\text{F}]\text{2-FA}$  binding in the medial frontal cortex and nucleus basalis magnocellularis of AD patients (Maas et al., 2000). PET imaging with  $[^{18}\text{F}]\text{flubatine}$ , a new-generation  $\alpha_4\beta_2$  tracer with more favorable kinetics, reveals receptor deficiency within the basal forebrain-cortical and septo-hippocampal cholinergic projections (Sabri et al., 2018). Episodic memory, working memory and executive functions are well-correlated with impairment of  $\alpha_4\beta_2$  nAChR in the corresponding cortices. Initial imaging studies with the  $\alpha_7$  nAChR selective radioligand  $[^{18}\text{F}]\text{ASEM}$  in healthy controls and MCI subjects indicated elevation of this receptor subtype with healthy aging, and in MCI, in a direction opposite of that for  $\alpha_4\beta_2$  nAChR in

AD (Coughlin et al., 2018, 2019). A preliminary imaging study of M4 mAChR in AD revealed reduced uptake of [ $^{11}\text{C}$ ]MK-6884 primarily in the parietotemporal cortex in a pattern consistent with clinical symptom presentations and FDG hypometabolism (Masdeu et al., 2020).

## Discussion

PET imaging studies with tracers for both pre- and post-synaptic cholinergic targets have confirmed the abnormalities of cholinergic transmission *in vivo*, in AD, as manifested in altered levels of AChE, VAcHT, and  $\alpha_4\beta_2$  and  $\alpha_7$  nAChRs, and their correlations with A $\beta$  deposition and cognitive functions. The  $\alpha_7$  nAChR is a target gaining increasing focus in recent years, due to its newly discovered participation in preventing amyloid toxicity

and tau hyper-phosphorylation, in increasing synaptic strength and stability, and in modulating neuroinflammation by acting on non-neuronal cells (Wang et al., 2003; Conejero-Goldberg et al., 2008; Halff et al., 2014; de Oliveira et al., 2016; Maurer and Williams, 2017; Gamage et al., 2020). Renewed interests have also been seen in the mAChR, especially the M1 and M4 subtypes, for therapeutic development for AD (Levey, 1996; Schliebs and Arendt, 2011; Melancon et al., 2013). Investigation of these additional targets with recently available PET tracers will lead to a more thorough understanding of cholinergic involvement in AD etiology and progression.

## PET TRACERS FOR IMAGING SYNAPTIC DENSITY

### Overview

The total number of synapses in the neocortices is approximately  $164 \times 10^{12}$  (Tang et al., 2001). Synapses are critical for neurotransmission in neuron-neuron interaction, the deficiency of which would result in neuronal dysfunction and consequent occurrence of neuropsychiatric symptoms including amnesia, apathy and executive dysfunction. Loss of synapses has long been regarded as a pathologic hallmark of AD (Scheff et al., 1990; Terry et al., 1991; Scheff and Price, 2006) and correlates strongly with cognitive impairment (Hamos et al., 1989; DeKosky and Scheff, 1990; Terry et al., 1991; DeKosky et al., 1996; Robinson et al., 2014). Synaptic density reductions are seen in the neocortex and limbic system in MCI, a prodromal form of AD and other dementias (Masliah et al., 1994, 2001; Pham et al., 2010). Accumulation of toxic A $\beta$  oligomers is believed to lead to the loss of synapses and presynaptic proteins in MCI patients (Pham et al., 2010; Wei et al., 2010; Beerli et al., 2012; Robinson et al., 2014). More recent research also suggests an emerging role for tau mediated toxicity at the synapses (Pooler et al., 2014; Wang and Mandelkow, 2016). Thus PET imaging of the synapses provides a tool for direct visualization of synaptic density loss along the AD pathogenesis and progression pathway.

### Tracer Development

Synaptic vesicle glycoprotein 2 (SV2) is one of the synaptic proteins highly expressed on the presynaptic membrane. Among the 3 forms of SV2, only SV2A is extensively expressed in glutamatergic and GABAergic neurons throughout the CNS (Dong et al., 2006). Traditionally, synapses can only be observed by electron microscopic and immunohistochemical examinations in biopsy and autopsy tissue samples. Recently a series of novel PET radiotracers selectively targeting SV2A have been developed (Figure 8) (Mercier et al., 2014; Estrada et al., 2016; Nabulsi et al., 2016; Becker et al., 2017; Li et al., 2019; Cai et al., 2020a), enabling non-invasive observation and quantification of synaptic density in humans (Finnema et al., 2016; Bahri et al., 2017; Cai et al., 2020b; Naganawa et al., 2021a).

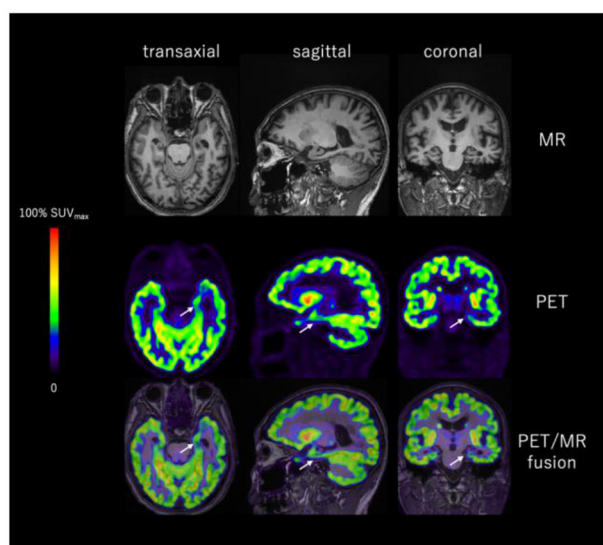

## Imaging Research Findings and Clinical Relevance

A recent human SV2A PET study using [ $^{11}\text{C}$ ]UCB-J in cohorts of MCI/AD patients and age-matched cognitively intact elderly

**FIGURE 8** | Structures of representative PET radiotracers for SV2A.

**FIGURE 9** | Representative images of T1WI MRI and  $[^{18}\text{F}]\text{SynVesT-1}$  PET of a  $[^{18}\text{F}]\text{Florbetapir}$  positive AD patient. SV2A binding is significantly reduced in the left hippocampus (white arrow). Images provided by PET Center, Huashan Hospital, Fudan University and Department of Nuclear Medicine, East Hospital, Tongji University.

subjects revealed significant reduction of synaptic density in the hippocampus and entorhinal cortex (44 and 27%, respectively) (Chen et al., 2018). Moreover, statistically significant correlations were found between hippocampal synaptic density and episodic memory (Logical Memory II and Rey Auditory Verbal Learning Test,  $R = 0.56$ ,  $P = 0.01$ ) and global function (Clinical Dementia Rating Sum of Boxes,  $R = -0.61$ ,  $P = 0.003$ ) (Chen et al., 2018). These findings suggest that  $[^{11}\text{C}]\text{UCB-J}$  can capture the early pathological alterations in the hippocampus and entorhinal cortices, brain structures not readily analyzed in FDG PET compared to neocortices due to attenuated sensitivity introduced by size-related partial volume effect despite their early involvement in AD's Braak Staging (Braak and Braak, 1997).

The loss of synaptic density in the hippocampus of AD patients was replicated in a study using another SV2A

radiotracer  $[^{18}\text{F}]\text{UCB-H}$ , in which a 11 ~ 18% reductions of synaptic density in the basal forebrain and anterior/dorsomedial thalamus were found to be correlated with cognitive alterations (Bastin et al., 2020; Mecca et al., 2020). In a more recent  $[^{11}\text{C}]\text{UCB-J}$  study with a larger cohort of 34 AD and MCI patients, the significant loss of synaptic density measured by PET in the hippocampus and entorhinal cortex followed by parahippocampal cortex, amygdala, lateral temporal cortex, pre-frontal cortex, posterior cingulate cortex/precuneus, lateral parietal cortex, and pericentral cortex was found to be generally correlated with atrophy measured by structural MRI which is in line with autopsy reports, and was more significantly correlated with CDR-SB ( $r = -0.54$ ,  $P = 0.00003$ ) and episodic memory ( $r = 0.56$ ,  $P = 0.00001$ ) than in the smaller sample reported earlier (de Wilde et al., 2016; Chen et al., 2018; Mecca et al., 2020). The relationship between cognitive performances and medial temporal (especially hippocampus and parahippocampal gyrus) synaptic density loss in aMCI was strengthened by a mutually correlated regional tau accumulation, as was revealed by a multi-tracer PET study using  $[^{18}\text{F}]\text{MK-6240}$  and  $[^{11}\text{C}]\text{UCB-J}$  (Vanhaute et al., 2020).

## Discussion

SV2A PET has shown great promise as a biomarker for the non-invasive detection of synaptic density, which can serve as a useful tool for studying synaptopathies in neurodegenerative and psychiatric disorders including AD (Cai et al., 2019; Heurling et al., 2019). Due to the ubiquitous distribution of synaptic vesicles throughout the CNS, a highly selective molecular probe such as SV2A PET tracer can spot the subtle alterations of synaptic density both quantitatively and topographically.

It is anticipated that with the help of multi-target molecular imaging approaches, the correlation between synaptic loss and other pathophysiological factors related to AD can be further elucidated. For instance, the relationship between pathological amyloid and tau protein aggregations, neuronal glucose utility impairment, dysfunctions in various neurotransmitter systems and synaptic loss would be better understood. Since pathological synaptic alterations emerge in the early stage of AD and continue throughout its course, many unanswered questions and controversial issues, e.g., sequence on the emergence

of pathologic and physiological biomarkers, energetic, and neurotransmitter system abnormalities, and their relative impacts on disease progression, would be hopefully settled. It is perceivable that SV2A PET has the potential in AD early detection, differential diagnosis and conversion prediction of the prodromal stage subjects. Many studies using SV2A PET imaging in AD and other neurodegenerative diseases are ongoing, and results are emerging rapidly in publications. The introduction of additional  $^{18}\text{F}$ -labeled SV2A radiotracers with favorable kinetics and high specific binding profiles, such as [ $^{18}\text{F}$ ]SynVesT-1 (also known as [ $^{18}\text{F}$ ]SDM-8 and [ $^{18}\text{F}$ ]MNI-1126) and [ $^{18}\text{F}$ ]SynVesT-2 (also known as [ $^{18}\text{F}$ ]SDM-2), should facilitate these studies since they are suitable for central production and distribution for use in off-site imaging facilities (Figures 8, 9). Further, PET imaging with these SV2A radiotracers will be useful as endpoint measure in AD drug clinical trials (e.g. NCT03493282: Effect of CT1812 treatment on brain synaptic density).

## SUMMARY AND CONCLUDING REMARKS

Alzheimer's disease, characterized by impairments of cognitive functions and memory loss, is an extremely complex neurodegenerative disorder involving multiple pathophysiological processes, from loss of synapses and neurons, to neuroinflammation, to deposition of A $\beta$  plaques and neurofibrillary tau tangles. Early diagnosis is the key to effectively treat the disease before manifestation of clinical symptoms. The past two decades have witnessed the development of PET imaging agents targeting various pathologic and physiological biomarkers in AD which has greatly contributed to the investigation and diagnosis of this disease.

Radiotracers targeting pathologic hallmarks of AD such as A $\beta$  and tau proteins have allowed the differentiation of AD and non-AD dementia, the tracking of pathological protein burden over the temporal course of the disease, the stratification of patients for clinical trials, and the monitoring of biological effects of therapeutic agents. Nonetheless, there remained a few unanswered questions to be further studied concerning the relationship between these targets and the etiology of AD.

Pathophysiological alterations such as neuroinflammation as well as neurotransmitter and synaptic dysfunction are increasingly thought to commence from the earliest stage of the pathological changes in AD, and PET radiotracers targeting these biomarkers may help to elucidate their roles in AD progression in synergy with the core pathologies.

Measurement of synaptic density through PET imaging of the synaptic biomarker SV2A opens a new avenue for the investigation of neurodegenerative diseases. Initial *in vivo* imaging results from prodromal AD and AD dementia cohorts were in excellent correlation with cognitive impairment. Preliminary results of healthy aging subjects also demonstrated the early involvement of synaptic density alterations and its relationship to tau aggregation, which is in concordance with autopsy neuropathological findings. SV2A PET imaging, now at its early discovery phase, is expected to provide

further important information on synaptic protein alterations, along with other pathological changes, during the entire AD progression continuum, and contribute to the early detection of the disease.

PET imaging of biomarkers has played an important role in AD drug development. This trend will continue, as newer imaging biomarkers are increasingly incorporated into clinical trials of next-generation AD drugs as outcome measures. It is expected that applications of PET imaging biomarkers in drug clinical trials will continue to greatly facilitate the development of AD therapeutics.

The United States National Institute of Aging (NIA) and the Alzheimer's Association (AA) recently put forward a research framework for AD, i.e., the NIA-AA Research Framework, which is based on the current understanding of the AD continuum and grounded on a biomarker-based definition of AD (Jack et al., 2018). Biomarkers are grouped into three categories: A $\beta$  deposition, pathologic tau, and neurodegeneration (ATN) based on the nature of the pathologic process that each measures. Biomarkers of A $\beta$  plaques (labeled "A") are represented by cortical A $\beta$  plaque burden assessed by amyloid PET imaging or decreased CSF A $\beta_{42}$ . Biomarkers of fibrillar tau (labeled "T") are elevated CSF phosphorylated tau (p-tau) and/or cortical tau tangles measured by tau PET imaging. Biomarkers of neurodegeneration or neuronal injury (labeled "N") are based on CSF total tau (t-tau), hypometabolism as revealed by FDG PET imaging, and brain atrophy detected by MRI. It is evident that PET imaging targeting various biomarkers is an essential component of this ATN research framework, as it provides one biomarker measurement for each of the arms: amyloid PET for A, tau PET for T, and FDG PET for N. The recent emergence of synaptic PET imaging targeting SV2A may provide another biomarker for N, neurodegeneration that more closely tracks with the progression of the disease and cognitive impairment, and less sensitive to confounding factors such as blood glucose level, stimulation and medication which affect FDG PET, a surrogate measure of synaptic/neuronal function (Herholz, 2008; Burns et al., 2013; Ishibashi et al., 2015). These advancements in the development of PET radiotracers for AD biomarkers have been made possible through the efforts of numerous researchers in the PET imaging field in the last two decades. Collectively, AD imaging studies with various radiotracers have greatly increased our knowledge on the etiology and progression of this complex neurodegenerative disorder, and facilitated the research and development of AD therapeutics. It is believed that PET imaging with effective tracers targeting various AD pathophysiological biomarkers will continue to advance our understanding of the disease, and hopefully provides a sensitive and definitive tool for early diagnosis and monitoring of treatment effect.

## AUTHOR CONTRIBUTIONS

WB and YH drafted the manuscript. FX, CZ, and YG participated in revision of manuscript. All authors contributed to the article and approved the submitted version.

# FUNDING

This work was supported by grants (Project No. 82071962, 82021002, & 81971641) from the National Natural Science

Foundation of China, grant (Project No. IDF151025) from Major Project Pre-research (pilot) Project of Fudan University, and grant 1R01AG065474 from the National Institute on Aging, National Institutes of Health, United States.

doi: 10.3389/fnins.2021.612940

**Objective:** Magnetic resonance-guided focused ultrasound (MRgFUS) is a minimum-invasive surgical approach to non-incisionally cause the thermos-coagulation inside the human brain. The skull score (SS) has already been approved as one of the most dominant factors related to a successful MRgFUS treatment. In this study, we first reveal the SS distribution of the tremor patients, and correlate the SS with the image feature from customized skull density ratio (cSDR). This correlation might give a direction to future clinical studies for improving the SS.

**Methods:** Two hundred and forty-six patients received a computed tomography (CT) scan of the brain, and a bone-enhanced filter was applied and reconstructed to a high spatial resolution CT images. The SS of all patients would be estimated by the MRgFUS system after importing the reconstructed CT images into the MRgFUS system. The histogram and the cumulative distribution of the SS from all the patients were calculated to show the percentage of the patients whose SS lower than 0.3 and 0.4. The same CT images of all patients were utilized to calculate the cSDR by first segmented the trabecular bone and the cortical bone from the CT images and divided the average trabecular bone intensity (aTBI) by the average cortical bone intensity (aCBI). The Pearson's correlations between the SS and the cSDR, aTBI, and the aCBI were calculated, respectively.

**Results:** There were 19.19 and 50% of the patient who had the SS lower than the empirical threshold 0.3 and 0.4, respectively. The Pearson's correlation between the SS and the cSDR, aCBI, and the aTBI were  $R = 0.8145$ ,  $0.5723$ , and  $0.8842$ .

**Conclusion:** Half of the patients were eligible for the MRgFUS thalamotomy based on the SS, and nearly 20% of patients were empirically difficult to achieve a therapeutic

temperature during MRgFUS. The SS and our cSDR are highly correlated, and the SS had a higher correlation with aTBI than with aCBI. This is the first report to explicitly reveal the SS population and indicate a potential way to increase the chance to achieve a therapeutic temperature for those who originally have low SS.

**Keywords:** tremor, skull density ratio, skull score, MR-guided focused ultrasound thalamotomy, essential tremor

## INTRODUCTION

High intensity focused ultrasound (HIFU) is an incisionless surgical device that has been widely used in medical research and clinical trials including the treatment of tumors (Kennedy, 2005) such as the liver (Kennedy et al., 2004; Illing et al., 2005), and kidney for over 50 years (Kennedy et al., 2003). By using the heating or cavitation at a variable distance from the transducer, HIFU can cause selectively thermal coagulation in a well-defined volume.

Sharing similar principles of the HIFU, recently the transcranial magnetic resonance-guided focused ultrasound (MRgFUS) has been widely used in different clinical trials to treat various neurological disorders in the human brain (Elias et al., 2016; Leinenga et al., 2016). MRgFUS can perform a thermal ablation around the subcortical area or opening the blood-brain barrier (Abbott et al., 2006) for drug delivery with different ultrasound frequency. One of the important keys to these successes was the phase aberration correction (Fry and Barger, 1978; Sun and Hynynen, 1998; Hynynen et al., 2004) across thousands of the ultrasound beams when passing through the skull (Chang et al., 2016; Jung et al., 2019) that produce a constructive focusing at the target area which maximize the energy-heat efficiency without causing any thermal coagulation outside the target. A high spatial resolution (<2 mm slice thickness) of a volumetric computed tomography (CT) scan with bone-enhanced filtering was used not only to delineate the entire skull for the phase aberration correction during the treatment but also to estimate a general skull score (SS) to screen patients before the treatment. The SS, which is offered by the InSightec, directly correlated with the temperature efficiency in the MRgFUS thalamotomy (Chang et al., 2016), and the empirical criterion of the SS for the MRgFUS thalamotomy is 0.40 (Wang et al., 2018). However, no literature was reported regarding the percentage of patients who can feasibly receive MRgFUS thalamotomy under this empirical criterion.

In this study, we tried to reveal the population distribution of the SS in tremor patients of Taiwanese people to address the aforementioned question, and report on the relationship between the SS and a customized skull density ratio (cSDR) by our algorithm, to determine the reliability of cSDR and the importance of the trabecular bone or the cortical bone separately in bone density calculation to provide fundamental information before designing a solution for low SS in MRgFUS treatment.

## MATERIALS AND METHODS

### Patient Selection

Two hundred and forty-six patients ( $62.4 \pm 12.0$  years old, ranging from 23 to 89 years old, 162 male and 84 female) with tremor dominant symptoms visited our site for the MRgFUS thalamotomy screening and were recruited in this study. Enrolled patients gave informed consent and were diagnosed by neurologists specializing in movement disorders based on tremor criteria (Wang et al., 2018). The experiments conformed to the standards set by the Declaration of Helsinki and were approved by the Chang Bing Show Chwan Memorial Hospital, Taiwan. Conventional CT scans were arranged for those who were willing to join the MRgFUS thalamotomy screening with no unnecessary radiation exposure.

### Conventional CT Scan

A sixteen-slice CT scanner (LightSpeed, GE, United States) was used to acquire the brain CT image. The scanning parameters followed the head routine scan protocol in our hospital and they were: peak X-ray tube voltage = 120 kVp, tube current = 250 mA, and scan time = 1.0 s. The scanning slices were parallelly aligned with the orbital-meatus (OM) line by the visual check of a radiographer. All the projection images of respective patients were used to reconstruct a volumetric image with a slice thickness of 0.625 mm. A high-pass filter (Bone + filter) was applied to the reconstructed CT images to enhance the dynamic range of the skull while suppressing that of the other parts in the images.

### SS Calculation

The CT images of each patient were uploaded into the ExAblate Neuro platform (InSightec Inc., Israel) and followed the procedures suggested by InSightec to calculate the SS. Specifically, the volumetric CT images with high-pass filtering of each patient were first uploaded into the ExAblate Neuro platform, and the anterior commissure, posterior commissure, and mid-sagittal point were defined on the platform. We used the built-in tool named target defined by AC-PC in the ExAblate Neuro platform to simulate a target for the MRgFUS thalamotomy. The spatial position of a simulated MRgFUS transducer helmet was then adjusted to align the ultrasound transducer focus and the simulated target of each patient. After the target selection, the calcification of each patient on the CT images was manually marked to turn off the ultrasound transducers which routes to the target pass

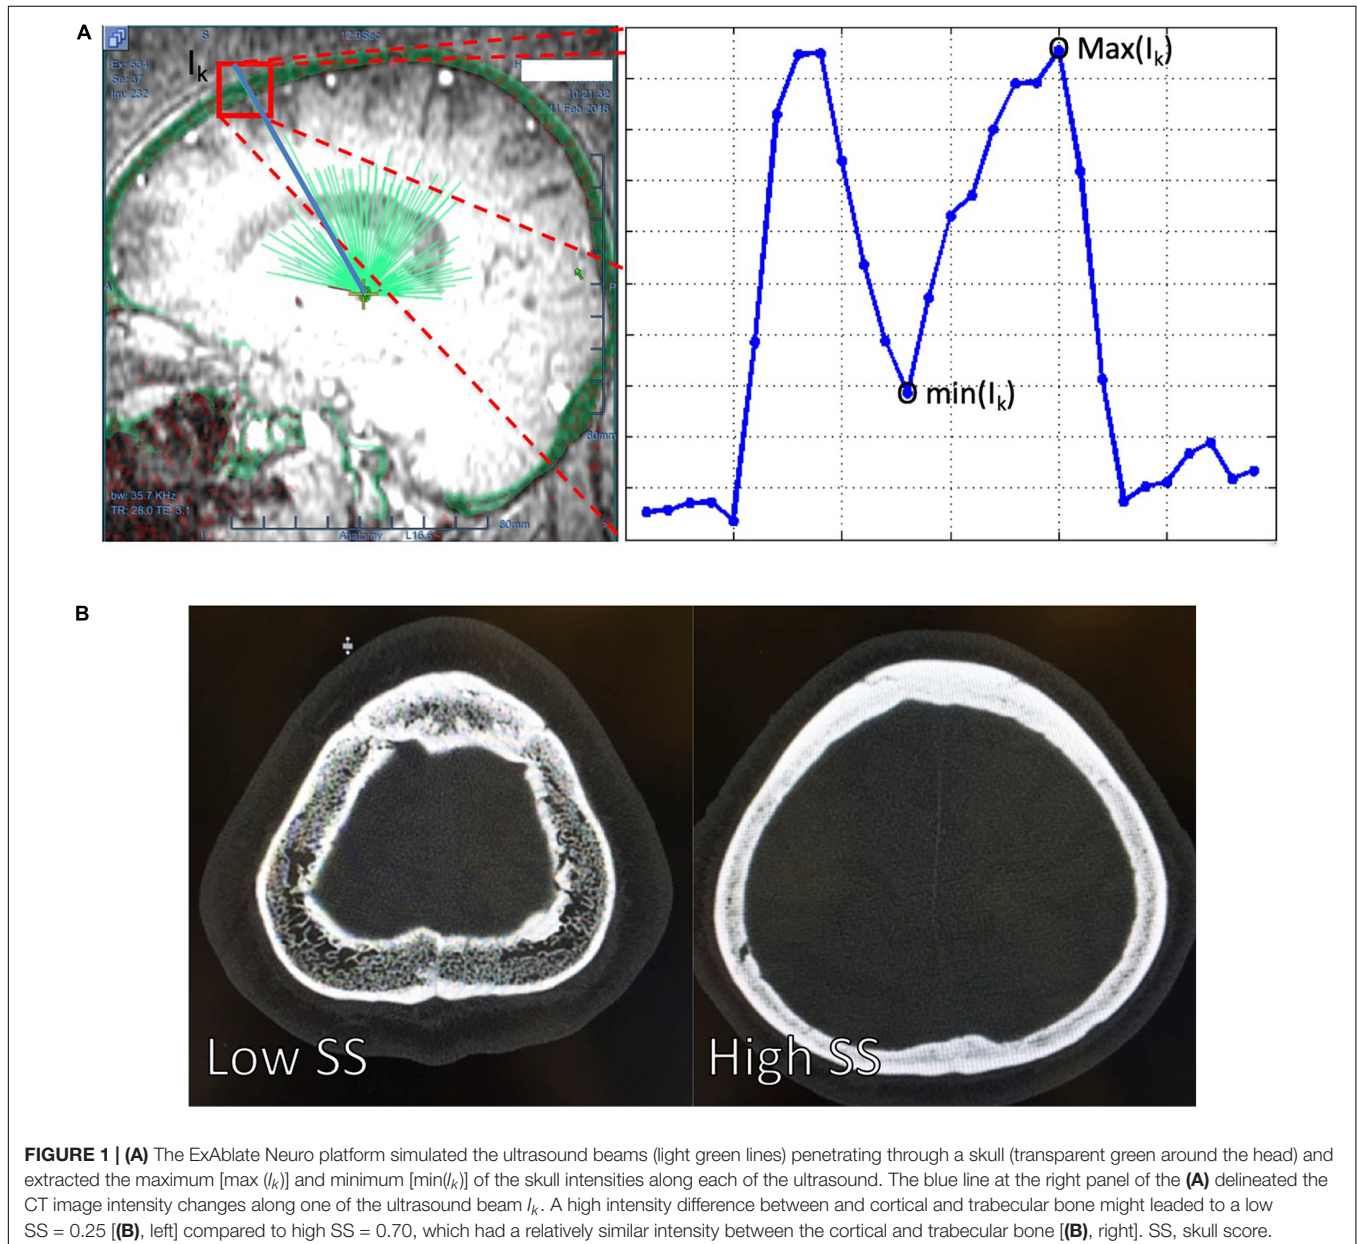

through the marked calcification. After the brain calcification selection, the treatment protocol will be selected and the fiducial will be manually placed. In the treatment tag of the ExAblate Neuro platform, the SS from respective patients were reported from the ExAblate Neuro platform. **Figure 1A** showed how the ExAblate Neuro platform simulated the ultrasound beams penetrated through the skull, and the definition of the maximum and minimum values of the skull along the  $I_k$ -th ultrasound beam. The SS for each patient was calculated by Eq. (1),

$$SS = \frac{\sum_{k=1}^P \min(I_k) / \max(I_k)}{P} \quad (1)$$

where  $P$  indicated the number of ultrasound beams from the transducer.

### cSDR Calculation

The same CT images of each patient were used to calculate the SS ratio by our method. Specifically, we first used the image contrast window and level provided by a high-pass filter to enhance the cortical and trabecular bone and used Otsu's method (Otsu, 1979) to separate the bone from the non-bone objects in the volumetric CT image. A mask volume was created by setting the intensity of bone to unity and that of non-bone to zero. The middle slice of the mask volume was used as the initial slice for the following analysis. Repeated image erosion was performed on the initial slice, and stopped before all the binary voxels were eroded. One of the remaining voxels was randomly selected and used as the seed point for the region growing on the initial slice. The candidates of the seed points for region growing of the adjacent slices to

**FIGURE 1 | (A)** The ExAblate Neuro platform simulated the ultrasound beams (light green lines) penetrating through a skull (transparent green around the head) and extracted the maximum [ $\max(I_k)$ ] and minimum [ $\min(I_k)$ ] of the skull intensities along each of the ultrasound. The blue line at the right panel of the (A) delineated the CT image intensity changes along one of the ultrasound beam  $I_k$ . A high intensity difference between cortical and trabecular bone might lead to a low SS = 0.25 [(B), left] compared to high SS = 0.70, which had a relatively similar intensity between the cortical and trabecular bone [(B), right]. SS, skull score.

the previous slice were selected from the overlap between two adjacent slices to ensure spatial continuity. The region growing procedure was stopped until all the slices of the CT mask image were performed. The mask image from the results after region growing was used to define the entire skull. The aforementioned procedure to the volumetric CT image was repeatedly performed for 30 times by considering the balance between the computation time and the accuracy of the skull definition. All the 30 masked images were added together into one masked image, with the voxel values ranging from 0 to 30. We used the part of the skull where the masked image value equals 30, indicating the part most spatially continuous from the initial slice, to exclude the part of the bone that might be less related to the regions of the MRgFUS thalamotomy, such as maxillary bone. The Otsu's method was again used to obtain the image intensity threshold of the cortical bone and trabecular bone of the skull. The SDR (Eq. 2) was calculated by dividing the average trabecular bone intensity (aTBI) across all  $N$  voxels by the average cortical bone intensity (aCBI) across all  $M$  voxels.

$$aTBI = \frac{\sum_{i=1}^N TBI_i}{N}, aCBI = \frac{\sum_{j=1}^M CBI_j}{M}, cSDR = \frac{aTBI}{aCBI} \quad (2)$$

All the aforementioned calculations were performed on the MATLAB (MathWorks, United States) platform.

## SDR Calculation

The histogram of all SSs from 246 patients was computed with the bin range from 0.1 to 0.8 and a step size of 0.01. The cumulative distribution function (Park, 2018) of the SS was computed from each bin of the histogram, leading a range from 0.1 to 0.8 and step size of 0.01.

## Correlation Between SS and cSDR

The linear correlations between the SS and the cSDR across all the patients were estimated by calculating the Pearson's correlation coefficient between the SS and the cSDR from each of the patients. Specifically, the bootstrap sampling (Efron, 1979) was applied to produce 24,600 pairs of SS-cSDR pairs by repeatedly selecting 246 samples from our 246 data. For example, one can select [1,1,1,2,2,3,3,3,..., 122] or [1,2,3,4,5,6,...,246] from our 246 data while the number here in the bracket means the data index. A new SS-cSDR pair was produced by averaging across the SS and cSDR of each of the selections. The data selection and averaging were repeated 24,600 times, then we had 24,600 SS-cSDR pairs. The linear correlation between the SS and the cSDR after bootstrap sampling was estimated by calculating the Pearson's correlation coefficient across all the bootstrapped pairs. Similarly, the linear correction of the SS-aCBI and SS-aTBI pairs across all the patients was respectively estimated to evaluate the influence of the aCBI and the aTBI on the SS. The correlation coefficient of the aforementioned calculation was done on MATLAB (MATLAB and Statistics Toolbox Release 2018a, The MathWorks, Inc., Natick, MA, United States) by using the *corrcoef* function. The Pearson's correlation coefficient and the  $p$ -value of this calculation were reported accordingly.

## RESULTS

The 246 patients' demographic characteristics are summarized in **Table 1**. There were 114 clinically diagnosed essential tremor (ET) patients, and the rest of them experiencing other types of tremors, including Parkinson's disease and psychogenic tremor, etc. **Figure 1B** shows an exemplar of the trans-axial CT images with low (SS = 0.25) and high (SS = 0.70). The main difference between the CT images with the low (**Figure 1B**, left) and the high SS (**Figure 1B**, right) was that the contrast between the cortical and trabecular bone was higher in the low SS CT image than that in the high SS CT image. According to Eq. (1), a high intensity difference between the cortical and trabecular bone would lead to a high SS.

## SS Distribution Calculation

The mean and the standard deviation of the SS from the total 246 patients were  $0.419 \pm 105$  and ranged from 0.16 to 0.73. **Figure 2A** shows the histogram of the SS of the included patients and there was a population peak at the SS = 0.41. **Figure 2B** shows the cumulative distribution function of the SS.

## Correlation Between SS and cSDR

The total 2,46,000 bootstrapped samples (**Figure 3**) resulted in the SS ranging from 0.38 to 0.44 and cSDR ranging from 0.712 to 0.728. The Pearson's correlation coefficient between the SS and cSDR was 0.8145 with the statistical significance ( $p < 10^{-5}$ ), and linear relation between the SS and cSDR:

$$SDR = 0.2154 \times SS + 0.6312 \quad (3)$$

**Figures 4A,B** show that the aCBI and aTBI were linearly correlated with SS, and the linear relations were:

$$aCBI = 375.5 \times SS + 2426 \quad (4)$$

$$aTBI = 826 \times SS + 1518 \quad (5)$$

between aCBI and aTBI to SS, respectively. However, the aCBI was less correlated ( $R = 0.5723$ ) to SS than that of aTBI to SS

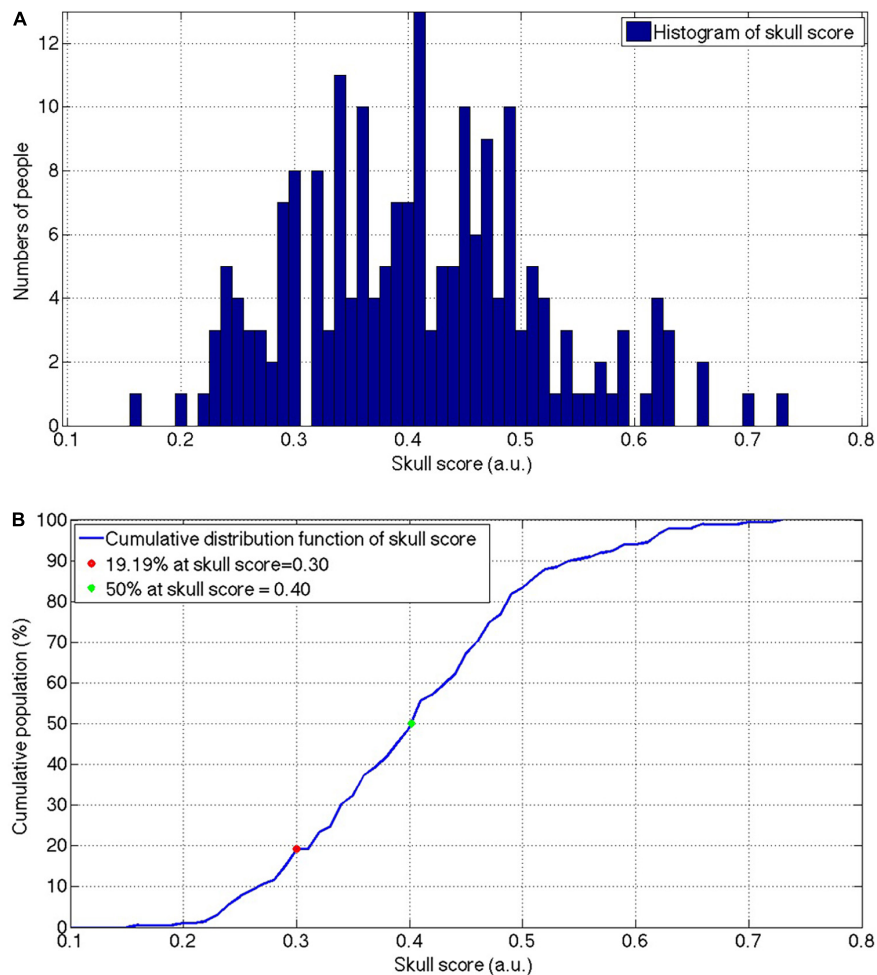

**TABLE 1** | Demographic characteristics in subjects with tremor.

Variables	Number (%)	Mean $\pm$ SD	$p$ -value
Female/male	83/163 (33.7/66.3)		
Age (years)		62.41 $\pm$ 12.04	
ET/non-ET	192/54 (78/22)		
SS (total)		0.41 $\pm$ 0.12	
SS (female)		0.40 $\pm$ 0.12	
SS (male)		0.41 $\pm$ 0.12	0.88 <sup>1</sup>
SS (ET)		0.41 $\pm$ 0.12	
SS (non-ET)		0.41 $\pm$ 0.13	0.66 <sup>2</sup>

ET, essential tremor; non-ET, non-essential tremor; SS, skull score.

<sup>1</sup> Comparison of SS between female and male.

<sup>2</sup> Comparison of SS between ET and non-ET.

**FIGURE 2 |** The histogram (A) and the cumulative distribution function (B) of the SS for the patients who received the MRgFUS thalamotomy screening. The envelope of the histogram showed a slightly positive skewed distribution and the peak was located at 0.41. The slope of the cumulative population was visually consistent from the beginning and start to decrease after the SS = 0.50. SS, skull score; MRgFUS, Magnetic resonance-guided focused ultrasound.

( $R = 0.8842$ ). Moreover, the slope of the linear relation between the aTBI and the SS was higher (Eq. 5, slope = 826) than that between the aCBI and the SS (Eq. 4, slope = 375.5).

## DISCUSSION

This study demonstrated the distribution of SS in the population of tremor dominant patients in Taiwan. Only half of the patients fulfilled the empirical SS criteria for the MRgFUS treatment. To our knowledge, this is the first report of SS distribution in patients with tremors.

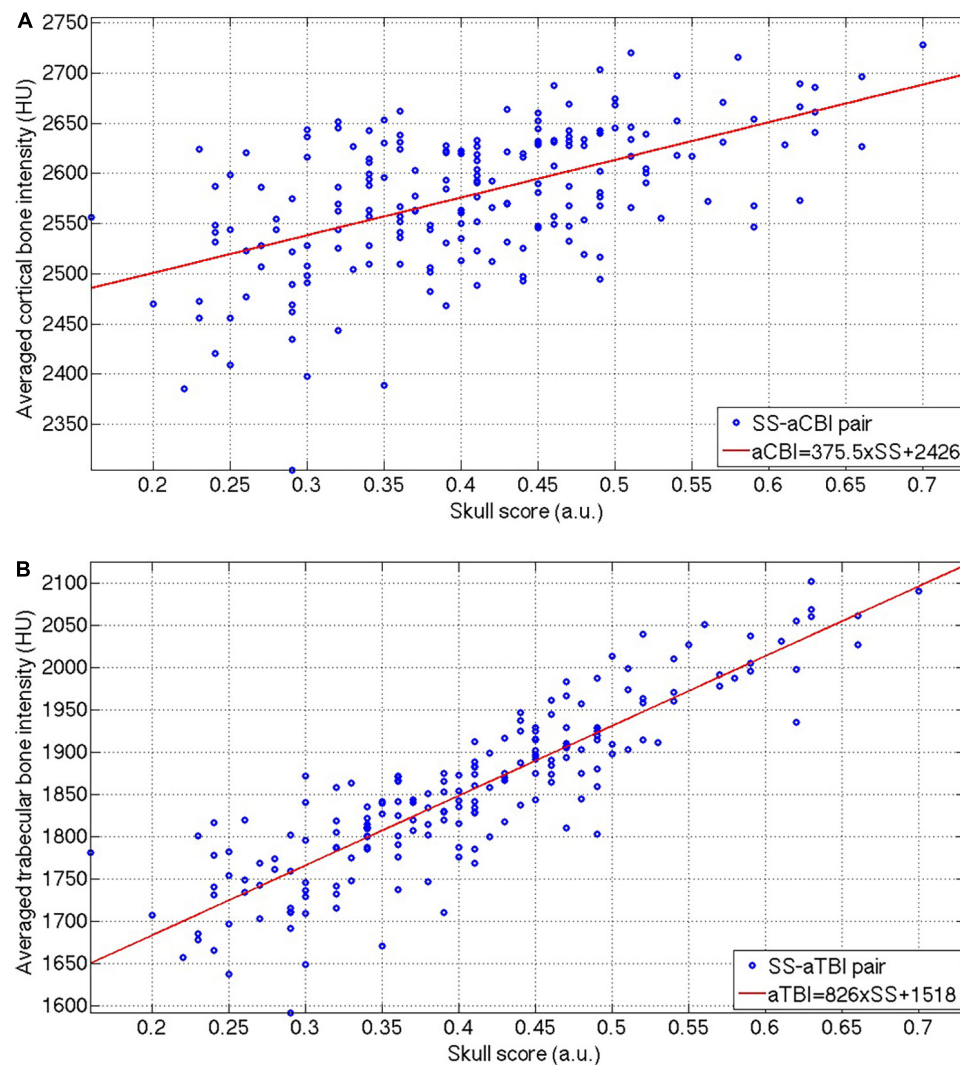

In this study, we screened 246 patients, and ET patients occupied about 46% (114/246) of total participants. This result was consistent with the perception that ET is the most common movement disorder compared to others (Thanvi et al., 2006) in elderly people. However, the average age of the participants enrolled in this study was high and this limitation might affect the following analysis of the SS or SDR distributions.

**FIGURE 3 |** The distribution of the bootstrapped SS-cSDR pairs and the linear correction between these SS-SDR pairs. The blue dots show the total 2,46,000 bootstrapped samples, and the red line indicates the linear fitting of these bootstrapped samples. SS, skull score; cSDR, customized skull density ratio.

Traditional SDR calculation is done by first defining the regions of cortical bone and trabecular bone of the skull and then

**FIGURE 4 |** The distribution of the SS-aCBI (A) and SS-aTBI (B) pairs, and the respective linear fitting (red lines) of these two pairs. SS, skull score; aCBI, average cortical bone intensity; aTBI, average trabecular bone intensity.

dividing the average trabecular image intensity by the average cortical image intensity. Our approach differed, and the SS, which is offered by InSightec Inc., was calculated by averaging across all the ratios of the minimum and the maximum of the HU number of the skull CT image along thousands of spatial pathways from the ultrasound transducer to the simulated target in the subcortical area. The traditional SDR is in practice the same as the cSDR in this study in terms of the calculation, which is the averaged tubercular bone intensity over the averaged cortical bone intensity. We used our customized algorithm to automatically extract the skull which has a similar skull region for the SS calculation and then calculate the traditional SDR. Compared with the SS, our cSDR calculation is free from complex steps when calculating the SS.

A high SS suggested a high possibility of success to the MRgFUS thalamotomy to relieve the tremor (Chang et al., 2016). However, according to the SS distribution from our results (Figure 2B), nearly half of the patients have an SS lower than

0.4 in tremor patients of Taiwanese descent, indicating that for those patients, it might be difficult to raise the temperature to the therapeutic 54-degree during the MRgFUS thalamotomy. It is noteworthy that there was a closed 20% of the patients with SS lower than 0.3, indicating the bare success of the MRgFUS thalamotomy for those patients. It minimizes the feasibility of treatment in Asia.

Interestingly, SS is correlated with the trabecular bone rather than the cortical bone. The bootstrapped samples of the SS-cSDR pairs showed a high correlation between SS and cSDR (Figure 3), and the value of the SS was always lower than cSDR in our data. Theoretically, the highest value in the SS calculation indicated the intensity of the cortical bone while the lowest value might not necessarily come from the trabecular bone. The lowest value may represent the intensity of the trabecular bone space or the partial volume of the trabecular bone. The larger difference between the highest and lowest value would lead to a smaller SS. In comparison, our cSDR calculation only use the trabecular bone

value, and it would decrease the difference to the cortical bone, leading to a larger cSDR value than the SS. Moreover, according to Eq. (3), SS was more sensitive than cSDR to the cortical and trabecular bone differences since 1 SS would only produce 0.8466 SDR. In **Figures 4A,B**, both the aTBI and the aCBI have a linear correlation with the SS, and the slope of the respective linear fitting indicating that the aTBI increased higher than the aCBI when increasing the SS, and vice versa. This might be due to the fact that the CBI has smaller variation across patients than the TBI. Here, our data showed a reliable relation of cSDR with SS. Moreover, a possible solution for low SDR should be focused on the aTBI rather than aCBI.

## CONCLUSION

To our knowledge, this is the first report of the SS population for the MRgFUS thalamotomy in Taiwanese tremor patients. Our results suggest that in nearly half of the Taiwanese patients with tremors it might not be feasible to achieve the therapeutic temperature using current MRgFUS thalamotomy. Accordingly, it is crucial to improve the energy-temperature efficiency for the MRgFUS thalamotomy.

Moreover, our results showed a linear relationship between the SS and our cSDR. In addition, SS correlated more to the trabecular bone than cortical bone. Clinically, seeking a medical approach to increase the aTBI intensity might increase the SS, and further improve the energy-temperature efficiency during the MRgFUS treatment.

**Background:** Alzheimer's disease (AD) is one of the major threats of the twenty-first century and lacks available therapy. Identification of novel molecular markers for diagnosis and treatment of AD is urgently demanded, and genetic biomarkers show potential prospects.

**Method:** We identify and intersected differentially expressed genes (DEGs) from five microarray datasets to detect consensus DEGs. Based on these DEGs, we conducted Gene Ontology (GO), performed the Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis, constructed a protein–protein interaction (PPI) network, and utilized Cytoscape to identify hub genes. The least absolute shrinkage and selection operator (LASSO) logistic regression was applied to identify potential diagnostic biomarkers. Gene set enrichment analysis (GSEA) was performed to investigate the biological functions of the key genes.

**Result:** We identified 608 consensus DEGs, several dysregulated pathways, and 18 hub genes. Sixteen hub genes dysregulated as AD progressed. The diagnostic model of 35 genes was constructed, which has a high area under the curve (AUC) value in both the validation dataset and combined dataset (AUC = 0.992 and AUC = 0.985, respectively). The model can also differentiate mild cognitive impairment and AD patients from controls in two blood datasets. Brain-derived neurotrophic factor (BDNF) and WW domain-containing transcription regulator protein 1 (WWTR1), which are associated with the Braak stage, A $\beta$  42 levels, and  $\beta$ -secretase activity, were identified as critical genes of AD.

**Conclusion:** Our study identified 16 hub genes correlated to the neuropathological stage and 35 potential biomarkers for the diagnosis of AD. WWTR1 were identified as candidate genes for future studies. This study deepens our understanding of the transcriptomic and functional features and provides new potential diagnostic biomarkers and therapeutic targets for AD.

## INTRODUCTION

Alzheimer's disease (AD) is the most common neurodegenerative disease in the elderly, affecting more than 35.6 million people worldwide (Querfurth and LaFerla, 2010; Kumar et al., 2015). Epidemiological analysis has predicted that the number will rise to 65.7 million in 2030 and approximately 115.4 million in 2050 (Prince et al., 2013). The symptoms usually start with subtle memory loss and gradually progress to affect other cognitive domains as the condition deteriorates, such as language, visuospatial skills, motor skills, executive function, and activities of daily living (McKhann et al., 2011; Huang and Mucke, 2012). As AD usually has concealed onset, most patients with AD are already at an advanced stage at the time of diagnosis. Furthermore, the long-term care and related costs of AD contribute a substantial economic burden to the society and family. It is reported that the global societal cost for dementia is projected to grow to approximately \$2 trillion in 2030 (Wimo et al., 2017). Unfortunately, despite recent progress in understanding the neurobiology and pathophysiology of AD so far, no therapeutic strategies can effectively prevent or cure AD. Therefore, research directed toward identifying AD biomarkers is needed for the early diagnosis, prevention, and treatment of AD.

AD is a characteristic “complex” disease resulting from the interaction of genetic and environmental factors. It is known that the primary pathogenesis of AD was  $\beta$ -amyloid ( $A\beta$ ) abnormal deposition, neurofibrillary tangles induced by phosphorylation of tau proteins, inflammatory response, oxidative stress, and neuronal apoptosis. All these processes involve alterations in the expression and regulation of numerous genes. Studies suggest that genetic factors are estimated to attribute up to 79% to the risk for AD (Wingo et al., 2012). The apolipoprotein E (APOE)  $\epsilon 4$  allele has been identified as the most substantial risk factor for AD (Rogaev et al., 1995; Sherrington et al., 1995). Mutations in the genes which enhanced generation and aggregation of  $A\beta$ , such as amyloid precursor protein (APP), presenilin (1) (PSEN1), and presenilin (2) (PSEN2), were included in the established genetic causes of familial AD (Sorbi et al., 2001; Tanzi and Bertram, 2005). Moreover, genetic analyses have suggested that the individual differences and complicated pathogenesis of AD may be influenced by multiple genes and their variants involved in numerous biological functions and substantially increase the risk of the disease (Hokama et al., 2014; Stopa et al., 2018). Therefore, identification and comprehensive analyses of potential candidate genes will considerably increase our understanding of the biological mechanisms involved in disease pathogenesis and could potentially be used as diagnostic or predictive biomarkers for AD.

In recent years, bioinformatics analysis is widely applied in molecular biology experiments and clinical practice (Banwait and Bastola, 2015), revealing the key pathways and drug targets in complex diseases (Khan et al., 2018). Thus, joint analysis of the array-based data of AD may be a novel analytical strategy. Our present study aims to reveal the transcriptomic characteristics and identification of novel biomarkers of AD for diagnosis

and treatment. We identified co-differentially expressed genes (DEGs) in AD of five microarray datasets in the Gene Expression Omnibus (GEO). Based on the results, we performed a series of analyses, including Gene Ontology (GO), Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment pathway analysis, protein–protein interaction (PPI) analysis, and least absolute shrinkage and selection operator (LASSO) logistic regression analysis. We identified 18 hub genes and tested their expression levels in different Braak stages. A 35-gene-based diagnosis model was constructed, and then we test the diagnostic values for AD and mild cognitive impairment (MCI). Finally, two key genes were identified by overlapping the 18 hub genes and 35 diagnosis genes. We further explored their correlations with  $\beta$ -secretase activity and  $A\beta$  42 levels. Gene set enrichment analysis (GSEA) was used to explore the potential biological functions of hub genes. Our present study could provide more insights into the molecular mechanism of AD and provided potential biomarker candidates for clinical diagnosis and treatment.

## MATERIALS AND METHODS

### Data Processing

GEO<sup>1</sup> is a public functional genomics data repository of high-throughput gene expression data, chips, and microarrays. According to the following criteria, datasets were considered eligible for our analysis: (1) datasets with AD samples; (2) datasets supported by peer-reviewed PubMed-indexed publications; and (3) studies with information about the technology and platform utilized for studies. We selected 10 datasets (GSE33000, GSE36980, GSE48350, GSE5281, GSE122063, GSE106241, GSE4226, GSE97760, GSE63060, and GSE63061) related to AD for analysis. A total of 757 non-demented healthy control subjects (NDHCS) and 932 AD patients were analyzed. We extracted the whole data of a single study, including all brain regions, for analysis. The data sample collection is shown in **Table 1**. The flowchart of the study is illustrated in **Figure 1**.

The GSE33000 (platform GPL4372) was composed of postmortem prefrontal cortex (PFC) samples of 157 NDHCS and 310 AD patients with matched genotype and clinical data. The GSE36980 (platform GPL6244) was composed of the frontal cortex (FC), temporal cortex (TC), and hippocampus (HPC) from 47 NDHCS and 32 AD patients. From GSE48350 (platform GPL570), we selected data from the HPC, entorhinal cortex (EC), superior frontal cortex (SFC), and post-central gyrus (PCGY) derived from 253 postmortem brains, among which 80 cases were diagnosed as having AD. The GSE122063 (platform GPL16699) was composed of tissues collected from FC and TC, 44 tissues from NDHCS and 56 from AD patients. The GSE5281 (platform GPL570) was composed of tissues collected by laser capture microscopy (LCM) from 74 NDHCS and 87 AD patients. The brain regions included the EC, HPC, medial temporal gyrus, posterior cingulate, SFC, and primary visual cortex. The GSE106241 was enrolled for independent external validation. In

The first five datasets were used for combined analysis, GSE106241 was used for independent validation analysis, and the last four datasets were used for evaluating the diagnosis model in peripheral blood. AD, Alzheimer's disease; MCI, mild cognitive impairment; NDHCS, non-demented healthy control subjects. GPL, Gene Expression Omnibus Platform.

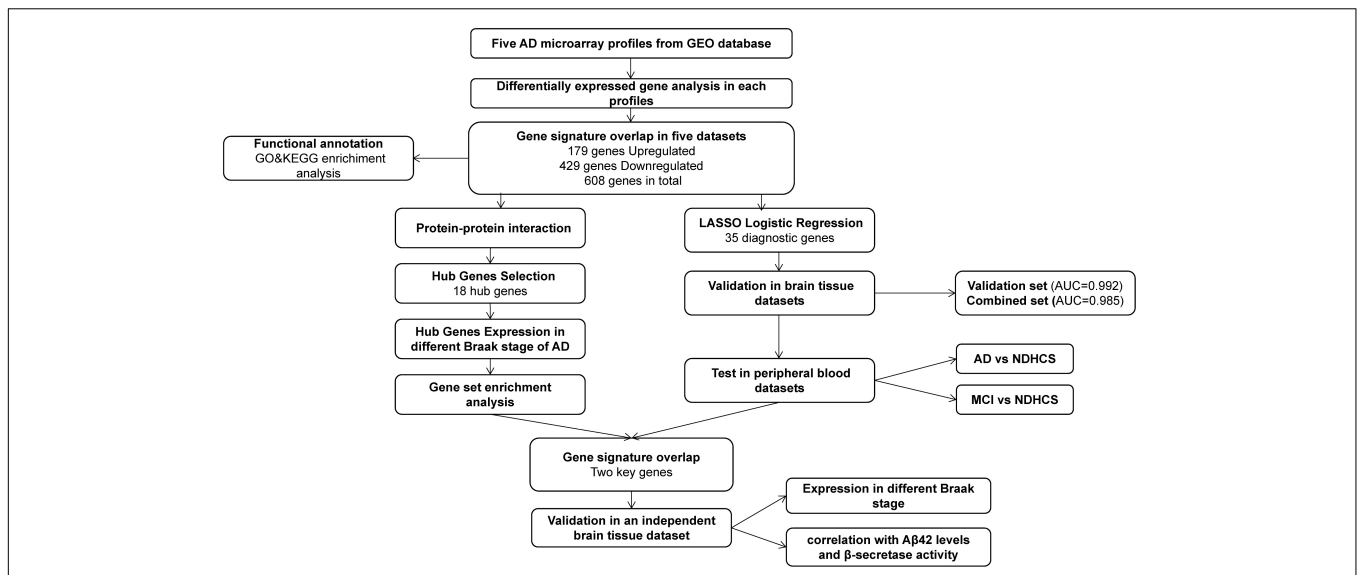

this dataset, 60 human temporal cortical tissue samples were included and divided into seven groups based on Braak staging.

Gene expression profiles of peripheral blood were obtained from GSE97760, GSE4226, GSE63060, and GSE63061. Study subjects from GSE97760 (platform GPL16699) were all female, including nine subjects with advanced AD and 10 age-matched NDHCS. The GSE4226 (platform GPL1211) was composed of peripheral blood mononuclear cells from 14 NDHCS and 14 AD patients. Datasets GSE63060 and GSE63061 were composed of MCI patients, AD patients, and NDHCS. There are 329 samples (145 AD, 80 MCI, and 104 NDHCS) in GSE63060 and 382 samples (139 AD, 109 MCI, 134 NDHCS) in GSE63061. Three borderline MCI samples, one NDHCS-to-AD sample,

one MCI-to-NDHCS sample, and one other sample, were excluded from GSE63061.

## Identification of Consensus DEGs

As single datasets and few samples may weaken the credibility of the results, data integration is necessary to look for findings supported by several pieces of evidence and investigate the complex genetic mechanisms (Pineda et al., 2015). Therefore, five brain tissue datasets (GSE33000, GSE36980, GSE48350, GSE5281, and GSE122063) were selected to identify consensus DEGs. We used the impute package to supplement missing data (Troyanskaya et al., 2001). Then, the normalizeBetweenArrays function in the limma package was used to normalize gene

**FIGURE 1 |** Flowchart for bioinformatics analysis in this study. AD, Alzheimer's disease; MCI, mild cognitive impairment; NDHCS, non-demented healthy control subjects; AUC, area under the curve; GSEA, gene set enrichment analysis; GEO, Gene Expression Omnibus; GO, Gene Ontology; KEGG, Kyoto Encyclopedia of Genes and Genomes.

expression. Next, we performed the differential analysis in each of the datasets. We screened DEGs by comparing AD tissues to NDHCS tissues in the R computing environment using the limma package (Ritchie et al., 2015). DEGs were determined by  $|\log_2 FC| > 0$ , adjusted  $p$ -value  $< 0.05$ . Volcano plots were generated using ggplot 2 in R. In order to obtain a consensus of DEGs, Venn analysis was performed using Draw Venn Diagram, a Web-based tool,<sup>2</sup> to identify common DEGs from the five datasets. The heatmap of the consensus DEGs was drawn using the R pheatmap package. We performed the batch correction, followed by normalization between arrays to remove the heterogeneity among multiple microarray datasets using sva and limma packages (Leek et al., 2012). Finally, principal component analysis (PCA) was performed to compare the difference of consensus DEGs between AD and NDHCS groups in different brain regions.

## GO Enrichment and KEGG Pathway Analysis of the DEGs

GO enrichment analyses were performed in R using the function of clusterProfiler14. Metascape<sup>3</sup> was used to perform the KEGG pathway analysis. Functional and pathway enrichment analyses were conducted separately for upregulated and downregulated genes. In this analysis, a  $p$ -value  $< 0.05$  was considered significant for the screening of significant GO terms and KEGG pathways. Furthermore, we performed the differential analysis separately in 10 brain regions. DEGs were determined by  $|\log_2 FC| > 0$ , adjusted  $p$ -value  $< 0.05$ . The top 100 upregulated DEGs and top 100 downregulated DEGs of each brain region were used for GO enrichment analyses. Finally, we take the intersection of

pathways of each brain region to identify common and specific dysregulated pathways.

## PPI Network Construction, Hub Gene Selection, and Hub Gene Expression in Different Braak Stages of AD

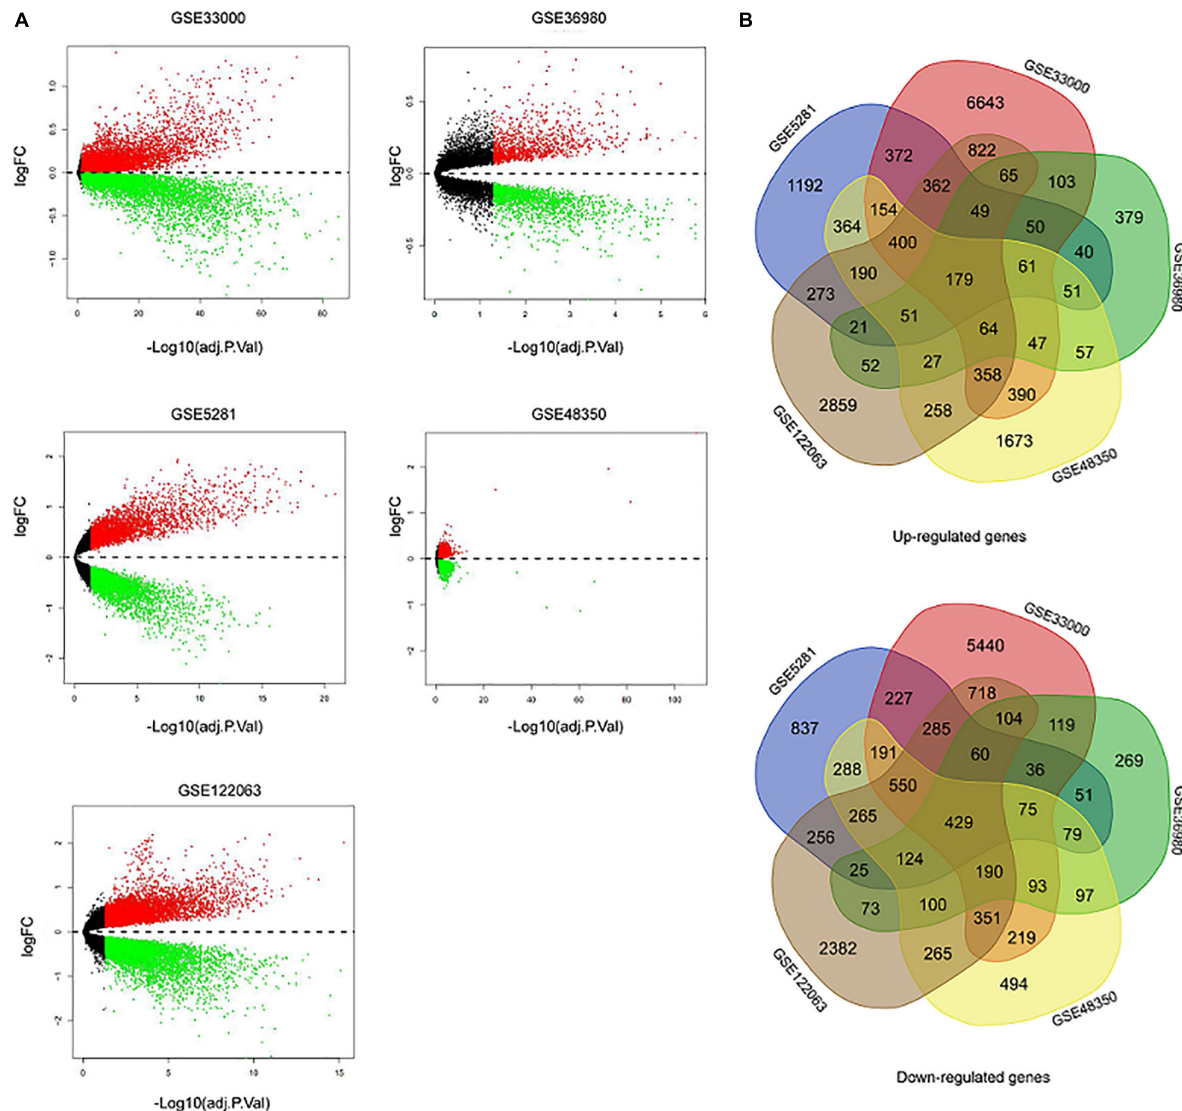

To further explore the interactions among DEGs, PPI network analysis was performed using the online database STRING with an interaction score of 0.4 as the threshold. Next, we utilized Cytoscape (version 3.7.1) to construct and visualize the main regulatory network. We used cytoHubba, a plugin of Cytoscape, to select the hub genes in the PPI network. Five methods (degree, maximum neighborhood component (MNC), radiality centrality, stress centrality, closeness centrality) were used to sequence and evaluate central genes (Chin et al., 2014). The five ranked methods selected the top 20 hub genes. Venn analysis was performed to identify central genes by overlapping the top 20 genes. Finally, we validate hub gene expressions in different Braak stages using the HPC and superior frontal cortex (SPF) samples in the dataset GSE48350. Overall differences between groups were tested with the Kruskal–Wallis (K-W) test, and differences between groups were compared by the Wilcoxon test. The boxplot was drawn by R package ggplot 2. The top 10 hub genes were also further evaluated based on the difference in the gene expression of GSE48350.

## Identification of Potential Biomarkers of AD Using LASSO Logistic Regression

The LASSO, a penalized shrunken regression method, has a strong predictive value and low correlation and is applied to select the best features for high-dimensional data. The samples from five brain tissue datasets were randomly assigned to the

<sup>2</sup><http://bioinformatics.psb.ugent.be/webtools/Venn/>

<sup>3</sup><http://metascape.org>

**FIGURE 2 |** Identification of DEGs between AD and NDHCS samples. **(A)** The volcano plot of the genes in the five datasets. **(B)** Venn diagram analysis of common downregulated DEGs and common upregulated DEGs. AD, Alzheimer's disease; NDHCS, non-demented healthy control subjects.

training set (30%) and validation set (70%). The expression profiles of consensus DEGs were extracted and fit into LASSO logistic regression by the glmnet package. In order to evaluate the ability of the LASSO model to identify AD, receiver operating characteristic (ROC) analysis was completed using the package of pROC in the validation set and combined set (Robin et al., 2011). The area under the curve (AUC) was calculated, and AUC values close to 1 ( $AUC > 0.7$ ) refer to good classifier models. We also investigated the diagnosis effect of the top 10 hub genes in the combined set.

## Evaluate the Diagnosis Model in Peripheral Blood Datasets

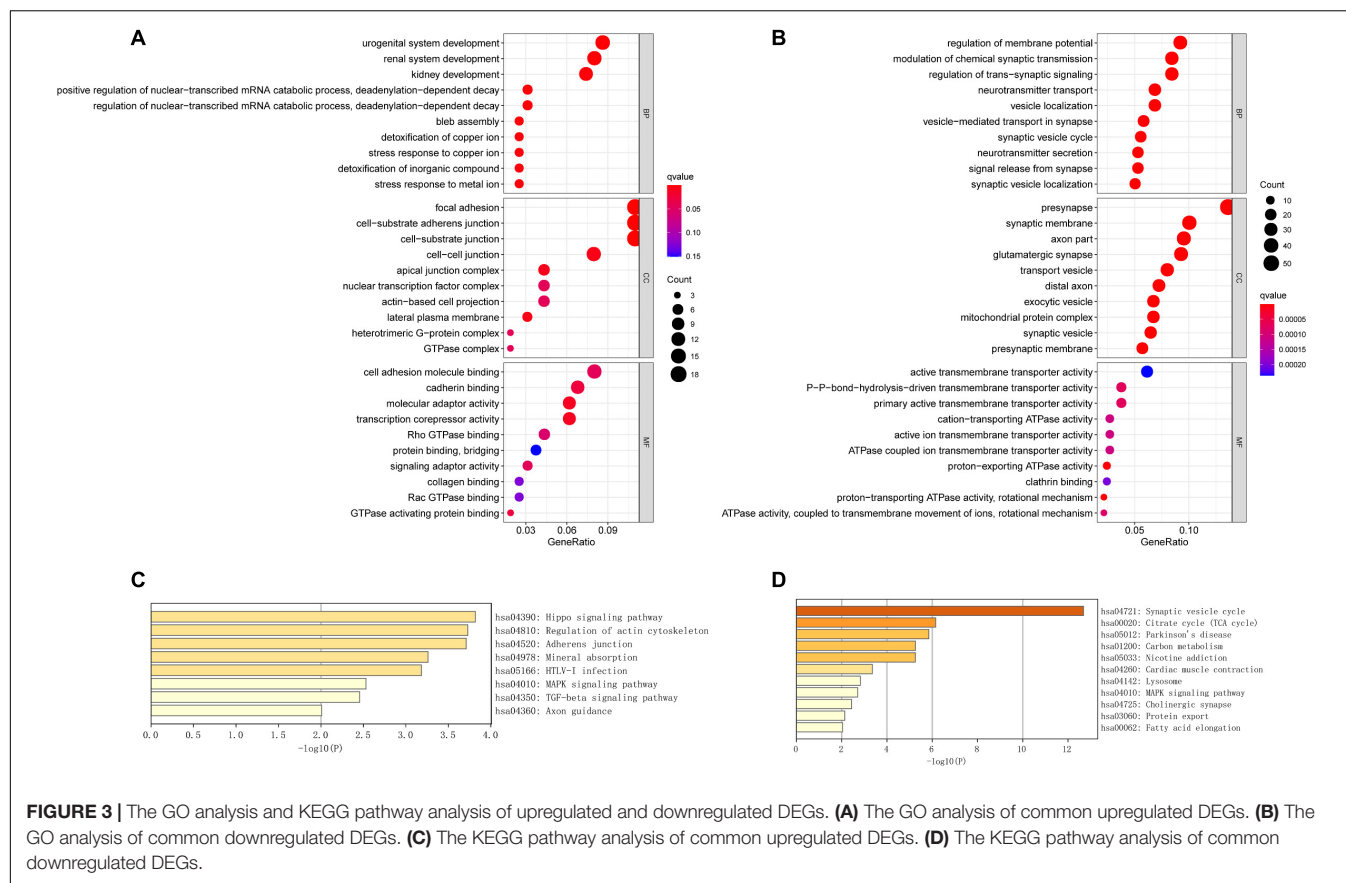

As it is hard to obtain brain tissues for diagnosis in clinical practice, we attempted to enroll independent peripheral blood

datasets to evaluate the clinical utility of our diagnosis model. We performed ROC analyses in GSE4226 and GSE97760 to examine the ability to differentiate AD from NDHCS. The datasets GSE63060 and GSE63061 were used to verify the accuracy of the model to differentiate MCI and AD from NDHCS. ROC curves were plotted using the "pROC" package.

## GSEA and Independent Validation Analysis

GSEA was performed to identify biological process (BP) GO terms of the top 10 hub genes that may be correlated to AD in GSE48350 datasets. We performed GSEA using the R package clusterProfiler for analysis. The c5.bp.v 7.0.symbols.gmt datasets in the MsigDB V 6.2 database<sup>4</sup> were used as reference

<sup>4</sup><http://software.broadinstitute.org/gsea/msigdb/>

gene sets, and those with an adjusted  $p$ -value  $< 0.05$  after 1,000 permutations were considered significantly enriched gene sets (Subramanian et al., 2005). We determined the key genes by overlapping the hub genes selected from the PPI network and potential diagnosis genes identified from the LASSO regression model. Next, we enrolled another independent dataset (GSE106241) and compared the expression level of key genes in different Braak stages using the K-W test. Moreover, we investigated their associations with  $\beta$ -secretase activity and A $\beta$  42 levels in AD samples from GSE106241 using the Spearman correlation analysis.  $p$ -values less than 0.05 ( $p < 0.05$ ) were considered significant. The violin plots and correlation analysis in this section were all generated in R 3.6.3.

## RESULTS

### Identification of Consensus DEGs

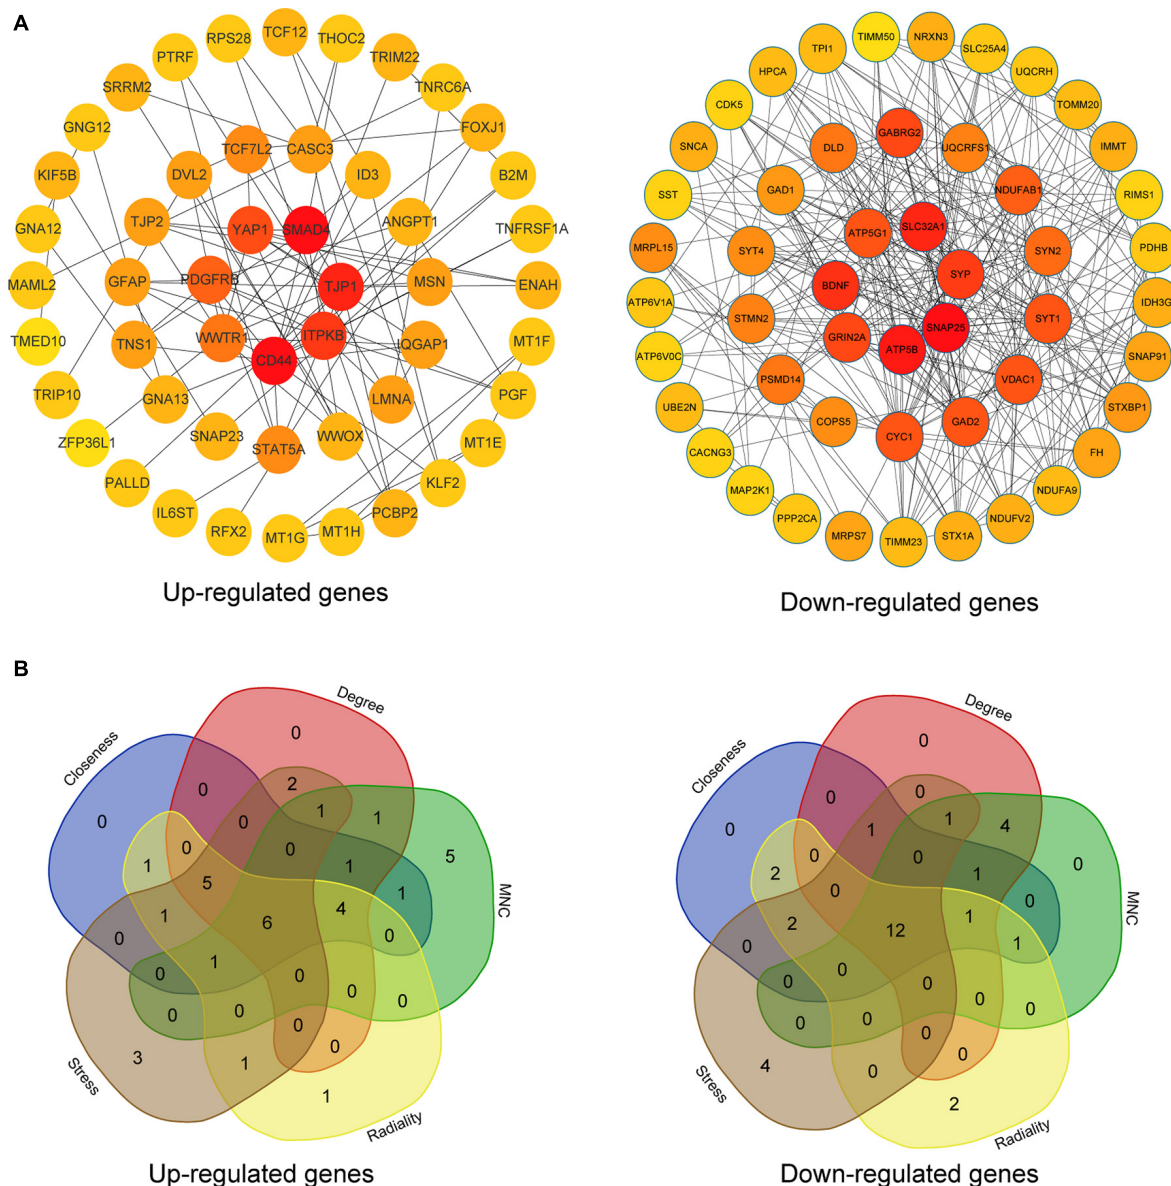

Five microarray datasets, including GSE33000, GSE36980, GSE48350, GSE5281, and GSE122063, were downloaded from the National Center of Biotechnology Information-GEO (NCBI-GEO). Details of the five datasets are presented in Table 1. A total of 1,060 samples (495 NDHCS subjects and 565 AD patients) were available for DEG analysis, including microarray data from 10 brain regions: the EC, FC, HPC, medial temporal gyrus, PCGY, posterior cingulate, PFC, primary visual cortex,

SFC, and TC. After background correction and normalization, we used the limma package to identify DEGs between NDHCS and AD samples of GEO data. Gene difference analysis found that there were 19,206 DEGs in GSE33000, 3,220 DEGs in GSE36980, 8,134 DEGs in GSE48350, 7,587 DEGs in GSE5281, and 12,207 DEGs in GSE122063 compared with AD patients and NDHCS (Supplementary Table 1). Volcano plots in Figure 2A show the number of DEGs identified from each of the five datasets. Subsequently, we intersected these DEGs from the five datasets and finally identified 608 common DEGs, of which 179 DEGs were upregulated and 429 DEGs were downregulated (Figure 2B and Supplementary Table 1). To compare the DEGs between the AD and NDHCS groups, the heatmap showed the expression of common DEGs from five datasets (Supplementary Figure 1). PCA revealed that the expression of common DEGs differed significantly between NDHCS and AD samples in each brain region, indicating that the DEGs we found were common core genes in AD (Supplementary Figure 2).

### GO Enrichment and KEGG Pathway Analysis of the DEGs

We performed GO term, KEGG pathway, and functional enrichment analyses to explore the potential biological functions of the common DEGs. The GO annotation results include BP, molecular function (MF), and cellular component (CC). The results revealed that the BP primarily associated

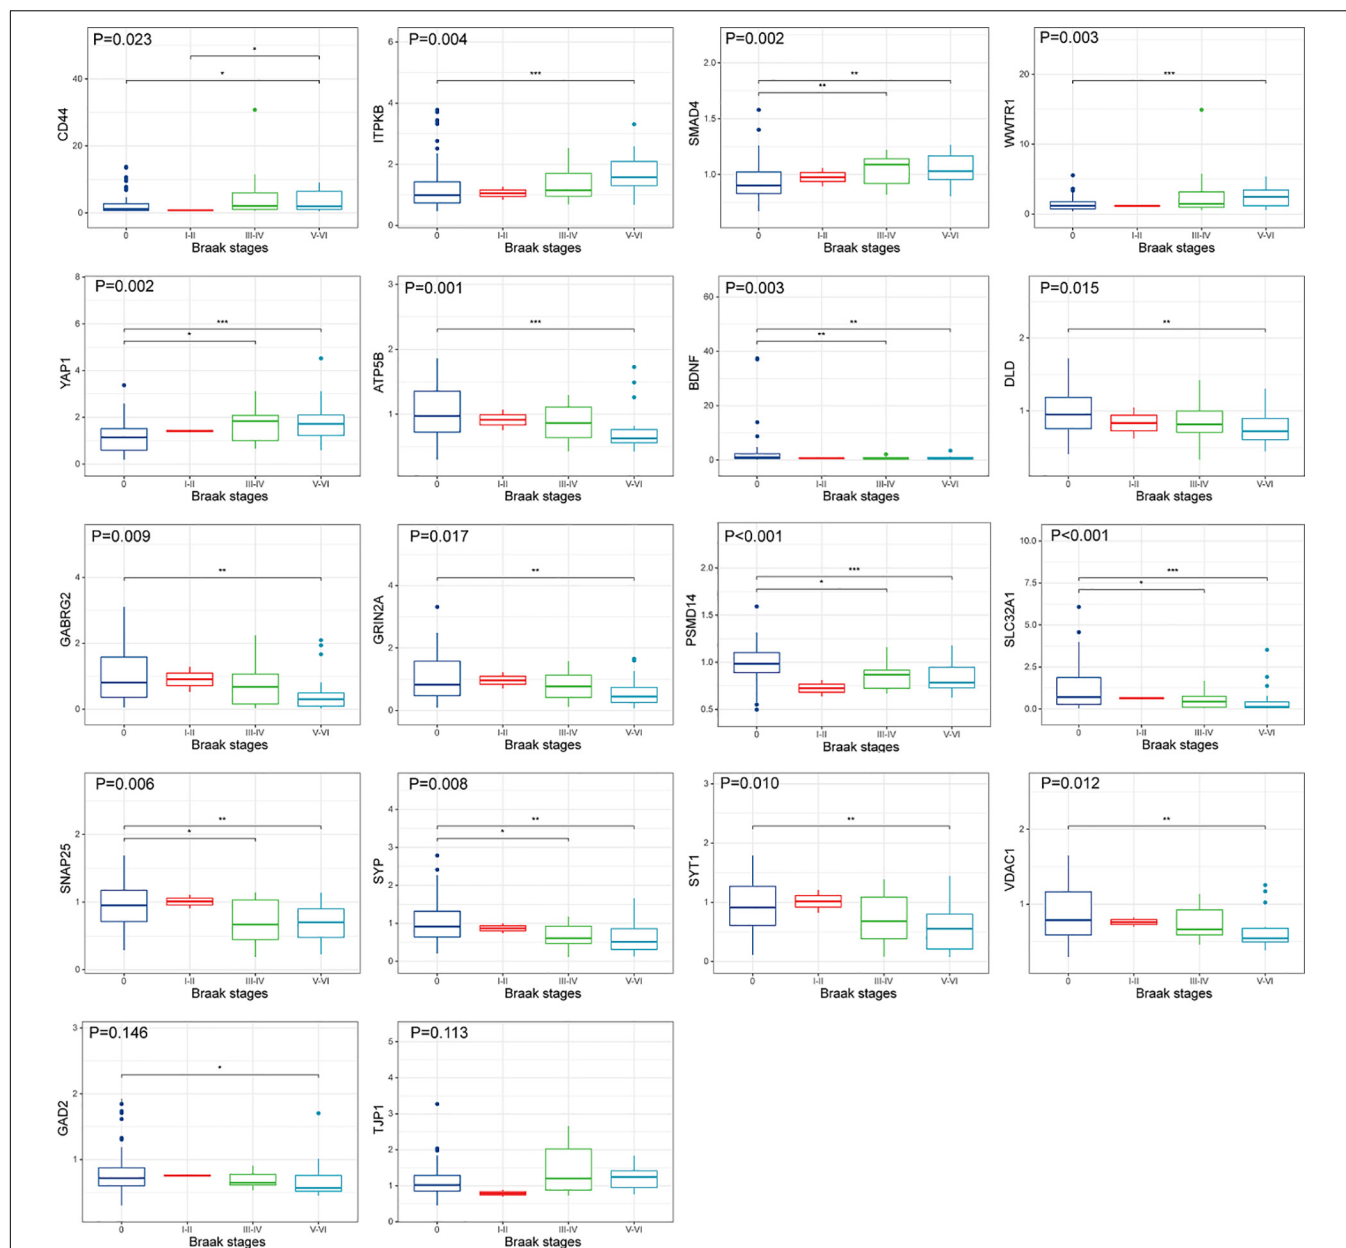

**FIGURE 4 |** PPI network and hub gene selection. **(A)** The top 50 hub genes in the PPI network of the upregulated and downregulated DEGs according to node degree. **(B)** Hub genes were identified by overlapping the first 20 genes in the five classification methods of cytoHubba.

with the upregulated genes, including the regulation of the nuclear-transcribed mRNA catabolic process, bleb assembly, detoxification of copper ion, stress response to copper ion, detoxification of inorganic compound, and stress response to metal ion. For CC enrichment analysis, the results showed that upregulated genes significantly took part in the focal adhesion, cell—substrate adherens junction, cell—substrate junction, and cell—cell junction. For MF analysis, upregulated genes are mainly enriched in cell adhesion molecule binding, cadherin binding, molecular adaptor activity, and transcription corepressor activity (**Figure 3A**). For downregulated genes, regulation of membrane potential, modulation of chemical synaptic transmission, regulation of transsynaptic signaling, and neurotransmitter

transport were dominant BPs. For CC enrichment analysis, downregulated genes mainly take part in presynapse, synaptic membrane, axon part, and glutamatergic synapse. In the enrichment analysis of MF, the downregulated genes mainly revolved in active transmembrane transporter activity, P—P-bond-hydrolysis-driven transmembrane transporter activity, and primary active transmembrane transporter activity (**Figure 3B**). The KEGG pathway analysis showed that the upregulated genes were significantly enriched in the Hippo signaling pathway, regulation of actin cytoskeleton, adherens junction, mineral absorption, MAPK signaling pathway, and TGF-beta signaling pathway, while the downregulated DEGs were mainly enriched in the synaptic vesicle cycle, citrate cycle (TCA cycle), Parkinson's

disease, lysosome, MAPK signaling pathway, and cholinergic synapse. The KEGG pathway enrichment analysis results are illustrated in **Figures 3C,D**. The complete results of GO and KEGG analyses can be found in **Supplementary Table 2**.

## Specific Dysregulated Pathways for Each Brain Region

We performed GO enrichment analyses using the top 100 upregulated DEGs and top 100 downregulated DEGs of each

brain region. Then we identified the specific dysregulated pathways of each brain region. There were two specific pathways in the EC and the PCGY, 20 pathways in the FC, 12 pathways in the HPC, 145 pathways in the medial temporal gyrus, 38 pathways in the posterior cingulate, 47 pathways in the primary visual cortex, four pathways in the TC, and 58 pathways in the PFC (**Supplementary Table 2**). There was no specific pathway in the SFC. The HPC was associated with the neuron projection organization. The medial temporal gyrus was associated with neuron projection maintenance, neurotransmitter receptor

transport to the plasma membrane, neurotransmitter receptor transport to the postsynaptic membrane, and response to A $\beta$ . The dysregulated genes in the posterior cingulate were significantly enriched in pathways, including the branching morphogenesis of a nerve, glutamate metabolic process, positive regulation of synaptic transmission, and glutamatergic pathway. In the primary visual cortex, the dysregulated genes were involved in neuromuscular synaptic transmission, neuroinflammatory response, and cell aging. The neurotransmitter reuptake was associated with TC. Peripheral nervous system development and nerve development were significantly enriched pathways in PFC.

### PPI Network Construction, Hub Gene Selection, and Hub Gene Expression in Different Braak Stages of AD

The upregulated and downregulated DEGs were uploaded into the online tool STRING<sup>5</sup> to gain PPI information separately. Based on the degree of connectivity, we constructed the PPI network and selected the top 50 hub genes, and the result was visualized by Cytoscape (Figure 4A). Next, we used cytoHubba to choose hub genes. According to the five classification methods in cytoHubba, we selected the top 20 hub genes, as shown in Supplementary Table 3. Finally, six upregulated and 12 downregulated central genes were identified by overlapping the first 20 genes (Figure 4B and Supplementary Table 3). Then, we used samples in the dataset GSE48350 to explore whether the

expression levels of these central genes varied in different Braak stages in the HPC and SPF (Supplementary Table 4). We found that five hub genes were upregulated and 11 hub genes were downregulated as AD progressed ( $p < 0.05$ ). Predominantly, SMAD 4 and YAP 1 were significantly upregulated in Braak III and IV and Braak V and VI compared with Braak 0. Brain-derived neurotrophic factor (BDNF), PSMD14, SLC32A1, SNAP25, and SYP were identified to be downregulated in Braak III and IV and Braak V and VI compared with Braak 0 (Figure 5).

### Identification of Potential Biomarkers of AD Using LASSO Logistic Regression

To identify potential biomarkers for AD, we extracted the expression profile of the DEGs and fit them into LASSO logistic regression. We separated all samples (565 AD samples and 495 NDHCS) into training and validation cohorts (Supplementary Table 5). Thirty-five potential predictors in the training cohort were identified and were features with nonzero coefficients in the LASSO logistic regression model (Figures 6A,B and Table 2). Next, we evaluated the ability of the LASSO regression model in differentiating between AD and NDHCS, suggesting that the AUC of the 35-gene-based model was 0.992 in the validation set and 0.985 in the combined set (Figure 6C). The results indicate that our 35-gene-based diagnosis model can correctly classify AD samples and NDHCS in brain tissues. The diagnosis effect of the top 10 hub genes was also investigated and presented in Supplementary Figure 3. Only BDNF had the ability to differentiate AD from NDHCS (AUC = 0.703).

UniProt ID	Protein name	Gene name
P21291	Cysteine- and glycine-rich protein 1	CSRP1
Q01628	Interferon-induced transmembrane protein 3	IFITM3
P13640	Metallothionein-1 G	MT1G
P04732	Metallothionein-I E	MT1E
Q9Y2D9	Zinc finger protein 652	ZNF652
Q7Z3K3	Pogo transposable element with ZNF domain	POGZ
Q9GZV5	WW domain-containing transcription regulator protein 1	WWTR1
Q9NZH0	G-protein-coupled receptor family C group 5 member B	GPRC5B
P23949	mRNA decay activator protein ZFP36L2	ZFP36L2
Q9BX66	Sorbin and SH3 domain-containing protein 1	SORBS1
Q8N8S7	Protein enabled homolog	ENAH
Q68DX3	FERM and PDZ domain-containing protein 2	FRMPD2
P61278	Somatostatin	SST
P23560	Brain-derived neurotrophic factor	BDNF
Q8N4V2	Synaptic vesicle 2-related protein	SVOP
Q8N967	Leucine-rich repeat and transmembrane domain-containing protein 2	LRTM2
Q99259	Glutamate decarboxylase 1	GAD1
Q16566	Calcium/calmodulin-dependent protein kinase type IV	CAMK4
O95206	Protocadherin-8	PCDH8
P61088	Ubiquitin-conjugating enzyme E2 N	UBE2N
O43768	Alpha-endosulfine	ENSA
Q9UIL1	Short coiled-coil protein	SCOC
Q13530	Serine incorporator 3	SERINC3
Q9Y5V3	Melanoma-associated antigen D 1	MAGED1
Q96F83	Clathrin-binding box of aftiphilin-containing protein 1	C14orf79
P80723	Brain acid soluble protein 1	BASP1
Q15904	V-type proton ATPase subunit S1, V-ATPase subunit S 1	ATP6AP1
O95197	Reticulon-3	RTN3
Q96CW1	AP-2 complex subunit mu	AP2M1
P17643	5,6-Dihydroxyindole-2-carboxylic acid oxidase	TYRP1
P50613	Cyclin-dependent kinase 7	CDK7
Q8N100	Protein atonal homolog 7	ATOH7
Q9Y6G3	39S ribosomal protein L 42, mitochondrial, L 42 mt, MRP-L 42	MRPL42
O00744	Protein Wnt-10 b	WNT10B
P84074	Neuron-specific calcium-binding protein hippocalcin	HPCA

## Evaluation of the Diagnosis Model in Peripheral Blood Datasets

To further discover whether this model is worth using in clinical practice, we test our diagnosis model on four independent peripheral blood datasets (**Supplementary Table 5**). In the GSE4226, composed of peripheral blood mononuclear cells, only 16 genes of the 35-gene-based model were covered. The ROC analysis was also conducted based on the 16 genes, and the AUC was 0.871 (**Figure 7A**). We applied the 35-gene-based model to GSE97760, which included patients with advanced

AD and NDHCS and showed the perfect discrimination ability (**Figure 7B**, AUC = 1.000). We also found that our diagnosis model had the ability to differentiate MCI and AD from NDHCS in the blood datasets. In GSE63060 (30 genes of the 35-gene-based model were covered), the AUC for differentiating MCI and NDHCS is 0.922, and the AUC for AD and NDHCS is 0.837 (**Figure 7C**). In GSE63061 (28 genes of the 35-gene-based model were covered), AUC for MCI and NDHCS is 0.763, and AUC for AD and NDHCS is 0.802 (**Figure 7D**). Conclusively, the results indicate that our 35-gene-based diagnosis model can classify AD and MCI from NDHCS in peripheral blood.

## GSEA and Independent Validation Analysis

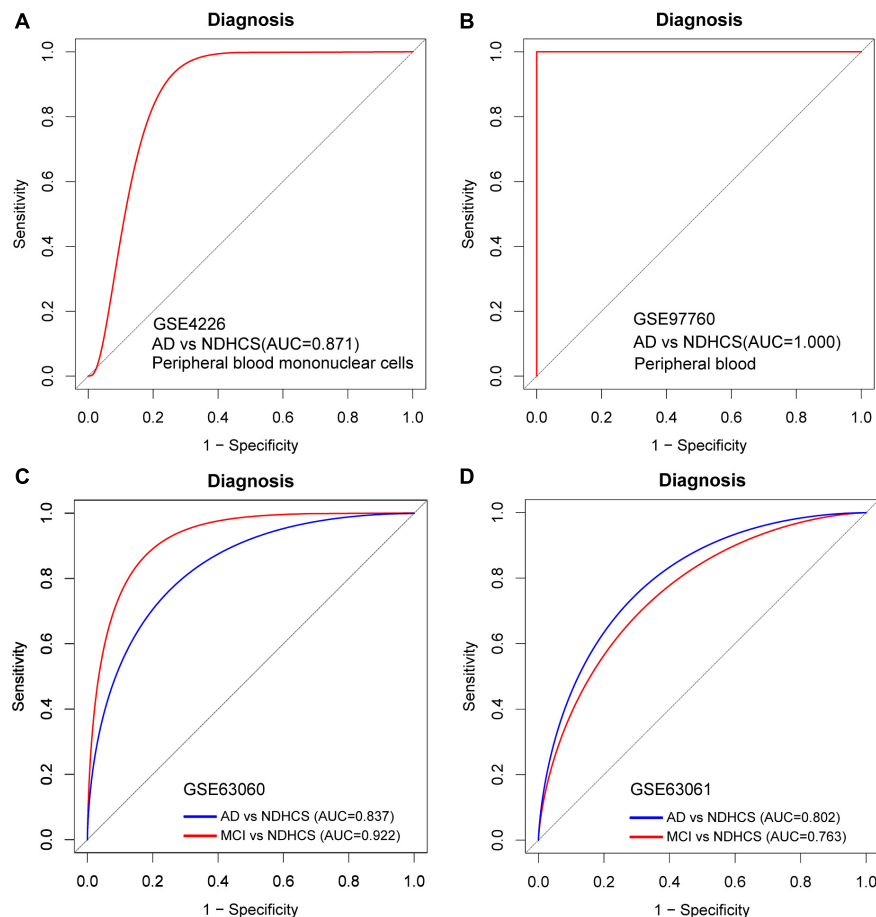

To gain new insights into the biological functions of the top 10 genes, we performed GSEA to identify the potential BPs between AD and NDHCS subjects. As indicated in **Figures 8A,B**, the BDNF was associated with cognition, HPC development, neuron death, regulation of neuronal synaptic plasticity, regulation of neurotransmitter levels, and transport. BPs such as neuroblast proliferation, neuroepithelial cell differentiation, neurotransmitter biosynthetic process and metabolic process, neuroinflammatory response, and regulation of neuroinflammatory response were associated with WW domain-containing transcription regulator protein 1 (WWTR1). The rest of the top 10 hub genes were also involved in several neuron-related pathways, including axon development (SMAD4, SLC32A1, and YAP1), neuron death (SNAP25 and ATP5B), and synapse organization (SMAD4 and SLC32A1). The results are shown in **Supplementary Figure 4**.

BDNF and WWTR1 were identified as key genes by overlapping the 18 hub genes in the PPI network and 35 potential predictors selected from the LASSO regression model. To confirm the result, we enrolled another independent dataset (GSE106241) to conduct validation analysis (**Supplementary Table 5**). As shown in **Figures 8C,D**, BDNF and WWTR1 showed significant differences among the different Braak stages ( $p = 0.001$  and  $0.041$ , respectively). Moreover, we found that BDNF was negatively associated with A $\beta$  42 levels and  $\beta$ -secretase activity ( $R = -0.35$  and  $R = -0.42$ , respectively, **Figures 8E,F**). WWTR1 was positively associated with A $\beta$  42 levels and  $\beta$ -secretase activity ( $R = 0.36$  and  $R = 0.61$ , respectively, **Figures 8G,H**). This result further proves that the two genes are essential and involved in the pathology of AD.

## DISCUSSION

Bioinformatics analysis has developed rapidly and applied to many diseases in recent decades, revealing the complex pathogenesis and identifying new biomarkers for diagnosis and treatment (Ali et al., 2018). Nevertheless, integrated bioinformatics analysis has not yet been systematically used in AD. Previous researches were usually based on single datasets and few samples that may weaken the credibility of the results. However, our current study has recruited five open public datasets for DEGs to significantly improve the number of samples

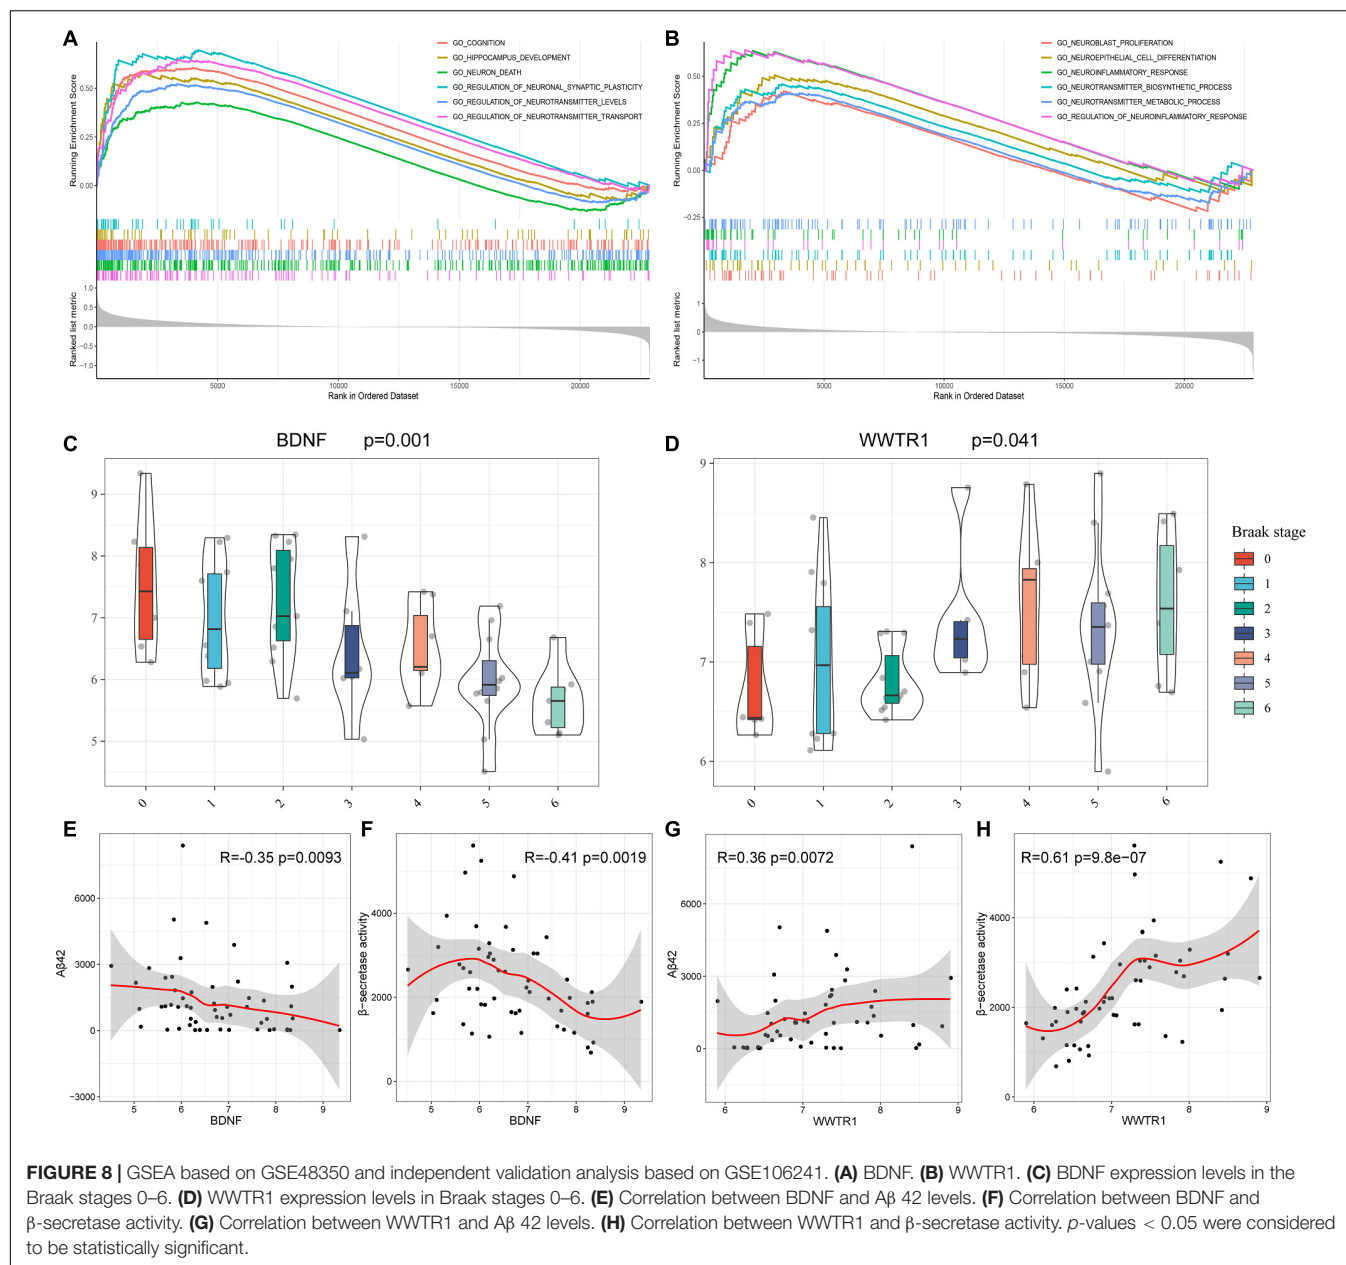

**FIGURE 7 |** ROC curve analysis in blood datasets. **(A)** ROC curves of peripheral blood mononuclear cell data from GSE4226. **(B)** ROC curves of peripheral blood data from GSE97760. **(C)** ROC curve analysis of GSE63060. **(D)** ROC curve analysis of GSE63061. AD, Alzheimer's disease; MCI, mild cognitive impairment; NDHCS, non-demented healthy control subjects; AUC, area under the curve.

(495 NDHCS vs. 656 AD samples). Thus, our study provides more credible and trustworthy results. We performed a series of integrative analyses based on DEGs, including GO and KEGG enrichment analyses, a constructed PPI network, LASSO logistic regression, and GSEA. In this way, we provide valuable clues for investigating the molecular mechanisms underlying the initiation and development of AD.

The KEGG pathway enrichment analysis showed significant enrichment in pathways including the Hippo signaling pathway, the TGF-beta signaling pathway, the MAPK signaling pathway, the synaptic vesicle cycle, lysosome, and the cholinergic synapse. A recent study confirmed that the Hippo pathway is associated with the pathogenesis of AD. The precursor of A $\beta$  can promote the nuclear translocation of FOXO 3a by inducing MST1-dependent phosphorylation of Foxo 3a. The MST-Foxo pathway, which is considered a branch of the Hippo pathway, activates a proapoptotic member of the Bcl-2 family and triggers an intrinsic apoptotic pathway, resulting in neuronal death (Wang and Wang, 2016). Regarding the TGF-beta signaling pathway, previous studies showed that the expression of TGF- $\beta$  1 and TGF- $\beta$  2 increased in the brains of patients with AD

(Zetterberg et al., 2004). Given the current evidence of microglial dysfunction in neurodegeneration, we speculate that changes in brain TGF- $\beta$  signaling in AD could alter microglial state and trigger their pathogenic functions (Salter and Stevens, 2017). It is well documented that lysosomal dysfunction is a prominent feature in AD brains, resulting in a failure to clear accumulated protein aggregates and contributes to the process of the pathogenesis of AD (Fraldi et al., 2016). Similarly, the MAPK signal pathways are activated in vulnerable brain regions of AD patients and are involved in the progress of AD (Zhu et al., 2002; Guillot et al., 2016). Therefore, the MAPKs have been proposed as therapeutic targets for AD. Previous studies also confirm that cholinergic transmission impairments are correlated with the neuropathological stage of AD (Amberla et al., 1993). A decrease in the cholinergic activity and disruption of synaptic function contribute to memory impairment (Sayer et al., 2004). Furthermore, the GO analysis indicated that the DEGs are involved in a wide range of BPs and have different MFs. We also found several specific dysregulated pathways in each brain region. Our results indicated that the changes in BPs, CCs, MFs,

and pathways might play critically important roles in the pathogenesis of AD.

We identified 18 hub genes by overlapping five sequencing methods in cytoHubba, of which 16 hub genes were significantly dysregulated as AD progressed. Some of these genes have been previously reported to be associated with AD. For example, the reduction of SNAP25 causes postsynaptic loss and learning and memory impairment (Ren et al., 2018). A recent study has demonstrated that SNAP25 is an effective biomarker for predicting AD 5–7 years before cognitive impairment (Jia et al., 2020). SYP can affect the synaptic structure and neurotransmitter release to regulate synaptic plasticity (Zhu et al., 2019). The dysfunction of ATP5B is associated with neurofibrillary tangle burden in the AD brain and with cognition (Wang et al., 2017).

The decrease of BDNF correlates with the neuropathological stage of AD (Laske et al., 2006). Further studies are required to investigate their features, functions, and mechanisms.

In the present study, we constructed a 35 gene-based LASSO model, which can accurately predict AD in both validation and combined brain tissue datasets. Among the 35 genes, previous studies have reported that the expressions of IFITM3 (Correani et al., 2017), SORBS1 (Blalock et al., 2004), ENAH (de Oliveira-Júnior et al., 2015), SST (Solarski et al., 2018), ENSA (Boettcher et al., 2008), C14orf40 (Chung et al., 2018), BASP1 (Zhou et al., 2020), RTN3 (Zou et al., 2018), CDK7 (Zhu et al., 2000), and HPCA (Jiang et al., 2016) were associated with AD or have functions in neural tissue, indicating possible therapeutic targets. For example, IFITM3 is a reliable biomarker of the inflammatory

microglial phenotype in AD damaged tissues (Correani et al., 2017), and the expression of SORBS1 is higher, while the expression of ENSA is lower in the brain of patients with AD (Blalock et al., 2004; Boettcher et al., 2008). SST interferes with A $\beta$  fibrillization and promotes the formation of A $\beta$  assemblies (Solarski et al., 2018). However, the molecular mechanism of these 35 genes contributing to AD pathogenesis is still poorly understood, and further exploration of potential mechanisms may be valuable.

To assess and confirm its clinical application value, we validated our gene signature on peripheral blood. According to ROC curves, the 35-gene-based model is able to distinguish MCI and AD samples from NDHCS samples in the blood. Especially in GSE97760, the model shows the perfect ability to select advanced AD patients (AUC = 1.000). Our results indicate that this diagnosis model could be beneficial for clinical applications. It is known that the blood–brain barrier (BBB) controls substance exchange strictly between the brain and blood. However, studies indicate that the breakdown of BBB could enhance the movement of proteins between the brain and blood in either direction (Zipser et al., 2007). Thus, some proteins in the blood might be associated with AD pathology. Recent studies have also adopted the strategy to integrate brain and blood datasets to identify potential AD biomarkers (Yao et al., 2018; Zhu et al., 2020). Our results shed new light on diagnosis biomarker identification. Further large-sample studies with a different analysis in the blood are required to confirm our results.

This study detected two key genes, BDNF and WWTR1, as potential biomarkers for clinical diagnosis and therapeutic monitoring in AD. Both of them have been identified as hub genes in the PPI network and varied significantly in the different neuropathological stages of AD. They were also selected as potential diagnostic biomarkers from LASSO logistic regression. GSEA suggests that the BDNF and WWTR1 could function as key players in a broad array of essential signaling pathways. Moreover, an independent validation showed that BDNF and WWTR1 are associated with the Braak stage, A $\beta$  42 levels, and  $\beta$ -secretase activity.

BDNF, located on chromosome 11 p 14, is reported to play an essential role in regulating neurodevelopment, promoting neuronal survival, and supporting basal forebrain cholinergic projections to the HPC and neocortex (Marmigère et al., 2003; Huang et al., 2007). Previous studies indicate that BDNF depletion led to an increase in cortical amyloid plaque numbers and size (Braun et al., 2017). It has also been reported that the expression of BDNF decreased in the brain tissue of patients with AD (Connor and Dragunow, 1998; Fields et al., 2014). This is consistent with our results that BDNF is negatively correlated with the Braak stage, and GSEA suggested that it is involved in HPC development, cognition, neuron death, and neurotransmitter regulation. Thus, the downregulation of

BDNF may play a crucial role in the pathogenesis of AD. WWTR1 is another potential diagnosis biomarker and may contribute to the development of AD. Functional enrichment analysis showed that WWTR1 was significantly involved in the neuroinflammatory response and neurotransmitter biosynthetic and metabolic pathways. Previous research indicates that WWTR1 is playing a crucial role in the Hippo and TGF- $\beta$  pathways, which is associated with the progress of AD (Lei et al., 2008; Deiana et al., 2018). However, the mechanisms of WWTR1 and AD remain undefined. More research is needed to elucidate the functions and underlying mechanisms of WWTR1 and AD. Although we enrolled an additional dataset for external validation, high-quality validation experiments are still required to prove the value of BDNF and WWTR1 in AD pathology.

## CONCLUSION

In conclusion, we identified 608 consensus DEGs, several dysregulated pathways, and 16 hub genes associated with AD progress by a series of bioinformatics analyses. The diagnostic model of 35 genes was constructed, which has a high AUC value in not only brain tissue but also peripheral blood. BDNF and WWTR1 were identified as candidate genes for future molecular studies. Our current study deepens our understanding of underlying molecular mechanisms in AD and provides new potential diagnostic and therapeutic biomarkers.

## DATA AVAILABILITY STATEMENT

The datasets generated for this study can be found in the online repositories. The names of the repository/repositories and accession number(s) can be found in the article/Supplementary Material.

## AUTHOR CONTRIBUTIONS

WuY and YL designed the study. WuY, WeY, and YY performed the statistical analysis and wrote the manuscript. All authors reviewed the manuscript and gave the final approval for publication.

## SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fnagi.2021.602781/full#supplementary-material>

**Background:** Increasing evidence has shown that amyotrophic lateral sclerosis (ALS) can result in abnormal energy metabolism and sleep disorders, even before motor dysfunction. Although the hypothalamus and thalamus are important structures in these processes, few ALS studies have reported abnormal MRI structural findings in the hypothalamus and thalamus.

**Purpose:** We aimed to investigate volumetric changes in the thalamus and hypothalamus by using the automatic brain structure volumetry tool AccuBrain®.

**Methods:** 3D T1-weighted magnetization-prepared gradient echo imaging (MPRAGE) scans were acquired from 16 patients with ALS with normal cognitive scores and 16 age-, sex- and education-matched healthy controls. Brain tissue and structure volumes were automatically calculated using AccuBrain®.

**Results:** There were no significant differences in bilateral thalamic ( $F = 1.31$ ,  $p = 0.287$ ) or hypothalamic volumes ( $F = 1.65$ ,  $p = 0.213$ ) between the ALS and control groups by multivariate analysis of covariance (MANCOVA). Left and right hypothalamic volumes were correlated with whole-brain volume in patients with ALS ( $t = 3.19$ ,  $p = 0.036$ ;  $t = 3.03$ ,  $p = 0.044$ ), while the correlation between age and bilateral thalamic volumes tended to be significant after Bonferroni correction ( $t = 2.76$ ,  $p = 0.068$ ;  $t = 2.83$ ,  $p = 0.06$ ). In the control group, left and right thalamic volumes were correlated with whole-brain volume ( $t = 4.26$ ,  $p = 0.004$ ;  $t = 4.52$ ,  $p = 0.004$ ).

**Conclusion:** Thalamic and hypothalamic volumes did not show differences between patients with normal frontotemporal function ALS and healthy controls, but further studies are still needed.

**Keywords:** amyotrophic lateral sclerosis, thalamus, hypothalamus, volumetric analysis, MRI

## BACKGROUND

Amyotrophic lateral sclerosis is a multiple-system neurodegenerative disease that has a far greater impact than motor system dysfunction. In recent years, more researchers in neurosciences have expanded their interest beyond motor dysfunction and explored other research axes, such as energy homeostasis and sleep disorder, in patients with amyotrophic lateral sclerosis (ALS). Patients with

ALS generally have normal or low body mass index (BMI). Weight loss may begin before the onset of motor symptoms, which is probably caused by dysphagia and hypermetabolism. Early weight loss is associated with a higher rate of ALS progression with a grimmer prognosis (Dupuis et al., 2011; Gallo et al., 2013; O'Reilly et al., 2013; Huisman et al., 2015; Ahmed et al., 2016). Clinical trials have demonstrated that strengthening intake may benefit patients with ALS (Wills et al., 2014; Dorst et al., 2015). In addition to energy homeostasis, sleep disorders are also fairly common in patients with ALS (Diaz-Abad et al., 2018; Liu et al., 2018; Congiu et al., 2019). Animal studies have shown that sleep disorders may initiate before the onset of motor symptoms (Liu et al., 2015; Zhang et al., 2018). Interestingly, as both energy metabolism and sleep are closely related to the function of the hypothalamus (Vercruysse et al., 2018), it is not surprising that pathological abnormalities in the hypothalamus were found in patients with ALS (Cykowski et al., 2014; Nakamura et al., 2015). In 33 autopsy-confirmed patients with ALS, six patients presented TDP-43 pathology in the hypothalamus (Cykowski et al., 2014). In the autopsy of a patient with familial ALS, SOD1 immunohistochemistry showed neuronal cytoplasmic inclusions, glial cytoplasmic inclusions, and dystrophic neurites in the brain and spinal cord, with a predilection for the hypothalamus and central gray matter (Nakamura et al., 2015). Hypothalamic neuropeptide levels were shown to be changed in ALS mouse models (Vercruysse et al., 2016). In addition to these biomolecular abnormalities, structural changes have also been reported: Up to 15% of patients diagnosed with behavioral variant frontotemporal dementia (bvFTD), a similar but different disease within the spectrum of ALS (Strong et al., 2017; van Es et al., 2017), were reported to have hypothalamic atrophy (Bocchetta et al., 2015; Ahmed et al., 2017). However, few studies have reported hypothalamic atrophy in patients with ALS (Gorges et al., 2017).

C9orf72 repeat expansion is one of the most important gene mutations in the ALS-FTD disease spectrum (Gijselink et al., 2012; Balendra and Isaacs, 2018). In addition to commonly reported brain areas, such as the motor cortex, frontal and temporal lobes, and corpus callosum (Foerster et al., 2013), changes in the thalamus have been the focus of relatively few studies. Machts reported bilateral thalamic atrophy in patients with ALS-FTD (Machts et al., 2015). Schönecker's study subsequently showed thalamic atrophy in ALS/FTD C9orf72 mutation carriers that extended beyond the expected atrophy in the prefrontal and temporal subregions (Schönecker et al., 2018). However, Westeneng found that, although patients with ALS with C9orf72 repeat expansion had more severe bilateral thalamic atrophy, 21% of patients with ALS without the C9orf72 mutation had a similar neuroimaging phenotype (Westeneng et al., 2016). Chipika also found thalamic atrophy in patients with ALS without the C9orf72 mutation (Chipika et al., 2020). Some earlier studies found structural or functional changes in the thalamus in patients with ALS but lacked cognitive and behavioral assessments (Douaud et al., 2011; Sharma et al., 2011, 2013). Therefore, it remains unclear whether thalamic atrophy could occur in patients with pure ALS.

AccuBrain® (BrainNow Ltd., Shenzhen, China) is a cloud-based National Medical Products Administration (NMPA)

and Conformité Européenne (CE)-marked software tool that performs brain MRI segmentation. It is based on a multi-atlas segmentation method with a statistical anatomical atlas previously generated by experienced experts, and it automatically calculates the brain volume of various brain structures. AccuBrain® presents less inter-scanner variability than FreeSurfer and FSL-FIRST based on the comparison of their coefficient of variation values of brain volumetry, especially in basal ganglia structures, such as the thalamus ( $p < 0.001$ ) (Liu et al., 2020). Abrigo's study showed that AccuBrain® could provide accurate automated hippocampal segmentation in accordance with the EADCADNI standard (Abrigo et al., 2018). The clinical value of AccuBrain® has also been demonstrated in various neurological disease studies (Guo et al., 2019; Wang et al., 2019; Zhao et al., 2019; Dou et al., 2020; Hou et al., 2020; Liu et al., 2020). AccuBrain® may, therefore, be a rapid and sensitive tool for detecting brain structures in neurodegenerative diseases.

The aim of this study was to determine whether thalamic and hypothalamic atrophy occurs in patients with ALS by using the AccuBrain® technique.

## MATERIALS AND METHODS

### Participants

In total, 16 right-handed patients who met the ALS-revised El Escorial criteria (Brook et al., 2000) at Peking University Third Hospital (PUTH) between 2011 and 2012 and 16 right-handed healthy controls were enrolled. All the patients underwent the Mini-Mental State Examination (MMSE), Frontal Assessment Battery (FAB), verbal fluency (VF), and prospective memory (PM) tests before inclusion. The exclusion criteria were as follows: (1) dementia or cognitive dysfunction, brain trauma, epilepsy, stroke, psychiatric disorders, and other central nervous system diseases; (2) absolute or relative contraindication for MRI; and (3) pregnancy.

The clinical characteristics are shown in **Table 1**. The patients with ALS were followed up until death; during this follow-up period, contact with eight of 16 patients was lost before this endpoint. The life span was the time from the disease onset to death. All the participants provided informed consent. The study was approved by the ethics committee of PUTH.

### MRI Acquisition

The data for 16 patients with ALS and 16 healthy controls were acquired on a Siemens 3.0 T Trio TIM MR scanner. Structural MRI data were obtained using a high-resolution 3-D T1-weighted magnetization-prepared gradient echo imaging (MPRAGE) sequence [192 sagittal slices, no gap, layer thickness = 1 mm; field of view (FOV) = 256 mm × 256 mm; repetition time (TR) = 2,530 ms; echo time (TE) = 3.44 ms; inversion time (TI) = 1,100 ms; acquisition time = 363 s].

### Brain Volumetry

All images were processed using AccuBrain® (BrainNow Medical Technology Ltd., China), which is a brain quantification tool that performs brain structure and tissue segmentation and

quantification in a fully automatic mode. Given the T1-weighted MRI data, several brain structures and three major brain tissues are segmented automatically based on prior anatomical knowledge specified by experienced radiologists. The anatomical information is automatically transformed onto the individual brain. The absolute volume (in ml) of 20 brain structures and their bilateral components were automatically calculated. These measures and structures included but were not limited to intracranial volume, whole-brain parenchyma, hippocampus, amygdala, ventricular system, lateral ventricle, third ventricle, inferior lateral ventricle, caudate, putamen, pallidum, hypothalamus, thalamus, pons, midbrain, and gray matter in different lobes.

## Statistics

During enrollment, although trying to meet the similarity between the ALS and control groups in sex, age, and education, paired enrollment was still not strictly performed. Therefore, when comparing the clinical characteristics between the ALS and control groups, the chi-square test was used for sex. For age and education factors, *t*-tests were used when the variables were normally distributed, and Mann–Whitney *U* tests were used when the variables were not normally distributed. Multivariate analysis of covariance (MANCOVA) was used to compare the differences in thalamic and hypothalamic volumes between patients with ALS and controls. During the univariate analysis, when studying the relationship between brain volumes and age, years of education, duration of illness, revised functional rating scale (FRS-R) scores and life span, Pearson correlations were used when the data were continuous, normally distributed and had a linear relationship; otherwise, Spearman correlations were performed. When studying the relationship between brain

volumes and sex, bulbar involvement and disease stage, *t*-tests were used when the variables were normally distributed, and Mann–Whitney *U* tests were used when the variables were not normally distributed. ANOVA was used to compare the brain volumes among different diagnostic levels. Then, multivariable linear regression analysis was used. The standard statistical significance level was set at  $p < 0.05$ . IBM SPSS V20 software was used for all statistical analyses.

## RESULTS

### Comparisons of Thalamic Volume Between Patients With Amyotrophic Lateral Sclerosis and Healthy Controls

Multivariate analysis of covariance was used, in which volumes in the left thalamus and right thalamus were set as two dependent variables; patients with ALS or healthy controls were set as independent variables; and whole-brain volume, age, sex, and education years were set as covariates. The volumes were normally distributed. The patients with ALS and controls were two independent groups. There was homogeneity of variance-covariance matrices assessed using Box's *M* test of equality of covariance ( $F = 1.249$ ,  $p = 0.290$ ). However, there was no significant difference between the ALS and control groups ( $F = 1.311$ ,  $p = 0.287$ ). Descriptive measures of brain volumes were listed in **Supplementary Table 1**.

### Comparisons of Hypothalamic Volume Between Patients With Amyotrophic Lateral Sclerosis and Healthy Controls

Multivariate analysis of covariance was used, in which volumes in the left hypothalamus and right hypothalamus were set as two dependent variables; The patients with ALS or healthy controls were set as independent variables; and whole-brain volume, age, sex, and education years were set as covariates. The volumes were normally distributed. The patients with ALS and controls were two independent groups. There was homogeneity of variance-covariance matrices assessed using Box's *M* test of equality of covariance ( $F = 2.533$ ,  $p = 0.055$ ). However, there was no significant difference between the ALS and control groups ( $F = 1.647$ ,  $p = 0.213$ ). Descriptive measures of brain volumes are listed in **Supplementary Table 1**.

### Thalamic and Hypothalamic Volumes and Clinical Characteristics

Univariate analysis was first used to choose possible variants for multivariable linear regression analysis. Variants with  $p < 0.1$  were chosen (**Table 2**). Descriptive measures of categorical variables, such as disease stages, sex, and bulbar involvement, are listed in **Supplementary Table 2**.

Multivariable linear regression analysis was separately performed with bilateral thalamic and hypothalamic volumes as the dependent variables and whole-brain volume and factors chosen above as the independent variables. The results are shown in **Tables 3, 4**. However, after Bonferroni correction ( $p < 0.0125$ ), left and right hypothalamic volumes were

**TABLE 2 |** Univariate analysis of brain volumes and clinical characteristics.

	Left thalamus	Right thalamus	Left hypothalamus	Right hypothalamus
Age (r, p)	−0.54, 0.03	−0.61, 0.01	0.17, 0.54	0.21, 0.44
Sex (t, p)	0.21, 0.84	0.17, 0.87	1.92, 0.08	1.93, 0.08
Years of education (r, p)	0.45, 0.08	0.41, 0.12	0.27, 0.31	0.37, 0.15
Duration of illness (r, p)	−0.07, 0.79	−0.08, 0.76	−0.20, 0.46	−0.23, 0.39
Bulbar involved (t, p)	0.59, 0.57	0.68, 0.51	0.80, 0.44	0.38, 0.71
Diagnostic level (F, p)	2.54, 0.11	2.07, 0.16	2.30, 0.13	2.46, 0.11
Disease stage (t, p)	0.35, 0.73	0.01, 0.99	2.16, 0.05	2.22, 0.04
ALSFRS-R score (r, p)	−0.07, 0.79	−0.13, 0.64	0.28, 0.29	0.07, 0.79
Life span (r, p)	0.12, 0.78	0.02, 0.95	0.25, 0.55	−0.17, 0.69

Factors with  $p < 0.1$  were chosen as variants for multiple linear regression.

**TABLE 3 |** Multiple linear regression of brain volumes and clinical characteristics in ALS.

	Left thalamus	Right thalamus	Left hypothalamus	Right hypothalamus

correlated with whole-brain volume in the patients with ALS, while the correlation between age and bilateral thalamic volumes tended to be significant. In the control group, left and right thalamic volumes were correlated with whole-brain volume, and sex was correlated with left hypothalamus volume.

## Validation of the Automatic Segmentation of the Thalamus

Validation of the automatic segmentation of the thalamus was conducted by comparing the automatically generated

**TABLE 5 |** Validation of the automatic segmentations of thalamus and hypothalamus.

Brain region	Mean dice	Min-max
Left thalamus	0.998	0.990–1.000
Right thalamus	0.999	0.986–1.000
Left hypothalamus	0.995	0.958–1.000
Right hypothalamus	0.994	0.967–1.000

segmentation labels with the corrected labels manually performed based on the automatic results. The dice similarity coefficient (range: 0–1) was used as the metric of segmentation accuracy (Table 5).

## DISCUSSION

In this study, hypothalamic volume was not different ( $F = 1.65$ ,  $p = 0.213$ ) between the patients with ALS and healthy controls after adjusting for age, sex, education year, and whole-brain volume. Although relatively few studies have reported hypothalamic volume in patients with ALS, Cykowski and Nakamura found pathological changes in ALS autopsy (Cykowski et al., 2014; Nakamura et al., 2015), and Gorges found hypothalamic atrophy in patients with ALS (Gorges et al., 2017). The probable reasons for the negative result in this study include the following: (1) the study did not include subregional analysis of the hypothalamus, which might have covered some potential significance; (2) the sensitivity of AccuBrain® software: Although

the study provided a comparison with post-segmentation manual correction, it was not comparable to validation studies of alternative software (Wolff et al., 2018; Billot et al., 2020); and (3) the sample of this study was small, which might have affected the accuracy of the analyses.

Thalamic volume was also not different ( $F = 1.31$ ,  $p = 0.287$ ) between the patients with ALS and healthy controls after adjusting for age, sex, education year, and whole-brain volume in this study. There were actually more reports of thalamic atrophy than hypothalamic atrophy in the patients with ALS (Douaud et al., 2011; Sharma et al., 2011, 2013; Machts et al., 2015; Westeneng et al., 2016; Christidi et al., 2018; Chipika et al., 2020), although this study did not show a difference. In addition to the probable reasons listed as hypothalamic volume, thalamic atrophy was most commonly reported in the patients with ALS who also had frontotemporal dysfunctions (Machts et al., 2015; Westeneng et al., 2016; Christidi et al., 2018). Other studies did not mention cognitive function (Douaud et al., 2011; Sharma et al., 2011, 2013). Patients with normal cognitive function have seldom been reported. Since the cognition of this group of the patients with ALS was normal, we hypothesize that thalamic atrophy in the patients with ALS may be more related to frontotemporal dysfunction and needs further study.

Age is commonly recognized to have a negative correlation with brain volumes. However, although there were trends of significance between age and thalamic volume, there were no significant differences between age and hypothalamic volume in either the patients with ALS or controls. Gorges's (Gorges et al., 2017) study found that the age at the onset was correlated with anterior hypothalamic volume but not with total or posterior hypothalamic volumes. Our study did not divide the hypothalamus into anterior and posterior parts; thus, it is unknown whether any subregional differences exist. It is also worth noting that, unlike the thalamus, hypothalamic volume was not correlated with whole-brain volume in healthy controls but was significantly correlated in the patients with ALS. Thus, we speculate that hypothalamic volume may be a potential age-independent biomarker for ALS. Additionally, hypothalamic volume was not correlated with the disease stage. These characteristics suggest that further in-depth investigation is required to determine the structural and functional roles of the hypothalamus.

Generally, there are some limitations of this study. First, the sample size was small, which may have affected the accuracy of the analyses, and the results need confirmation in further large-sample studies. Second, we did not divide subregions of the thalamus and hypothalamus, which may have different brain network connections. Third, we used the AccuBrain® technique to analyze thalamic and hypothalamic volumes. The software is commercial and inaccessible to other researchers; therefore, it is not easy to replicate by fellow colleagues. As our study did not provide commonly accepted measures but only a comparison with the post-segmentation manual correction, it is not comparable to validation studies assessing alternative software. For future work, it will be important to compare volumes by using these different sensitive techniques

to confirm the results. Much work remains to be done for automated thalamus and hypothalamus volumetry, requiring larger sample sizes to compensate for the measurement errors and to provide a deeper understanding of the role of the thalamus and hypothalamus.

## CONCLUSION

Thalamic and hypothalamic volumes did not show differences between the patients with normal frontotemporal function ALS and healthy controls, but further studies are needed.

# Advantages of publishing in Frontiers

## OPEN ACCESS

Articles are free to read  
for greatest visibility  
and readership

## FAST PUBLICATION

Around 90 days  
from submission  
to decision

## HIGH QUALITY PEER-REVIEW

Rigorous, collaborative,  
and constructive  
peer-review

## TRANSPARENT PEER-REVIEW

Editors and reviewers  
acknowledged by name  
on published articles

## Frontiers

Avenue du Tribunal-Fédéral 34  
1005 Lausanne | Switzerland

Visit us: [www.frontiersin.org](http://www.frontiersin.org)

Contact us: [frontiersin.org/about/contact](http://frontiersin.org/about/contact)

## REPRODUCIBILITY OF RESEARCH

Support open data  
and methods to enhance  
research reproducibility

## DIGITAL PUBLISHING

Articles designed  
for optimal readership  
across devices

## FOLLOW US

@frontiersin

## IMPACT METRICS

Advanced article metrics  
track visibility across  
digital media

## EXTENSIVE PROMOTION

Marketing  
and promotion  
of impactful research

## LOOP RESEARCH NETWORK

Our network  
increases your  
article's readership
